results()
Return a CoverageResults object that contains the cumulative results of all previous calls to run, runctx and runfunc for the given Trace instance. Does not reset the accumulated trace results.

class traceCoverageResults
A container for coverage results, created by Trace.results(). Should not be created directly by the user.

update(other)
Merge in data from another CoverageResults object.

write_results(show_missing=True, summary=False, coverdir=None)
Write coverage results. Set show_missing to show lines that had no hits. Set summary to include in the output the coverage summary per module. coverdir specifies the directory into which the coverage result files will be output. If None, the results for each source file are placed in its directory.

A simple example demonstrating the use of the programmatic interface:

```python
import sys
import trace

# create a Trace object, telling it what to ignore, # do tracing or line-counting or both.
tracer = trace.Trace(
    ignoredirs=[sys.prefix, sys.exec_prefix],
    trace=0,
```
count=1)

# run the new command using the given tracer
tracer.run('main()')

# make a report, placing output in the current directory
r = tracer.results()
r.write_results(show_missing=True, coverdir=".")
27.7. tracemalloc — Trace memory allocations

New in version 3.4.

Source code: Lib/tracemalloc.py

The tracemalloc module is a debug tool to trace memory blocks allocated by Python. It provides the following information:

- Traceback where an object was allocated
- Statistics on allocated memory blocks per filename and per line number: total size, number and average size of allocated memory blocks
- Compute the differences between two snapshots to detect memory leaks

To trace most memory blocks allocated by Python, the module should be started as early as possible by setting the PYTHONTRACEMALLOC environment variable to 1, or by using -X tracemalloc command line option. The tracemalloc.start() function can be called at runtime to start tracing Python memory allocations.

By default, a trace of an allocated memory block only stores the most recent frame (1 frame). To store 25 frames at startup: set the PYTHONTRACEMALLOC environment variable to 25, or use the -X tracemalloc=25 command line option.
# 27.7.1. Examples

## 27.7.1.1. Display the top 10

Display the 10 files allocating the most memory:

```python
import tracemalloc

tracemalloc.start()

# ... run your application ...

snapshot = tracemalloc.take_snapshot()
top_stats = snapshot.statistics('lineno')

print("[ Top 10 ]")
for stat in top_stats[:10]:
    print(stat)
```

Example of output of the Python test suite:

```
[ Top 10 ]
<frozen importlib._bootstrap>:716: size=4855 KiB, count=1446, average=70.4 B /
/usr/lib/python3.4/unittest/case.py:381: size=185 KiB, count=1454, average=52.0 B /
<string>:5: size=49.7 KiB, count=148, average=344 B /
```

We can see that Python loaded 4855 KiB data (bytecode and
constants) from modules and that the collections module allocated 244 KiB to build namedtuple types.

See Snapshot.statistics() for more options.

27.7.1.2. Compute differences

Take two snapshots and display the differences:

```python
import tracemalloc
tracemalloc.start()
# ... start your application ...

snapshot1 = tracemalloc.take_snapshot()
# ... call the function leaking memory ...
snapshot2 = tracemalloc.take_snapshot()

top_stats = snapshot2.compare_to(snapshot1, 'lineno')

print("[ Top 10 differences ]")
for stat in top_stats[:10]:
    print(stat)
```

Example of output before/after running some tests of the Python test suite:

```
[ Top 10 differences ]
<frozen importlib._bootstrap>:716: size=8173 KiB (+4
/usr/lib/python3.4/linecache.py:127: size=940 KiB (+
/usr/lib/python3.4/unittest/case.py:571: size=298 Ki
<frozen importlib._bootstrap>:284: size=1005 KiB (+1
/usr/lib/python3.4/mimetypes.py:217: size=112 KiB (+
/usr/lib/python3.4/http/server.py:848: size=96.0 KiB
```
We can see that Python has loaded 8173 KiB of module data (bytecode and constants), and that this is 4428 KiB more than had been loaded before the tests, when the previous snapshot was taken. Similarly, the linecache module has cached 940 KiB of Python source code to format tracebacks, all of it since the previous snapshot.

If the system has little free memory, snapshots can be written on disk using the Snapshot.dump() method to analyze the snapshot offline. Then use the Snapshot.load() method reload the snapshot.

27.7.1.3. Get the traceback of a memory block

Code to display the traceback of the biggest memory block:

```python
import tracemalloc

# Store 25 frames
tracemalloc.start(25)

# ... run your application ...

snapshot = tracemalloc.take_snapshot()
top_stats = snapshot.statistics('traceback')

# pick the biggest memory block
stat = top_stats[0]
print("%s memory blocks: %.1f KiB" % (stat.count, stat.size))
for line in stat.traceback.format():
    print(line)
```
Example of output of the Python test suite (traceback limited to 25 frames):

```
903 memory blocks: 870.1 KiB
File "<frozen importlib._bootstrap>"", line 716
    File "<frozen importlib._bootstrap>"", line 1036
    File "<frozen importlib._bootstrap>"", line 934
    File "<frozen importlib._bootstrap>"", line 1068
    File "<frozen importlib._bootstrap>"", line 619
    File "<frozen importlib._bootstrap>"", line 1581
    File "<frozen importlib._bootstrap>"", line 1614
    File "/usr/lib/python3.4/doctest.py", line 101
        import pdb
    File "<frozen importlib._bootstrap>"", line 284
    File "<frozen importlib._bootstrap>"", line 938
    File "<frozen importlib._bootstrap>"", line 1068
    File "<frozen importlib._bootstrap>"", line 619
    File "<frozen importlib._bootstrap>"", line 1581
    File "<frozen importlib._bootstrap>"", line 1614
    File "/usr/lib/python3.4/test/support/__init__.py"
        import doctest
    File "/usr/lib/python3.4/test/test_pickletools.py"
        support.run_doctest(pickletools)
    File "/usr/lib/python3.4/test/regrtest.py", line 1
        test_runner()
    File "/usr/lib/python3.4/test/regrtest.py", line 9
        display_failure=not verbose)
    File "/usr/lib/python3.4/test/regrtest.py", line 7
        match_tests=ns.match_tests)
    File "/usr/lib/python3.4/test/regrtest.py", line 1
        main()
    File "/usr/lib/python3.4/test/__main__.py", line 3
        regrtest.main_in_temp_cwd()
    File "/usr/lib/python3.4/runpy.py", line 73
        exec(code, run_globals)
    File "/usr/lib/python3.4/runpy.py", line 160
        "__main__", fname, loader, pkg_name)
```
We can see that the most memory was allocated in the importlib
module to load data (bytecode and constants) from modules: 870.1
KiB. The traceback is where the importlib loaded data most
recently: on the import pdb line of the doctest module. The
traceback may change if a new module is loaded.

27.7.1.4. Pretty top
Code to display the 10 lines allocating the most memory with a pretty
output, ignoring <frozen
importlib._bootstrap>
and
<unknown> files:
import linecache
import os
import tracemalloc
def display_top(snapshot, key_type='lineno', limit=10
snapshot = snapshot.filter_traces((
tracemalloc.Filter(False, "<frozen importlib._bootst
tracemalloc.Filter(False, "<unknown>"),
))
top_stats = snapshot.statistics(key_type)
print("Top %s lines" % limit)
for index, stat in enumerate(top_stats[:limit],
frame = stat.traceback[0]
# replace "/path/to/module/file.py" with "module/fil
filename = os.sep.join(frame.filename.split(
print("#%s: %s:%s: %.1f KiB"
% (index, filename, frame.lineno, stat
line = linecache.getline(frame.filename, frame
if line:
print('
%s' % line)


other = top_stats[limit:]

if other:
    size = sum(stat.size for stat in other)
    print("%s other: %.1f KiB" % (len(other), size))

total = sum(stat.size for stat in top_stats)
print("Total allocated size: %.1f KiB" % (total))

tracemalloc.start()

# ... run your application ...

snapshot = tracemalloc.take_snapshot()
display_top(snapshot)

Example of output of the Python test suite:

<table>
<thead>
<tr>
<th></th>
<th>Path</th>
<th>Size</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>Lib/base64.py:414: 419.8 KiB</td>
<td></td>
</tr>
<tr>
<td>2.</td>
<td>Lib/base64.py:306: 419.8 KiB</td>
<td></td>
</tr>
<tr>
<td>3.</td>
<td>collections/<strong>init</strong>.py:368: 293.6 KiB</td>
<td></td>
</tr>
<tr>
<td>4.</td>
<td>Lib/abc.py:133: 115.2 KiB</td>
<td></td>
</tr>
<tr>
<td>5.</td>
<td>unittest/case.py:574: 103.1 KiB</td>
<td></td>
</tr>
<tr>
<td>6.</td>
<td>Lib/linecache.py:127: 95.4 KiB</td>
<td></td>
</tr>
<tr>
<td>7.</td>

<td></td>
</tr>
<tr>
<td>8.</td>
<td>&lt;string&gt;:5: 62.0 KiB</td>
<td></td>
</tr>
<tr>
<td>9.</td>
<td>Lib/_weakrefset.py:37: 60.0 KiB</td>
<td></td>
</tr>
<tr>
<td>10.</td>
<td>Lib/base64.py:142: 59.8 KiB</td>
<td></td>
</tr>
</tbody>
</table>
See `Snapshot.statistics()` for more options.
27.7.2. API

27.7.2.1. Functions

`tracemalloc.clear_traces()`
Clear traces of memory blocks allocated by Python.

See also `stop()`.

`tracemalloc.get_object_traceback(obj)`
Get the traceback where the Python object `obj` was allocated. Return a `Traceback` instance, or `None` if the `tracemalloc` module is not tracing memory allocations or did not trace the allocation of the object.

See also `gc.get_referrers()` and `sys.getsizeof()` functions.

`tracemalloc.get_traceback_limit()`
Get the maximum number of frames stored in the traceback of a trace.

The `tracemalloc` module must be tracing memory allocations to get the limit, otherwise an exception is raised.

The limit is set by the `start()` function.

`tracemalloc.get_traced_memory()`
Get the current size and peak size of memory blocks traced by the `tracemalloc` module as a tuple: `(current: int, peak: int)`. 
tracemalloc. `get_tracemalloc_memory()`

Get the memory usage in bytes of the tracemalloc module used to store traces of memory blocks. Return an int.

tracemalloc. `is_tracing()`

True if the tracemalloc module is tracing Python memory allocations, False otherwise.

See also start() and stop() functions.

tracemalloc. `start(nframe: int=1)`

Start tracing Python memory allocations: install hooks on Python memory allocators. Collected tracebacks of traces will be limited to nframe frames. By default, a trace of a memory block only stores the most recent frame: the limit is 1. nframe must be greater or equal to 1.

Storing more than 1 frame is only useful to compute statistics grouped by 'traceback' or to compute cumulative statistics: see the Snapshot.compare_to() and Snapshot.statistics() methods.

Storing more frames increases the memory and CPU overhead of the tracemalloc module. Use the get_tracemalloc_memory() function to measure how much memory is used by the tracemalloc module.

The PYTHONTRACEMALLOC environment variable (PYTHONTRACEMALLOC=NFRAME) and the -X tracemalloc=NFRAME command line option can be used to start tracing at startup.
See also `stop()`, `is_tracing()` and `get_traceback_limit()` functions.

`tracemalloc.stop()`  
Stop tracing Python memory allocations: uninstall hooks on Python memory allocators. Also clears all previously collected traces of memory blocks allocated by Python.

Call `take_snapshot()` function to take a snapshot of traces before clearing them.

See also `start()`, `is_tracing()` and `clear_traces()` functions.

`tracemalloc.take_snapshot()`  
Take a snapshot of traces of memory blocks allocated by Python. Return a new `Snapshot` instance.

The snapshot does not include memory blocks allocated before the `tracemalloc` module started to trace memory allocations.

Tracebacks of traces are limited to `get_traceback_limit()` frames. Use the `nframe` parameter of the `start()` function to store more frames.

The `tracemalloc` module must be tracing memory allocations to take a snapshot, see the `start()` function.

See also the `get_object_traceback()` function.

### 27.7.2.2. DomainFilter

```python
class tracemalloc.DominFilter(inclusive: bool, domain: int)
```
Filter traces of memory blocks by their address space (domain).

*New in version 3.6.*

**inclusive**
If `inclusive` is True (include), match memory blocks allocated in the address space `domain`.

If `inclusive` is False (exclude), match memory blocks not allocated in the address space `domain`.

**domain**
Address space of a memory block (int). Read-only property.

### 27.7.2.3. Filter

```python
class tracemalloc.Filter(inclusive: bool, filename_pattern: str, 
                        lineno: int=None, all_frames: bool=False, domain: int=None)
```

Filter on traces of memory blocks.

See the `fnmatch.fnmatch()` function for the syntax of `filename_pattern`. The `'.pyc'` file extension is replaced with `'.py'`.

Examples:

- `Filter(True, subprocess.__file__)` only includes traces of the `subprocess` module
- `Filter(False, tracemalloc.__file__)` excludes traces of the `tracemalloc` module
- `Filter(False, '<unknown>')` excludes empty tracebacks
Changed in version 3.5: The `.pyo` file extension is no longer replaced with `.py`.

Changed in version 3.6: Added the `domain` attribute.

**domain**
Address space of a memory block (int or None).

**inclusive**
If `inclusive` is `True` (include), only match memory blocks allocated in a file with a name matching `filename_pattern` at line number `lineno`.

If `inclusive` is `False` (exclude), ignore memory blocks allocated in a file with a name matching `filename_pattern` at line number `lineno`.

**lineno**
Line number (int) of the filter. If `lineno` is `None`, the filter matches any line number.

**filename_pattern**
Filename pattern of the filter (str). Read-only property.

**all_frames**
If `all_frames` is `True`, all frames of the traceback are checked. If `all_frames` is `False`, only the most recent frame is checked.

This attribute has no effect if the traceback limit is 1. See the `get_traceback_limit()` function and `Snapshot.traceback_limit` attribute.
27.7.2.4. Frame

class tracemalloc.Frame

Frame of a traceback.

The Traceback class is a sequence of Frame instances.

filename

Filename (str).

lineno

Line number (int).

27.7.2.5. Snapshot

class tracemalloc.Snapshot

Snapshot of traces of memory blocks allocated by Python.

The take_snapshot() function creates a snapshot instance.

compare_to(old_snapshot: Snapshot, key_type: str, cumulative: bool=False)

Compute the differences with an old snapshot. Get statistics as a sorted list of StatisticDiff instances grouped by key_type.

See the Snapshot.statistics() method for key_type and cumulative parameters.

The result is sorted from the biggest to the smallest by: absolute value of StatisticDiff.size_diff, StatisticDiff.size, absolute value of
StatisticDiff.count_diff, Statistic.count and then by StatisticDiff.traceback.

dump(filename)
Write the snapshot into a file.

Use load() to reload the snapshot.

filter_traces(filters)
Create a new Snapshot instance with a filtered traces sequence, filters is a list of DomainFilter and Filter instances. If filters is an empty list, return a new Snapshot instance with a copy of the traces.

All inclusive filters are applied at once, a trace is ignored if no inclusive filters match it. A trace is ignored if at least one exclusive filter matches it.

Changed in version 3.6: DomainFilter instances are now also accepted in filters.

classmethod load(filename)
Load a snapshot from a file.

See also dump().

statistics(key_type: str, cumulative: bool=False)
Get statistics as a sorted list of Statistic instances grouped by key_type:

<table>
<thead>
<tr>
<th>key_type</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>'filename'</td>
<td>filename</td>
</tr>
</tbody>
</table>
If `cumulative` is `True`, cumulate size and count of memory blocks of all frames of the traceback of a trace, not only the most recent frame. The cumulative mode can only be used with `key_type` equals to `filename` and `lineno`.

The result is sorted from the biggest to the smallest by: `Statistic.size`, `Statistic.count` and then by `Statistic.traceback`.

**traceback_limit**

Maximum number of frames stored in the traceback of `traces`: result of the `get_traceback_limit()` when the snapshot was taken.

**traces**

Traces of all memory blocks allocated by Python: sequence of `Trace` instances.

The sequence has an undefined order. Use the `Snapshot.statistics()` method to get a sorted list of statistics.

### 27.7.2.6. Statistic

```python
class tracemalloc.Statistic
    Statistic on memory allocations.
```

`Snapshot.statistics()` returns a list of `Statistic`
instances.

See also the `StatisticDiff` class.

**count**

Number of memory blocks (`int`).

**size**

Total size of memory blocks in bytes (`int`).

**traceback**

Traceback where the memory block was allocated, `Traceback` instance.

### 27.7.2.7. StatisticDiff

#### class `tracemalloc.StatisticDiff`

Statistic difference on memory allocations between an old and a new `Snapshot` instance.

`Snapshot.compare_to()` returns a list of `StatisticDiff` instances. See also the `Statistic` class.

**count**

Number of memory blocks in the new snapshot (`int`): 0 if the memory blocks have been released in the new snapshot.

**count_diff**

Difference of number of memory blocks between the old and the new snapshots (`int`): 0 if the memory blocks have been allocated in the new snapshot.

**size**
Total size of memory blocks in bytes in the new snapshot (int): 0 if the memory blocks have been released in the new snapshot.

**size_diff**
Difference of total size of memory blocks in bytes between the old and the new snapshots (int): 0 if the memory blocks have been allocated in the new snapshot.

**traceback**
Traceback where the memory blocks were allocated, `Traceback` instance.

### 27.7.2.8. Trace

**class tracemalloc.Trace**
Trace of a memory block.

The `Snapshot.traces` attribute is a sequence of `Trace` instances.

**size**
Size of the memory block in bytes (int).

**traceback**
Traceback where the memory block was allocated, `Traceback` instance.

### 27.7.2.9. Traceback

**class tracemalloc.Traceback**
Sequence of `Frame` instances sorted from the most recent frame
to the oldest frame.

A traceback contains at least 1 frame. If the `tracemalloc` module failed to get a frame, the filename "<unknown>" at line number 0 is used.

When a snapshot is taken, tracebacks of traces are limited to `get_traceback_limit()` frames. See the `take_snapshot()` function.

The `Trace.traceback` attribute is an instance of `Traceback` instance.

**format**(*limit=None*)

Format the traceback as a list of lines with newlines. Use the `linecache` module to retrieve lines from the source code. If `limit` is set, only format the `limit` most recent frames.

Similar to the `traceback.format_tb()` function, except that `format()` does not include newlines.

Example:

```python
print("Traceback (most recent call first):")
for line in traceback:
    print(line)
```

Output:

```
Traceback (most recent call first):
  File "test.py", line 9
    obj = Object()
  File "test.py", line 12
    tb = tracemalloc.get_object_traceback(f())
```
28. Software Packaging and Distribution

These libraries help you with publishing and installing Python software. While these modules are designed to work in conjunction with the Python Package Index, they can also be used with a local index server, or without any index server at all.

  - 28.4.4. Examples
  - 28.4.5. The Python Zip Application Archive Format
28.1. distutils — Building and installing Python modules

The distutils package provides support for building and installing additional modules into a Python installation. The new modules may be either 100%-pure Python, or may be extension modules written in C, or may be collections of Python packages which include modules coded in both Python and C.

Most Python users will not want to use this module directly, but instead use the cross-version tools maintained by the Python Packaging Authority. In particular, setuptools is an enhanced alternative to distutils that provides:

- support for declaring project dependencies
- additional mechanisms for configuring which files to include in source releases (including plugins for integration with version control systems)
- the ability to declare project “entry points”, which can be used as the basis for application plugin systems
- the ability to automatically generate Windows command line executables at installation time rather than needing to prebuild them
- consistent behaviour across all supported Python versions

The recommended pip installer runs all setup.py scripts with setuptools, even if the script itself only imports distutils. Refer to the Python Packaging User Guide for more information.

For the benefits of packaging tool authors and users seeking a deeper understanding of the details of the current packaging and distribution
system, the legacy `distutils` based user documentation and API reference remain available:

- **Installing Python Modules (Legacy version)**
- **Distributing Python Modules (Legacy version)**
28. Software Packaging and Distribution
28.2. `ensurepip` —
Bootstrapping the pip installer

*New in version 3.4.*

The `ensurepip` package provides support for bootstrapping the `pip` installer into an existing Python installation or virtual environment. This bootstrapping approach reflects the fact that `pip` is an independent project with its own release cycle, and the latest available stable version is bundled with maintenance and feature releases of the CPython reference interpreter.

In most cases, end users of Python shouldn’t need to invoke this module directly (as `pip` should be bootstrapped by default), but it may be needed if installing `pip` was skipped when installing Python (or when creating a virtual environment) or after explicitly uninstalling `pip`.

**Note:** This module *does not* access the internet. All of the components needed to bootstrap `pip` are included as internal parts of the package.

**See also:**

- **Installing Python Modules**
  The end user guide for installing Python packages

- **PEP 453: Explicit bootstrapping of pip in Python installations**
  The original rationale and specification for this module.
28.2.1. Command line interface

The command line interface is invoked using the interpreter’s `-m` switch.

The simplest possible invocation is:

```
python -m ensurepip
```

This invocation will install `pip` if it is not already installed, but otherwise does nothing. To ensure the installed version of `pip` is at least as recent as the one bundled with `ensurepip`, pass the `--upgrade` option:

```
python -m ensurepip --upgrade
```

By default, `pip` is installed into the current virtual environment (if one is active) or into the system site packages (if there is no active virtual environment). The installation location can be controlled through two additional command line options:

- `--root <dir>`: Installs `pip` relative to the given root directory rather than the root of the currently active virtual environment (if any) or the default root for the current Python installation.
- `--user`: Installs `pip` into the user site packages directory rather than globally for the current Python installation (this option is not permitted inside an active virtual environment).

By default, the scripts `pipX` and `pipX.Y` will be installed (where X.Y stands for the version of Python used to invoke `ensurepip`). The scripts installed can be controlled through two additional command line options:
- **--altinstall**: if an alternate installation is requested, the pipX script will *not* be installed.
- **--default-pip**: if a “default pip” installation is requested, the pip script will be installed in addition to the two regular scripts.

Providing both of the script selection options will trigger an exception.
28.2.2. Module API

`ensurepip` exposes two functions for programmatic use:

`ensurepip.version()`

Returns a string specifying the bundled version of pip that will be installed when bootstrapping an environment.

`ensurepip.bootstrap(root=None, upgrade=False, user=False, altinstall=False, default_pip=False, verbosity=0)`

Bootstraps pip into the current or designated environment.

- `root` specifies an alternative root directory to install relative to. If `root` is None, then installation uses the default install location for the current environment.

- `upgrade` indicates whether or not to upgrade an existing installation of an earlier version of pip to the bundled version.

- `user` indicates whether to use the user scheme rather than installing globally.

By default, the scripts `pipX` and `pipX.Y` will be installed (where X.Y stands for the current version of Python).

If `altinstall` is set, then `pipX` will not be installed.

If `default_pip` is set, then pip will be installed in addition to the two regular scripts.

Setting both `altinstall` and `default_pip` will trigger `ValueError`.

`verbosity` controls the level of output to `sys.stdout` from the
bootstrapping operation.

**Note:** The bootstrapping process has side effects on both `sys.path` and `os.environ`. Invoking the command line interface in a subprocess instead allows these side effects to be avoided.

**Note:** The bootstrapping process may install additional modules required by `pip`, but other software should not assume those dependencies will always be present by default (as the dependencies may be removed in a future version of `pip`).
28.3. **venv** — Creation of virtual environments

*New in version 3.3.*

**Source code:** Lib/venv/

The **venv** module provides support for creating lightweight “virtual environments” with their own site directories, optionally isolated from system site directories. Each virtual environment has its own Python binary (allowing creation of environments with various Python versions) and can have its own independent set of installed Python packages in its site directories.

See [PEP 405](https://www.python.org/dev/peps/pep-0405/) for more information about Python virtual environments.

**Note:** The `pyvenv` script has been deprecated as of Python 3.6 in favor of using `python3 -m venv` to help prevent any potential confusion as to which Python interpreter a virtual environment will be based on.
28.3.1. Creating virtual environments

Creation of virtual environments is done by executing the command `venv`:

```
python3 -m venv /path/to/new/virtual/environment
```

Running this command creates the target directory (creating any parent directories that don’t exist already) and places a `pyvenv.cfg` file in it with a home key pointing to the Python installation from which the command was run. It also creates a `bin` (or `Scripts` on Windows) subdirectory containing a copy of the python binary (or binaries, in the case of Windows). It also creates an (initially empty) `lib/pythonX.Y/site-packages` subdirectory (on Windows, this is `Lib\site-packages`).

*Deprecated since version 3.6:* `pyvenv` was the recommended tool for creating virtual environments for Python 3.3 and 3.4, and is deprecated in Python 3.6.

*Changed in version 3.5:* The use of `venv` is now recommended for creating virtual environments.

**See also:** Python Packaging User Guide: Creating and using virtual environments

On Windows, invoke the `venv` command as follows:

```
c:\>c:\Python35\python -m venv c:\path\to\myenv
```

Alternatively, if you configured the `PATH` and `PATHEXT` variables for
your Python installation:

```
c:\>python -m venv myenv c:\path\to\myenv
```

The command, if run with `-h`, will show the available options:

```
             ENV_DIR [ENV_DIR ...]

Creates virtual Python environments in one or more target directories.

positional arguments:
  ENV_DIR                         A directory to create the environment in.

optional arguments:
  -h, --help                      show this help message and exit
  --system-site-packages            Give the virtual environment access to the system site-packages dir.
  --symlinks                       Try to use symlinks rather than copies, when symlinks are not the default for the platform.
  --copies                         Try to use copies rather than symlinks, even when symlinks are the default for the platform.
  --clear                          Delete the contents of the environment directory if it already exists, before environment creation.
  --upgrade                        Upgrade the environment directory to use this version of Python, assuming Python has been upgraded in-place.
  --without-pip                    Skips installing or upgrading pip in the virtual environment (pip is bootstrapped by default)

Once an environment has been created, you may wish to activate it, e.g. by sourcing an activate script in its bin directory.

*Changed in version 3.4:* Installs pip by default, added the `--system-site-packages` option.
without-pip and --copies options

_Changed in version 3.4:_ In earlier versions, if the target directory already existed, an error was raised, unless the --clear or --upgrade option was provided. Now, if an existing directory is specified, its contents are removed and the directory is processed as if it had been newly created.

The created pyvenv.cfg file also includes the include-system-site-packages key, set to true if venv is run with the --system-site-packages option, false otherwise.

Unless the --without-pip option is given, ensurepip will be invoked to bootstrap pip into the virtual environment.

Multiple paths can be given to venv, in which case an identical virtual environment will be created, according to the given options, at each provided path.

Once a virtual environment has been created, it can be “activated” using a script in the virtual environment’s binary directory. The invocation of the script is platform-specific:

<table>
<thead>
<tr>
<th>Platform</th>
<th>Shell</th>
<th>Command to activate virtual environment</th>
</tr>
</thead>
<tbody>
<tr>
<td>Posix</td>
<td>bash/zsh</td>
<td>$ source &lt;venv&gt;/bin/activate</td>
</tr>
<tr>
<td></td>
<td>fish</td>
<td>$. &lt;venv&gt;/bin/activate.fish</td>
</tr>
<tr>
<td></td>
<td>csh/tcsh</td>
<td>$ source &lt;venv&gt;/bin/activate.csh</td>
</tr>
<tr>
<td>Windows</td>
<td>cmd.exe</td>
<td>C:&gt; &lt;venv&gt;\Scripts\activate.bat</td>
</tr>
<tr>
<td></td>
<td>PowerShell</td>
<td>PS C:&gt; &lt;venv&gt;\Scripts\Activate.ps1</td>
</tr>
</tbody>
</table>
You don’t specifically need to activate an environment; activation just prepends the virtual environment's binary directory to your path, so that “python” invokes the virtual environment's Python interpreter and you can run installed scripts without having to use their full path. However, all scripts installed in a virtual environment should be runnable without activating it, and run with the virtual environment's Python automatically.

You can deactivate a virtual environment by typing “deactivate” in your shell. The exact mechanism is platform-specific: for example, the Bash activation script defines a “deactivate” function, whereas on Windows there are separate scripts called deactivate.bat and Deactivate.ps1 which are installed when the virtual environment is created.

*New in version 3.4:* fish and csh activation scripts.

**Note:** A virtual environment is a Python environment such that the Python interpreter, libraries and scripts installed into it are isolated from those installed in other virtual environments, and (by default) any libraries installed in a “system” Python, i.e., one which is installed as part of your operating system.

A virtual environment is a directory tree which contains Python executable files and other files which indicate that it is a virtual environment.

Common installation tools such as setuptools and pip work as expected with virtual environments. In other words, when a virtual environment is active, they install Python packages into the virtual environment without needing to be told to do so explicitly.

When a virtual environment is active (i.e., the virtual environment's
Python interpreter is running), the attributes `sys.prefix` and `sys.exec_prefix` point to the base directory of the virtual environment, whereas `sys.base_prefix` and `sys.base_exec_prefix` point to the non-virtual environment Python installation which was used to create the virtual environment. If a virtual environment is not active, then `sys.prefix` is the same as `sys.base_prefix` and `sys.exec_prefix` is the same as `sys.base_exec_prefix` (they all point to a non-virtual environment Python installation).

When a virtual environment is active, any options that change the installation path will be ignored from all distutils configuration files to prevent projects being inadvertently installed outside of the virtual environment.

When working in a command shell, users can make a virtual environment active by running an activate script in the virtual environment's executables directory (the precise filename is shell-dependent), which prepends the virtual environment's directory for executables to the PATH environment variable for the running shell. There should be no need in other circumstances to activate a virtual environment—scripts installed into virtual environments have a “shebang” line which points to the virtual environment's Python interpreter. This means that the script will run with that interpreter regardless of the value of PATH. On Windows, “shebang” line processing is supported if you have the Python Launcher for Windows installed (this was added to Python in 3.3 - see PEP 397 for more details). Thus, double-clicking an installed script in a Windows Explorer window should run the script with the correct interpreter without there needing to be any reference to its virtual environment in PATH.
28.3.2. API

The high-level method described above makes use of a simple API which provides mechanisms for third-party virtual environment creators to customize environment creation according to their needs, the EnvBuilder class.

```python
class venv.EnvBuilder(system_site_packages=False, clear=False, symlinks=False, upgrade=False, with_pip=False, prompt=None)
```

The EnvBuilder class accepts the following keyword arguments on instantiation:

- **system_site_packages** – a Boolean value indicating that the system Python site-packages should be available to the environment (defaults to False).
- **clear** – a Boolean value which, if true, will delete the contents of any existing target directory, before creating the environment.
- **symlinks** – a Boolean value indicating whether to attempt to symlink the Python binary (and any necessary DLLs or other binaries, e.g. pythonw.exe), rather than copying. Defaults to True on Linux and Unix systems, but False on Windows.
- **upgrade** – a Boolean value which, if true, will upgrade an existing environment with the running Python - for use when that Python has been upgraded in-place (defaults to False).
- **with_pip** – a Boolean value which, if true, ensures pip is installed in the virtual environment. This uses `ensurepip` with the `--default-pip` option.
- **prompt** – a String to be used after virtual environment is activated (defaults to None which means directory name of the environment would be used).
Changed in version 3.4: Added the `with_pip` parameter

New in version 3.6: Added the `prompt` parameter

Creators of third-party virtual environment tools will be free to use the provided `EnvBuilder` class as a base class.

The returned env-builder is an object which has a method, `create`:

**create**(env_dir)

This method takes as required argument the path (absolute or relative to the current directory) of the target directory which is to contain the virtual environment. The `create` method will either create the environment in the specified directory, or raise an appropriate exception.

The `create` method of the `EnvBuilder` class illustrates the hooks available for subclass customization:

```python
def create(self, env_dir):
    """
    Create a virtualized Python environment in
    env_dir is the target directory to create a
    """
    env_dir = os.path.abspath(env_dir)
    context = self.ensure_directories(env_dir)
    self.create_configuration(context)
    self.setup_python(context)
    self.setup_scripts(context)
    self.post_setup(context)
```

Each of the methods `ensure_directories()`, `create_configuration()`, `setup_python()`,
setup_scripts() and post_setup() can be overridden.

**ensure_directories**(env_dir)

Creates the environment directory and all necessary directories, and returns a context object. This is just a holder for attributes (such as paths), for use by the other methods. The directories are allowed to exist already, as long as either clear or upgrade were specified to allow operating on an existing environment directory.

**create_configuration**(context)

Creates the pyvenv.cfg configuration file in the environment.

**setup_python**(context)

Creates a copy of the Python executable (and, under Windows, DLLs) in the environment. On a POSIX system, if a specific executable python3.x was used, symlinks to python and python3 will be created pointing to that executable, unless files with those names already exist.

**setup_scripts**(context)

Installs activation scripts appropriate to the platform into the virtual environment.

**post_setup**(context)

A placeholder method which can be overridden in third party implementations to pre-install packages in the virtual environment or perform other post-creation steps.

In addition, EnvBuilder provides this utility method that can be called from setup_scripts() or post_setup() in subclasses to assist in installing custom scripts into the virtual environment.
**install_scripts**(context, path)

*path* is the path to a directory that should contain subdirectories “common”, “posix”, “nt”, each containing scripts destined for the bin directory in the environment. The contents of “common” and the directory corresponding to *os.name* are copied after some text replacement of placeholders:

- **__VENV_DIR__** is replaced with the absolute path of the environment directory.
- **__VENV_NAME__** is replaced with the environment name (final path segment of environment directory).
- **__VENV_PROMPT__** is replaced with the prompt (the environment name surrounded by parentheses and with a following space)
- **__VENV_BIN_NAME__** is replaced with the name of the bin directory (either bin or Scripts).
- **__VENV_PYTHON__** is replaced with the absolute path of the environment's executable.

The directories are allowed to exist (for when an existing environment is being upgraded).

There is also a module-level convenience function:

```
venv.create(env_dir, system_site_packages=False, clear=False, symlinks=False, with_pip=False)
```

Create an *EnvBuilder* with the given keyword arguments, and call its *create()* method with the *env_dir* argument.

*Changed in version 3.4:* Added the *with_pip* parameter
28.3.3. An example of extending EnvBuilder

The following script shows how to extend EnvBuilder by implementing a subclass which installs setuptools and pip into a created virtual environment:

```python
import os
import os.path
from subprocess import Popen, PIPE
import sys
import threading
from urllib.parse import urlparse
from urllib.request import urlretrieve
import venv

class ExtendedEnvBuilder(venv.EnvBuilder):
    """This builder installs setuptools and pip so that you can pip or easy_install other packages into the created virtual environment.

:param nodist: If True, setuptools and pip are not installed into the created virtual environment.
:param nopip: If True, pip is not installed into the created virtual environment.
:param progress: If setuptools or pip are installed, the progress of the installation can be monitored by passing a progress callable. If specified, it is called with two arguments: a string indicating some progress and a context indicating where the string is coming from. The context argument can have one of three values: 'main', indicating that it is called from virtualize() itself, and 'stdout' and 'stderr', which are obtained by reading lines from the output streams of a subprocess.
"""
```
which is used to install the app.

If a callable is not specified, information is output to sys.stderr.

```python
def __init__(self, *args, **kwargs):
    self.nodist = kwargs.pop('nodist', False)
    self.nopip = kwargs.pop('nopip', False)
    self.progress = kwargs.pop('progress', None)
    self.verbose = kwargs.pop('verbose', False)
    super().__init__(*args, **kwargs)

def post_setup(self, context):
    """
    Set up any packages which need to be pre-installed into the virtual environment being created.
    
    :param context: The information for the virtual environment creation request being processed
    """
    os.environ['VIRTUAL_ENV'] = context.env_dir
    if not self.nodist:
        self.install_setupertools(context)
    # Can't install pip without setuptools
    if not self.nopip and not self.nodist:
        self.install_pip(context)

def reader(self, stream, context):
    """
    Read lines from a subprocess' output stream and either pass to a progress callable (if specified) or write progress information to sys.stderr.
    """
    progress = self.progress
    while True:
        s = stream.readline()
        if not s:
            break
        if callable(progress):
            progress(s)
        else:
            sys.stderr.write(s)
```

break
if progress is not None:
    progress(s, context)
else:
    if not self.verbose:
        sys.stderr.write('..
    else:
        sys.stderr.write(s.decode('utf-8'))
        sys.stderr.flush()
stream.close()

def install_script(self, context, name, url):
    _, _, path, _, _, _ = urlparse(url)
    fn = os.path.split(path)[-1]
    binpath = context.bin_path
    distpath = os.path.join(binpath, fn)
    # Download script into the virtual environment
    urlretrieve(url, distpath)
    progress = self.progress
    if self.verbose:
        term = '\n'
    else:
        term = ''
    if progress is not None:
        progress('Installing %s ...%s' % (name,
    else:
        sys.stderr.write('Installing %s ...%s' %
        sys.stderr.flush())
    # Install in the virtual environment
    args = [context.env_exe, fn]
    p = Popen(args, stdout=PIPE, stderr=PIPE, cwd
    t1 = Thread(target=self.reader, args=(p.stdout,
    t1.start())
    t2 = Thread(target=self.reader, args=(p.stderr,
    t2.start())
    p.wait()  
    t1.join())
t2.join()
if progress is not None:
    progress('done.', 'main')
else:
    sys.stderr.write('done.
')
# Clean up - no longer needed
os.unlink(distpath)

def install_setuptools(self, context):
    """
    Install setuptools in the virtual environment.
    :param context: The information for the virtual environment creation request being processed.
    """
    url = 'https://bitbucket.org/pypa/setuptools/downloads/ez_setup.py'
self.install_script(context, 'setuptools', url)
    # clear up the setuptools archive which gets downloaded
    pred = lambda o: o.startswith('setuptools-')
    files = filter(pred, os.listdir(context.bin_path))
    for f in files:
        f = os.path.join(context.bin_path, f)
        os.unlink(f)

def install_pip(self, context):
    """
    Install pip in the virtual environment.
    :param context: The information for the virtual environment creation request being processed.
    """
    url = 'https://raw.github.com/pypa/pip/master/contrib/get-pip.py'
self.install_script(context, 'pip', url)

def main(args=None):
    compatible = True
    if sys.version_info < (3, 3):
compatible = False

elif not hasattr(sys, 'base_prefix'):
    compatible = False

if not compatible:
    raise ValueError('This script is only for use with ' +
                     'Python 3.3 or later')

else:
    import argparse

    parser = argparse.ArgumentParser(prog=__name__,
                                      description=
                                      'Create a virtual environment for a project.

                                      This script is only for use with Python 3.3 or later."
                                      
                                      It will install setuptools and pip by default, but
                                      you can suppress those by using the --no-setuptools
                                      option.

                                      The virtual environment will be created in the
                                      current directory.

                                      You can specify an environment directory with
                                      the --env option.

                                      You can specify an environment directory with
                                      the --env option.

                                      You can specify an environment directory with
                                      the --env option.

                                      If no system site packages are accessed, the virtual
                                      environment will not have access to them.

                                      The virtual environment will be created in the
                                      current directory.

                                      You can specify an environment directory with
                                      the --env option.

                                      You can specify an environment directory with
                                      the --env option.

                                      if os.name == 'nt':
                use_symlinks = False
            else:
                use_symlinks = True

            parser.add_argument('dirs', metavar='ENV_DIR',
                                help='A directory in which to create the virtual environment')

            parser.add_argument('--no-setuptools', default=False,
                                action='store_true',
                                help='Don’t install setuptools in the virtual environment')

            parser.add_argument('--no-pip', default=False,

        rc = 0
    except Exception as e:
This script is also available for download online.
28.4. zipapp — Manage executable python zip archives

New in version 3.5.

Source code: Lib/zipapp.py

This module provides tools to manage the creation of zip files containing Python code, which can be executed directly by the Python interpreter. The module provides both a Command-Line Interface and a Python API.
28.4.1. Basic Example

The following example shows how the Command-Line Interface can be used to create an executable archive from a directory containing Python code. When run, the archive will execute the main function from the module myapp in the archive.

```
$ python -m zipapp myapp -m "myapp:main"
$ python myapp.pyz
<output from myapp>
```
28.4.2. Command-Line Interface

When called as a program from the command line, the following form is used:

```
$ python -m zipapp source [options]
```

If `source` is a directory, this will create an archive from the contents of `source`. If `source` is a file, it should be an archive, and it will be copied to the target archive (or the contents of its shebang line will be displayed if the –info option is specified).

The following options are understood:

- **-o <output>, --output=<output>**
  Write the output to a file named `output`. If this option is not specified, the output filename will be the same as the input `source`, with the extension `.pyz` added. If an explicit filename is given, it is used as is (so a `.pyz` extension should be included if required).

  An output filename must be specified if the `source` is an archive (and in that case, `output` must not be the same as `source`).

- **-p <interpreter>, --python=<interpreter>**
  Add a `#!` line to the archive specifying `interpreter` as the command to run. Also, on POSIX, make the archive executable. The default is to write no `#!` line, and not make the file executable.

- **-m <mainfn>, --main=<mainfn>**
  Write a `__main__.py` file to the archive that executes `mainfn`. The `mainfn` argument should have the form “pkg.mod:fn”, where “pkg.mod” is a package/module in the archive, and “fn” is a callable
in the given module. The `__main__.py` file will execute that callable.

`--main` cannot be specified when copying an archive.

`--info`
Display the interpreter embedded in the archive, for diagnostic purposes. In this case, any other options are ignored and SOURCE must be an archive, not a directory.

`-h, --help`
Print a short usage message and exit.
28.4.3. Python API

The module defines two convenience functions:

```python
zipapp.create_archive(source, target=None, interpreter=None, main=None)
```

Create an application archive from `source`. The source can be any of the following:

- The name of a directory, or a `pathlib.Path` object referring to a directory, in which case a new application archive will be created from the content of that directory.
- The name of an existing application archive file, or a `pathlib.Path` object referring to such a file, in which case the file is copied to the target (modifying it to reflect the value given for the `interpreter` argument). The file name should include the `.pyz` extension, if required.
- A file object open for reading in bytes mode. The content of the file should be an application archive, and the file object is assumed to be positioned at the start of the archive.

The `target` argument determines where the resulting archive will be written:

- If it is the name of a file, or a `pathlib.Path` object, the archive will be written to that file.
- If it is an open file object, the archive will be written to that file object, which must be open for writing in bytes mode.
- If the target is omitted (or `None`), the source must be a directory and the target will be a file with the same name as the source, with a `.pyz` extension added.

The `interpreter` argument specifies the name of the Python interpreter with which the archive will be executed. It is written as a
“shebang” line at the start of the archive. On POSIX, this will be interpreted by the OS, and on Windows it will be handled by the Python launcher. Omitting the interpreter results in no shebang line being written. If an interpreter is specified, and the target is a filename, the executable bit of the target file will be set.

The main argument specifies the name of a callable which will be used as the main program for the archive. It can only be specified if the source is a directory, and the source does not already contain a __main__.py file. The main argument should take the form “pkg.module:callable” and the archive will be run by importing “pkg.module” and executing the given callable with no arguments. It is an error to omit main if the source is a directory and does not contain a __main__.py file, as otherwise the resulting archive would not be executable.

If a file object is specified for source or target, it is the caller’s responsibility to close it after calling create_archive.

When copying an existing archive, file objects supplied only need read and readline, or write methods. When creating an archive from a directory, if the target is a file object it will be passed to the zipfile.ZipFile class, and must supply the methods needed by that class.

zipapp.get_interpreter(archive)
Return the interpreter specified in the ! line at the start of the archive. If there is no ! line, return None. The archive argument can be a filename or a file-like object open for reading in bytes mode. It is assumed to be at the start of the archive.
28.4.4. Examples

Pack up a directory into an archive, and run it.

```
$ python -m zipapp myapp
$ python myapp.pyz
<output from myapp>
```

The same can be done using the `create_archive()` function:

```
>>> import zipapp
>>> zipapp.create_archive('myapp.pyz', 'myapp')
```

To make the application directly executable on POSIX, specify an interpreter to use.

```
$ python -m zipapp myapp -p "/usr/bin/env python"
$ ./myapp.pyz
<output from myapp>
```

To replace the shebang line on an existing archive, create a modified archive using the `create_archive()` function:

```
>>> import zipapp
>>> zipapp.create_archive('old_archive.pyz', 'new_archive.pyz')
```

To update the file in place, do the replacement in memory using a BytesIO object, and then overwrite the source afterwards. Note that there is a risk when overwriting a file in place that an error will result in the loss of the original file. This code does not protect against such errors, but production code should do so. Also, this method will only work if the archive fits in memory:
Note that if you specify an interpreter and then distribute your application archive, you need to ensure that the interpreter used is portable. The Python launcher for Windows supports most common forms of POSIX `#!` line, but there are other issues to consider:

- If you use `"/usr/bin/env python"` (or other forms of the “python” command, such as `"/usr/bin/python"`), you need to consider that your users may have either Python 2 or Python 3 as their default, and write your code to work under both versions.
- If you use an explicit version, for example `"/usr/bin/env python3"` your application will not work for users who do not have that version. (This may be what you want if you have not made your code Python 2 compatible).
- There is no way to say “python X.Y or later”, so be careful of using an exact version like `"/usr/bin/env python3.4"` as you will need to change your shebang line for users of Python 3.5, for example.
28.4.5. The Python Zip Application Archive Format

Python has been able to execute zip files which contain a __main__.py file since version 2.6. In order to be executed by Python, an application archive simply has to be a standard zip file containing a __main__.py file which will be run as the entry point for the application. As usual for any Python script, the parent of the script (in this case the zip file) will be placed on sys.path and thus further modules can be imported from the zip file.

The zip file format allows arbitrary data to be prepended to a zip file. The zip application format uses this ability to prepend a standard POSIX “shebang” line to the file (#!/path/to/interpreter).

Formally, the Python zip application format is therefore:

1. An optional shebang line, containing the characters b'#!' followed by an interpreter name, and then a newline (b'
') character. The interpreter name can be anything acceptable to the OS “shebang” processing, or the Python launcher on Windows. The interpreter should be encoded in UTF-8 on Windows, and in sys.getfilesystemencoding() on POSIX.

2. Standard zipfile data, as generated by the zipfile module. The zipfile content must include a file called __main__.py (which must be in the “root” of the zipfile - i.e., it cannot be in a subdirectory). The zipfile data can be compressed or uncompressed.

If an application archive has a shebang line, it may have the executable bit set on POSIX systems, to allow it to be executed directly.
There is no requirement that the tools in this module are used to create application archives - the module is a convenience, but archives in the above format created by any means are acceptable to Python.
29. Python Runtime Services

The modules described in this chapter provide a wide range of services related to the Python interpreter and its interaction with its environment. Here's an overview:

- **29.1. sys** — System-specific parameters and functions
- **29.2. sysconfig** — Provide access to Python's configuration information
  - 29.2.1. Configuration variables
  - 29.2.2. Installation paths
  - 29.2.3. Other functions
  - 29.2.4. Using sysconfig as a script
- **29.3. builtins** — Built-in objects
- **29.4. __main__** — Top-level script environment
- **29.5. warnings** — Warning control
  - 29.5.1. Warning Categories
  - 29.5.2. The Warnings Filter
    - 29.5.2.1. Default Warning Filters
  - 29.5.3. Temporarily Suppressing Warnings
  - 29.5.4. Testing Warnings
  - 29.5.5. Updating Code For New Versions of Python
  - 29.5.6. Available Functions
  - 29.5.7. Available Context Managers
- **29.6. contextlib** — Utilities for with-statement contexts
  - 29.6.1. Utilities
  - 29.6.2. Examples and Recipes
    - 29.6.2.1. Supporting a variable number of context managers
    - 29.6.2.2. Simplifying support for single optional context managers
    - 29.6.2.3. Catching exceptions from __enter__
methods

- 29.6.2.4. Cleaning up in an __enter__ implementation
- 29.6.2.5. Replacing any use of try-finally and flag variables
- 29.6.2.6. Using a context manager as a function decorator
  - 29.6.3. Single use, reusable and reentrant context managers
    - 29.6.3.1. Reentrant context managers
    - 29.6.3.2. Reusable context managers

- 29.7. abc — Abstract Base Classes
- 29.8. atexit — Exit handlers
  - 29.8.1. atexit Example
- 29.9. traceback — Print or retrieve a stack traceback
  - 29.9.1. TracebackException Objects
  - 29.9.2. StackSummary Objects
  - 29.9.3. FrameSummary Objects
  - 29.9.4. Traceback Examples
- 29.10. __future__ — Future statement definitions
- 29.11. gc — Garbage Collector interface
- 29.12. inspect — Inspect live objects
  - 29.12.1. Types and members
  - 29.12.2. Retrieving source code
  - 29.12.3. Introspecting callables with the Signature object
  - 29.12.4. Classes and functions
  - 29.12.5. The interpreter stack
  - 29.12.6. Fetching attributes statically
  - 29.12.7. Current State of Generators and Coroutines
  - 29.12.8. Code Objects Bit Flags
  - 29.12.9. Command Line Interface
- 29.13. site — Site-specific configuration hook
  - 29.13.1. Readline configuration
  - 29.13.2. Module contents
- 29.14. fpectl — Floating point exception control
29.14.1. Example
29.14.2. Limitations and other considerations
29.1. **sys** — System-specific parameters and functions

This module provides access to some variables used or maintained by the interpreter and to functions that interact strongly with the interpreter. It is always available.

**sys.abiflags**

On POSIX systems where Python was built with the standard `configure` script, this contains the ABI flags as specified by PEP 3149.

*New in version 3.2.*

**sys.argv**

The list of command line arguments passed to a Python script. `argv[0]` is the script name (it is operating system dependent whether this is a full pathname or not). If the command was executed using the `-c` command line option to the interpreter, `argv[0]` is set to the string `'-c'`. If no script name was passed to the Python interpreter, `argv[0]` is the empty string.

To loop over the standard input, or the list of files given on the command line, see the `fileinput` module.

**sys.base_exec_prefix**

Set during Python startup, before `site.py` is run, to the same value as `exec_prefix`. If not running in a virtual environment, the values will stay the same; if `site.py` finds that a virtual environment is in use, the values of `prefix` and `exec_prefix`
will be changed to point to the virtual environment, whereas
`base_prefix` and `base_exec_prefix` will remain pointing to
the base Python installation (the one which the virtual environment
was created from).

*New in version 3.3.*

**sys.base_prefix**
Set during Python startup, before `site.py` is run, to the same
value as `prefix`. If not running in a virtual environment, the values
will stay the same; if `site.py` finds that a virtual environment is in
use, the values of `prefix` and `exec_prefix` will be changed to
point to the virtual environment, whereas `base_prefix` and
`base_exec_prefix` will remain pointing to the base Python
installation (the one which the virtual environment was created
from).

*New in version 3.3.*

**sys.byteorder**
An indicator of the native byte order. This will have the value
*big* on big-endian (most-significant byte first) platforms, and
*little* on little-endian (least-significant byte first) platforms.

**sys.builtin_module_names**
A tuple of strings giving the names of all modules that are compiled
into this Python interpreter. (This information is not available in any
other way — `modules.keys()` only lists the imported modules.)

**sys.call_tracing(func, args)**
Call `func(*args)`, while tracing is enabled. The tracing state is
saved, and restored afterwards. This is intended to be called from
a debugger from a checkpoint, to recursively debug some other code.

**sys.copyright**

A string containing the copyright pertaining to the Python interpreter.

**sys._clear_type_cache()**

Clear the internal type cache. The type cache is used to speed up attribute and method lookups. Use the function only to drop unnecessary references during reference leak debugging.

This function should be used for internal and specialized purposes only.

**sys._current_frames()**

Return a dictionary mapping each thread’s identifier to the topmost stack frame currently active in that thread at the time the function is called. Note that functions in the `traceback` module can build the call stack given such a frame.

This is most useful for debugging deadlock: this function does not require the deadlocked threads’ cooperation, and such threads’ call stacks are frozen for as long as they remain deadlocked. The frame returned for a non-deadlocked thread may bear no relationship to that thread’s current activity by the time calling code examines the frame.

This function should be used for internal and specialized purposes only.

**sys._debugmallocstats()**

Print low-level information to stderr about the state of CPython’s
If Python is configured –with-pydebug, it also performs some expensive internal consistency checks.

New in version 3.3.

CPython implementation detail: This function is specific to CPython. The exact output format is not defined here, and may change.

**sys.dllhandle**

Integer specifying the handle of the Python DLL. Availability: Windows.

**sys.displayhook**

If `value` is not `None`, this function prints `repr(value)` to `sys.stdout`, and saves `value` in `builtins._`. If `repr(value)` is not encodable to `sys.stdout.encoding` with `sys.stdout.errors` error handler (which is probably 'strict'), encode it to `sys.stdout.encoding` with 'backslashreplace' error handler.

`sys.displayhook` is called on the result of evaluating an expression entered in an interactive Python session. The display of these values can be customized by assigning another one-argument function to `sys.displayhook`.

Pseudo-code:

```python
def displayhook(value):
    if value is None:
        return
    # Set '_' to None to avoid recursion
```
builtins._ = None
text = repr(value)
try:
    sys.stdout.write(text)
except UnicodeEncodeError:
    bytes = text.encode(sys.stdout.encoding,
    if hasattr(sys.stdout, 'buffer'):
        sys.stdout.buffer.write(bytes)
    else:
        text = bytes.decode(sys.stdout.encod
    sys.stdout.write(text)
sys.stdout.write("\n")
builtins._ = value

Changed in version 3.2: Use 'backslashreplace' error handler on UnicodeEncodeError.

sys.dont_write_bytecode
If this is true, Python won’t try to write .pyc files on the import of source modules. This value is initially set to True or False depending on the -B command line option and the PYTHONDONTWRITEBYTECODE environment variable, but you can set it yourself to control bytecode file generation.

sys.excepthook(type, value, traceback)
This function prints out a given traceback and exception to sys.stderr.

When an exception is raised and uncaught, the interpreter calls sys.excepthook with three arguments, the exception class, exception instance, and a traceback object. In an interactive session this happens just before control is returned to the prompt; in a Python program this happens just before the program exits.
The handling of such top-level exceptions can be customized by assigning another three-argument function to \texttt{sys.excepthook}.

\texttt{sys.__displayhook__}
\texttt{sys.__excepthook__}

These objects contain the original values of \texttt{displayhook} and \texttt{excepthook} at the start of the program. They are saved so that \texttt{displayhook} and \texttt{excepthook} can be restored in case they happen to get replaced with broken objects.

\texttt{sys.exc_info()}

This function returns a tuple of three values that give information about the exception that is currently being handled. The information returned is specific both to the current thread and to the current stack frame. If the current stack frame is not handling an exception, the information is taken from the calling stack frame, or its caller, and so on until a stack frame is found that is handling an exception. Here, “handling an exception” is defined as “executing an except clause.” For any stack frame, only information about the exception being currently handled is accessible.

If no exception is being handled anywhere on the stack, a tuple containing three \texttt{None} values is returned. Otherwise, the values returned are (\texttt{type, value, traceback}). Their meaning is: \texttt{type} gets the type of the exception being handled (a subclass of \texttt{BaseException}); \texttt{value} gets the exception instance (an instance of the exception type); \texttt{traceback} gets a traceback object (see the Reference Manual) which encapsulates the call stack at the point where the exception originally occurred.

\texttt{sys.exec_prefix}

A string giving the site-specific directory prefix where the platform-
dependent Python files are installed; by default, this is also '/usr/local'. This can be set at build time with the --exec-prefix argument to the configure script. Specifically, all configuration files (e.g. the pyconfig.h header file) are installed in the directory exec_prefix/lib/pythonX.Y/config, and shared library modules are installed in exec_prefix/lib/pythonX.Y/lib-dynload, where X.Y is the version number of Python, for example 3.2.

Note: If a virtual environment is in effect, this value will be changed in site.py to point to the virtual environment. The value for the Python installation will still be available, via base_exec_prefix.

sys.executable

A string giving the absolute path of the executable binary for the Python interpreter, on systems where this makes sense. If Python is unable to retrieve the real path to its executable, sys.executable will be an empty string or None.

sys.exit([arg])

Exit from Python. This is implemented by raising the SystemExit exception, so cleanup actions specified by finally clauses of try statements are honored, and it is possible to intercept the exit attempt at an outer level.

The optional argument arg can be an integer giving the exit status (defaulting to zero), or another type of object. If it is an integer, zero is considered “successful termination” and any nonzero value is considered “abnormal termination” by shells and the like. Most systems require it to be in the range 0–127, and produce undefined
results otherwise. Some systems have a convention for assigning specific meanings to specific exit codes, but these are generally underdeveloped; Unix programs generally use 2 for command line syntax errors and 1 for all other kind of errors. If another type of object is passed, None is equivalent to passing zero, and any other object is printed to stderr and results in an exit code of 1. In particular, sys.exit("some error message") is a quick way to exit a program when an error occurs.

Since exit() ultimately “only” raises an exception, it will only exit the process when called from the main thread, and the exception is not intercepted.

*Changed in version 3.6:* If an error occurs in the cleanup after the Python interpreter has caught SystemExit (such as an error flushing buffered data in the standard streams), the exit status is changed to 120.

**sys.flags**

The struct sequence flags exposes the status of command line flags. The attributes are read only.

<table>
<thead>
<tr>
<th>attribute</th>
<th>flag</th>
</tr>
</thead>
<tbody>
<tr>
<td>debug</td>
<td>-d</td>
</tr>
<tr>
<td>inspect</td>
<td>-i</td>

<tr>
<td>epsilon</td>
<td>DBL_EPSILON</td>
</tr>
<tr>
<td>dig</td>
<td>DBL_DIG</td>
</tr>
<tr>
<td>sys.float_info</td>
<td></td>
</tr>
</tbody>
</table>

**sys.float_info**

A struct sequence holding information about the float type. It contains low level information about the precision and internal representation. The values correspond to the various floating-point constants defined in the standard header file float.h for the ‘C’ programming language; see section 5.2.4.2.2 of the 1999 ISO/IEC C standard [C99], ‘Characteristics of floating types’, for details.
<table>
<thead>
<tr>
<th>Variable</th>
<th>Macro</th>
<th>Description</th>
</tr>

</tr>
<tr>
<td>radix</td>
<td>FLT_RADIX</td>
<td>radix of exponent representation</td>
</tr>
<tr>
<td>rounds</td>
<td>FLT_ROUNDS</td>
<td>integer constant representing the rounding mode used for arithmetic operations. This reflects the value of the system FLT_ROUNDS macro at interpreter startup time. See section 5.2.4.2.2 of the C99 standard for an explanation of the possible values and their meanings.</td>
</tr>
</tbody>
</table>
The attribute `sys.float_info.dig` needs further explanation. If `s` is any string representing a decimal number with at most `sys.float_info.dig` significant digits, then converting `s` to a float and back again will recover a string representing the same decimal value:

```
>>> import sys
>>> sys.float_info.dig
15
>>> s = '3.14159265358979'  # decimal string with 15 significant digits
>>> format(float(s), '.15g')  # convert to float and back again
'3.14159265358979'
```

But for strings with more than `sys.float_info.dig` significant digits, this isn’t always true:

```
>>> s = '9876543211234567'  # 16 significant digits is too many!
>>> format(float(s), '.16g')  # conversion changes value
'9876543211234568'
```

`sys.float_repr_style`

A string indicating how the `repr()` function behaves for floats. If the string has value 'short' then for a finite float `x`, `repr(x)` aims to produce a short string with the property that `float(repr(x)) == x`. This is the usual behaviour in Python 3.1 and later. Otherwise, `float_repr_style` has value 'legacy' and `repr(x)` behaves in the same way as it did in versions of Python prior to 3.1.

*New in version 3.1.*

`sys.getallocatedblocks()`
Return the number of memory blocks currently allocated by the interpreter, regardless of their size. This function is mainly useful for tracking and debugging memory leaks. Because of the interpreter’s internal caches, the result can vary from call to call; you may have to call \_clear_type_cache() and gc.collect() to get more predictable results.

If a Python build or implementation cannot reasonably compute this information, getallocatedblocks() is allowed to return 0 instead.

*New in version 3.4.*

**sys.getcheckinterval()**

Return the interpreter’s “check interval”; see getcheckinterval().

*Deprecated since version 3.2:* Use getswitchinterval() instead.

**sys.getdefaultencoding()**

Return the name of the current default string encoding used by the Unicode implementation.

**sys.getdlopenflags()**

Return the current value of the flags that are used for dlopen() calls. Symbolic names for the flag values can be found in the \os\ module (RTLD\_xxx constants, e.g. \os\RTLD\_LAZY). Availability: Unix.

**sys.getfilesystemencoding()**

Return the name of the encoding used to convert between Unicode filenames and bytes filenames. For best compatibility, str should be
used for filenames in all cases, although representing filenames as bytes is also supported. Functions accepting or returning filenames should support either str or bytes and internally convert to the system’s preferred representation.

This encoding is always ASCII-compatible.

`os.fsencode()` and `os.fsdecode()` should be used to ensure that the correct encoding and errors mode are used.

- On Mac OS X, the encoding is 'utf-8'.
- On Unix, the encoding is the locale encoding.
- On Windows, the encoding may be 'utf-8' or 'mbcs', depending on user configuration.

*Changed in version 3.2:* `getfilesystemencoding()` result cannot be None anymore.

*Changed in version 3.6:* Windows is no longer guaranteed to return 'mbcs'. See [PEP 529](https://www.python.org/dev/peps/pep-0529/) and `_enablelegacywindowsfsencoding()` for more information.

`sys.getfilesystemencodeerrors()`

Return the name of the error mode used to convert between Unicode filenames and bytes filenames. The encoding name is returned from `getfilesystemencoding()`.

`os.fsencode()` and `os.fsdecode()` should be used to ensure that the correct encoding and errors mode are used.

*New in version 3.6.*

`sys.getrefcount(object)`

Return the reference count of the `object`. The count returned is
generally one higher than you might expect, because it includes
the (temporary) reference as an argument to \texttt{getrefcount()}.

\texttt{sys.getrecursionlimit()}

Return the current value of the recursion limit, the maximum depth
of the Python interpreter stack. This limit prevents infinite recursion
from causing an overflow of the C stack and crashing Python. It
can be set by \texttt{setrecursionlimit()}.

\texttt{sys.getsizeof(object[, default])}

Return the size of an object in bytes. The object can be any type of
object. All built-in objects will return correct results, but this does
not have to hold true for third-party extensions as it is implementation specific.

Only the memory consumption directly attributed to the object is
accounted for, not the memory consumption of objects it refers to.

If given, \texttt{default} will be returned if the object does not provide
means to retrieve the size. Otherwise a \texttt{TypeError} will be raised.

\texttt{getsizeof()} calls the object's \underline{\texttt{__sizeof__}} method and adds
an additional garbage collector overhead if the object is managed
by the garbage collector.

See \texttt{recursive sizeof recipe} for an example of using \texttt{getsizeof()} recursivelly to find the size of containers and all their contents.

\texttt{sys.getswitchinterval()}

Return the interpreter's "thread switch interval"; see
\texttt{setswitchinterval()}.

\textit{New in version 3.2.}
sys._getframe([depth])

Return a frame object from the call stack. If optional integer depth is given, return the frame object that many calls below the top of the stack. If that is deeper than the call stack, ValueError is raised. The default for depth is zero, returning the frame at the top of the call stack.

**CPython implementation detail:** This function should be used for internal and specialized purposes only. It is not guaranteed to exist in all implementations of Python.

sys.getprofile()

Get the profiler function as set by setprofile().

sys.gettrace()

Get the trace function as set by settrace().

**CPython implementation detail:** The gettrace() function is intended only for implementing debuggers, profilers, coverage tools and the like. Its behavior is part of the implementation platform, rather than part of the language definition, and thus may not be available in all Python implementations.

sys.getwindowsversion()

Return a named tuple describing the Windows version currently running. The named elements are major, minor, build, platform, service_pack, service_pack_minor, service_pack_major, suite_mask, product_type and platform_version. service_pack contains a string, platform_version a 3-tuple and all other values are integers. The components can also be accessed by name, so sys.getwindowsversion()[0] is equivalent to sys.getwindowsversion().major. For compatibility with prior
versions, only the first 5 elements are retrievable by indexing.

*platform* will be 2 (VER_PLATFORM_WIN32_NT).

*product_type* may be one of the following values:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 (VER_NT_WORKSTATION)</td>
<td>The system is a workstation.</td>
</tr>
<tr>
<td>2 (VER_NT_DOMAIN_CONTROLLER)</td>
<td>The system is a domain controller.</td>
</tr>
<tr>
<td>3 (VER_NT_SERVER)</td>
<td>The system is a server, but not a domain controller.</td>
</tr>
</tbody>
</table>

This function wraps the Win32 GetVersionEx() function; see the Microsoft documentation on `OSVERSIONINFOEX()` for more information about these fields.

*platform_version* returns the accurate major version, minor version and build number of the current operating system, rather than the version that is being emulated for the process. It is intended for use in logging rather than for feature detection.

Availability: Windows.

*Changed in version 3.2:* Changed to a named tuple and added `service_pack_minor`, `service_pack_major`, `suite_mask`, and `product_type`.

*Changed in version 3.6:* Added `platform_version`

```python
sys.get_asyncgen_hooks()
```

Returns an `asyncgen_hooks` object, which is similar to a `namedtuple` of the form `(firstiter, finalizer)`, where `firstiter` and
finalizer are expected to be either None or functions which take an asynchronous generator iterator as an argument, and are used to schedule finalization of an asynchronous generator by an event loop.

New in version 3.6: See PEP 525 for more details.

**Note:** This function has been added on a provisional basis (see PEP 411 for details.)

sys. gets_coroutine_wrapper()  
Returns None, or a wrapper set by set_coroutine_wrapper().

New in version 3.5: See PEP 492 for more details.

**Note:** This function has been added on a provisional basis (see PEP 411 for details.) Use it only for debugging purposes.

sys. hash_info  
A struct sequence giving parameters of the numeric hash implementation. For more details about hashing of numeric types, see Hashing of numeric types.

<table>
<thead>
<tr>
<th>attribute</th>
<th>explanation</th>
</tr>
</thead>
<tbody>
<tr>

</table>

*New in version 3.2.*

*Changed in version 3.4:* Added `algorithm`, `hash_bits` and `seed_bits`

**sys.hexversion**

The version number encoded as a single integer. This is guaranteed to increase with each version, including proper support for non-production releases. For example, to test that the Python interpreter is at least version 1.5.2, use:

```python
if sys.hexversion >= 0x010502F0:
    # use some advanced feature

... else:
    # use an alternative implementation or warn the user
...```

This is called `hexversion` since it only really looks meaningful when viewed as the result of passing it to the built-in `hex()` function. The *struct sequence* `sys.version_info` may be used for a more human-friendly encoding of the same information.

More details of `hexversion` can be found at [API and ABI Versioning](#).

**sys.implementation**

An object containing information about the implementation of the
currently running Python interpreter. The following attributes are required to exist in all Python implementations.

`name` is the implementation’s identifier, e.g. `'cpython'`. The actual string is defined by the Python implementation, but it is guaranteed to be lower case.

`version` is a named tuple, in the same format as `sys.version_info`. It represents the version of the Python implementation. This has a distinct meaning from the specific version of the Python language to which the currently running interpreter conforms, which `sys.version_info` represents. For example, for PyPy 1.8 `sys.implementation.version` might be `sys.version_info(1, 8, 0, 'final', 0)`, whereas `sys.version_info` would be `sys.version_info(2, 7, 2, 'final', 0)`. For CPython they are the same value, since it is the reference implementation.

`hexversion` is the implementation version in hexadecimal format, like `sys.hexversion`.

`cache_tag` is the tag used by the import machinery in the filenames of cached modules. By convention, it would be a composite of the implementation’s name and version, like `'cpython-33'`. However, a Python implementation may use some other value if appropriate. If `cache_tag` is set to `None`, it indicates that module caching should be disabled.

`sys.implementation` may contain additional attributes specific to the Python implementation. These non-standard attributes must start with an underscore, and are not described here. Regardless of its contents, `sys.implementation` will not change during a
run of the interpreter, nor between implementation versions. (It may change between Python language versions, however.) See PEP 421 for more information.

*New in version 3.3.*

**sys.int_info**

A *struct sequence* that holds information about Python’s internal representation of integers. The attributes are read only.

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>bits_per_digit</td>
<td>number of bits held in each digit. Python integers are stored internally in base $2^{**int_info.bits_per_digit}$</td>
</tr>
<tr>
<td>sizeof_digit</td>
<td>size in bytes of the C type used to represent a digit</td>
</tr>
</tbody>
</table>

*New in version 3.1.*

**sys.__interactivehook__**

When this attribute exists, its value is automatically called (with no arguments) when the interpreter is launched in interactive mode. This is done after the PYTHONSTARTUP file is read, so that you can set this hook there. The site module sets this.

*New in version 3.4.*

**sys.intern(string)**

Enter *string* in the table of “interned” strings and return the interned string – which is *string* itself or a copy. Interning strings is useful to gain a little performance on dictionary lookup – if the keys in a dictionary are interned, and the lookup key is interned, the key comparisons (after hashing) can be done by a pointer compare
instead of a string compare. Normally, the names used in Python programs are automatically interned, and the dictionaries used to hold module, class or instance attributes have interned keys.

Interned strings are not immortal; you must keep a reference to the return value of `intern()` around to benefit from it.

```python
sys.is_finalizing()
```

Return `True` if the Python interpreter is shutting down, `False` otherwise.

*New in version 3.5.*

```python
sys.last_type
sys.last_value
sys.last_traceback
```

These three variables are not always defined; they are set when an exception is not handled and the interpreter prints an error message and a stack traceback. Their intended use is to allow an interactive user to import a debugger module and engage in post-mortem debugging without having to re-execute the command that caused the error. (Typical use is `import pdb; pdb.pm()` to enter the post-mortem debugger; see `pdb` module for more information.)

The meaning of the variables is the same as that of the return values from `exc_info()` above.

```python
sys.maxsize
```

An integer giving the maximum value a variable of type `Py_ssize_t` can take. It's usually `2**31 - 1` on a 32-bit platform and `2**63 - 1` on a 64-bit platform.
sys.**maxunicode**

An integer giving the value of the largest Unicode code point, i.e. 1114111 (0x10FFFF in hexadecimal).

*Changed in version 3.3:* Before **PEP 393**, sys.maxunicode used to be either 0xFFFF or 0x10FFFF, depending on the configuration option that specified whether Unicode characters were stored as UCS-2 or UCS-4.

sys.**meta_path**

A list of **meta path finder** objects that have their `find_spec()` methods called to see if one of the objects can find the module to be imported. The `find_spec()` method is called with at least the absolute name of the module being imported. If the module to be imported is contained in a package, then the parent package's `__path__` attribute is passed in as a second argument. The method returns a `module spec`, or `None` if the module cannot be found.

**See also:**

- `importlib.abc.MetaPathFinder`
  The abstract base class defining the interface of finder objects on `meta_path`.

- `importlib.machinery.ModuleSpec`
  The concrete class which `find_spec()` should return instances of.

*Changed in version 3.4:* **Module specs** were introduced in Python 3.4, by **PEP 451**. Earlier versions of Python looked for a method called `find_module()`. This is still called as a fallback if a `meta_path` entry doesn't have a `find_spec()` method.
**sys.modules**
This is a dictionary that maps module names to modules which have already been loaded. This can be manipulated to force reloading of modules and other tricks. However, replacing the dictionary will not necessarily work as expected and deleting essential items from the dictionary may cause Python to fail.

**sys.path**
A list of strings that specifies the search path for modules. Initialized from the environment variable `PYTHONPATH`, plus an installation-dependent default.

As initialized upon program startup, the first item of this list, `path[0]`, is the directory containing the script that was used to invoke the Python interpreter. If the script directory is not available (e.g. if the interpreter is invoked interactively or if the script is read from standard input), `path[0]` is the empty string, which directs Python to search modules in the current directory first. Notice that the script directory is inserted before the entries inserted as a result of `PYTHONPATH`.

A program is free to modify this list for its own purposes. Only strings and bytes should be added to `sys.path`; all other data types are ignored during import.

**See also:** Module `site` This describes how to use .pth files to extend `sys.path`.

**sys.path_hooks**
A list of callables that take a path argument to try to create a `finder` for the path. If a finder can be created, it is to be returned by the callable, else raise `ImportError`. 
Originally specified in PEP 302.

**sys.path_importer_cache**

A dictionary acting as a cache for finder objects. The keys are paths that have been passed to `sys.path_hooks` and the values are the finders that are found. If a path is a valid file system path but no finder is found on `sys.path_hooks` then None is stored. Originally specified in PEP 302.

*Changed in version 3.3:* None is stored instead of `imp.NullImporter` when no finder is found.

**sys.platform**

This string contains a platform identifier that can be used to append platform-specific components to `sys.path`, for instance.

For Unix systems, except on Linux, this is the lowercased OS name as returned by `uname -s` with the first part of the version as returned by `uname -r` appended, e.g. 'sunos5' or 'freebsd8', *at the time when Python was built*. Unless you want to test for a specific system version, it is therefore recommended to use the following idiom:

```python
if sys.platform.startswith('freebsd'):
    # FreeBSD-specific code here...
elif sys.platform.startswith('linux'):
    # Linux-specific code here...
```

For other systems, the values are:

<table>
<thead>
<tr>
<th>System</th>
<th>platform value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Linux</td>
<td>'linux'</td>
</tr>
<tr>
<td>System</td>
<td>Value</td>
</tr>
<tr>
<td>-----------------</td>
<td>---------</td>
</tr>
<tr>
<td>Windows</td>
<td>'win32'</td>
</tr>
<tr>
<td>Windows/Cygwin</td>
<td>'cygwin'</td>
</tr>
<tr>
<td>Mac OS X</td>
<td>'darwin'</td>
</tr>
</tbody>
</table>

*Changed in version 3.3:* On Linux, `sys.platform` doesn’t contain the major version anymore. It is always 'linux', instead of 'linux2' or 'linux3'. Since older Python versions include the version number, it is recommended to always use the `startswith` idiom presented above.

**See also:** `os.name` has a coarser granularity. `os.uname()` gives system-dependent version information. The `platform` module provides detailed checks for the system's identity.

**sys.prefix**

A string giving the site-specific directory prefix where the platform independent Python files are installed; by default, this is the string '/usr/local'. This can be set at build time with the `--prefix` argument to the `configure` script. The main collection of Python library modules is installed in the directory `prefix/lib/pythonX.Y` while the platform independent header files (all except `pyconfig.h`) are stored in `prefix/include/pythonX.Y`, where `X.Y` is the version number of Python, for example 3.2.

**Note:** If a virtual environment is in effect, this value will be changed in `site.py` to point to the virtual environment. The value for the Python installation will still be available, via `base_prefix`.
Strings specifying the primary and secondary prompt of the interpreter. These are only defined if the interpreter is in interactive mode. Their initial values in this case are '>>>' and '... '. If a non-string object is assigned to either variable, its `str()` is re-evaluated each time the interpreter prepares to read a new interactive command; this can be used to implement a dynamic prompt.

Set the interpreter’s “check interval”. This integer value determines how often the interpreter checks for periodic things such as thread switches and signal handlers. The default is 100, meaning the check is performed every 100 Python virtual instructions. Setting it to a larger value may increase performance for programs using threads. Setting it to a value <= 0 checks every virtual instruction, maximizing responsiveness as well as overhead.

*Deprecated since version 3.2:* This function doesn’t have an effect anymore, as the internal logic for thread switching and asynchronous tasks has been rewritten. Use `setswitchinterval()` instead.

Set the flags used by the interpreter for `dlopen()` calls, such as when the interpreter loads extension modules. Among other things, this will enable a lazy resolving of symbols when importing a module, if called as `sys.setdlopenflags(0)`. To share symbols across extension modules, call as `sys.setdlopenflags(os.RTLD_GLOBAL)`. Symbolic names for the flag values can be found in the `os` module (RTLD_XXX
constants, e.g. `os.RTLD_LAZY`).

Availability: Unix.

**sys.setprofile(profilefunc)**

Set the system’s profile function, which allows you to implement a Python source code profiler in Python. See chapter *The Python Profilers* for more information on the Python profiler. The system’s profile function is called similarly to the system’s trace function (see `settrace()`), but it isn’t called for each executed line of code (only on call and return, but the return event is reported even when an exception has been set). The function is thread-specific, but there is no way for the profiler to know about context switches between threads, so it does not make sense to use this in the presence of multiple threads. Also, its return value is not used, so it can simply return `None`.

**sys.setrecursionlimit(limit)**

Set the maximum depth of the Python interpreter stack to `limit`. This limit prevents infinite recursion from causing an overflow of the C stack and crashing Python.

The highest possible limit is platform-dependent. A user may need to set the limit higher when they have a program that requires deep recursion and a platform that supports a higher limit. This should be done with care, because a too-high limit can lead to a crash.

If the new limit is too low at the current recursion depth, a `RecursionError` exception is raised.

*Changed in version 3.5.1:* A `RecursionError` exception is now raised if the new limit is too low at the current recursion depth.
**sys.setswitchinterval**(interval)

Set the interpreter’s thread switch interval (in seconds). This floating-point value determines the ideal duration of the “timeslices” allocated to concurrently running Python threads. Please note that the actual value can be higher, especially if long-running internal functions or methods are used. Also, which thread becomes scheduled at the end of the interval is the operating system’s decision. The interpreter doesn’t have its own scheduler.

*New in version 3.2.*

**sys.settrace**(tracefunc)

Set the system’s trace function, which allows you to implement a Python source code debugger in Python. The function is thread-specific; for a debugger to support multiple threads, it must be registered using `settrace()` for each thread being debugged.

Trace functions should have three arguments: `frame`, `event`, and `arg`. `frame` is the current stack frame. `event` is a string: 'call', 'line', 'return', 'exception', 'c_call', 'c_return', or 'c_exception'. `arg` depends on the event type.

The trace function is invoked (with `event` set to 'call') whenever a new local scope is entered; it should return a reference to a local trace function to be used that scope, or `None` if the scope shouldn’t be traced.

The local trace function should return a reference to itself (or to another function for further tracing in that scope), or `None` to turn off tracing in that scope.

The events have the following meaning:
'call'
A function is called (or some other code block entered). The global trace function is called; \textit{arg} is \texttt{None}; the return value specifies the local trace function.

'line'
The interpreter is about to execute a new line of code or re-execute the condition of a loop. The local trace function is called; \textit{arg} is \texttt{None}; the return value specifies the new local trace function. See \texttt{Objects/1notab_notes.txt} for a detailed explanation of how this works.

'return'
A function (or other code block) is about to return. The local trace function is called; \textit{arg} is the value that will be returned, or \texttt{None} if the event is caused by an exception being raised. The trace function's return value is ignored.

'exception'
An exception has occurred. The local trace function is called; \textit{arg} is a tuple \((\text{exception, value, traceback})\); the return value specifies the new local trace function.

'c_call'
A C function is about to be called. This may be an extension function or a built-in. \textit{arg} is the C function object.

'c_return'
A C function has returned. \textit{arg} is the C function object.

'c_exception'
A C function has raised an exception. \textit{arg} is the C function object.

Note that as an exception is propagated down the chain of callers, an 'exception' event is generated at each level.
For more information on code and frame objects, refer to The standard type hierarchy.

**CPython implementation detail:** The `settrace()` function is intended only for implementing debuggers, profilers, coverage tools and the like. Its behavior is part of the implementation platform, rather than part of the language definition, and thus may not be available in all Python implementations.

```python
sys.set_asyncgen_hooks(firstiter, finalizer)
```

Accepts two optional keyword arguments which are callables that accept an asynchronous generator iterator as an argument. The `firstiter` callable will be called when an asynchronous generator is iterated for the first time. The `finalizer` will be called when an asynchronous generator is about to be garbage collected.

New in version 3.6: See PEP 525 for more details, and for a reference example of a `finalizer` method see the implementation of `asyncio.Loop.shutdown_asyncgens` in `Lib/asyncio/base_events.py`

**Note:** This function has been added on a provisional basis (see PEP 411 for details.)

```python
sys.set_coroutine_wrapper(wrapper)
```

Allows intercepting creation of coroutine objects (only ones that are created by an async def function; generators decorated with `types.coroutine()` or `asyncio.coroutine()` will not be intercepted).

The `wrapper` argument must be either:

- a callable that accepts one argument (a coroutine object);
• None, to reset the wrapper.

If called twice, the new wrapper replaces the previous one. The function is thread-specific.

The wrapper callable cannot define new coroutines directly or indirectly:

```python
def wrapper(coro):
    async def wrap(coro):
        return await coro
    return wrap(coro)
sys.set_coroutine_wrapper(wrapper)
async def foo():
    pass

# The following line will fail with a RuntimeError, because
# `wrapper` creates a `wrap(coro)` coroutine:
foo()
```

See also get_coroutine_wrapper().

*New in version 3.5:* See PEP 492 for more details.

---

**Note:** This function has been added on a provisional basis (see PEP 411 for details.) Use it only for debugging purposes.

```python
sys._enablelegacywindowsfsencoding()
```

Changes the default filesystem encoding and errors mode to ‘mbcs’ and ‘replace’ respectively, for consistency with versions of Python prior to 3.6.

This is equivalent to defining the
PYTHONLEGACYWINDOWSFSENCODING environment variable before launching Python.

Availability: Windows

New in version 3.6: See PEP 529 for more details.

```python
sys.stdin
sys.stdout
sys.stderr
```

File objects used by the interpreter for standard input, output and errors:

- **stdin** is used for all interactive input (including calls to `input()``
- **stdout** is used for the output of `print()` and `expression` statements and for the prompts of `input()``
- The interpreter’s own prompts and its error messages go to **stderr**.

These streams are regular text files like those returned by the `open()` function. Their parameters are chosen as follows:

- The character encoding is platform-dependent. Under Windows, if the stream is interactive (that is, if its `isatty()` method returns `True``), the console codepage is used, otherwise the ANSI code page. Under other platforms, the locale encoding is used (see `locale.getpreferredencoding()`).

Under all platforms though, you can override this value by setting the PYTHONIOENCODING environment variable before starting Python.
When interactive, standard streams are line-buffered. Otherwise, they are block-buffered like regular text files. You can override this value with the -u command-line option.

**Note:** To write or read binary data from/to the standard streams, use the underlying binary `buffer` object. For example, to write bytes to `stdout`, use `sys.stdout.buffer.write(b'abc')`. However, if you are writing a library (and do not control in which context its code will be executed), be aware that the standard streams may be replaced with file-like objects like `io.StringIO` which do not support the `buffer` attribute.

```python
sys.__stdin__
sys.__stdout__
sys.__stderr__
```

These objects contain the original values of `stdin`, `stdout` and `stderr` at the start of the program. They are used during finalization, and could be useful to print to the actual standard stream no matter if the `sys.std*` object has been redirected.

It can also be used to restore the actual files to known working file objects in case they have been overwritten with a broken object. However, the preferred way to do this is to explicitly save the previous stream before replacing it, and restore the saved object.

**Note:** Under some conditions `stdin`, `stdout` and `stderr` as well as the original values `__stdin__`, `__stdout__` and `__stderr__` can be `None`. It is usually the case for Windows GUI apps that aren’t connected to a console and Python apps started with `pythonw`. 
**sys.**thread_info

A struct sequence holding information about the thread implementation.

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Explanation</th>
</tr>
</thead>
</table>
| name      | Name of the thread implementation:  
  - 'nt': Windows threads  
  - 'pthread': POSIX threads  
  - 'solaris': Solaris threads |
| lock      | Name of the lock implementation:  
  - 'semaphore': a lock uses a semaphore  
  - 'mutex+cond': a lock uses a mutex and a condition variable  
  - None if this information is unknown |
| version   | Name and version of the thread library. It is a string, or None if these informations are unknown. |

*New in version 3.3.*

**sys.**tracebacklimit

When this variable is set to an integer value, it determines the maximum number of levels of traceback information printed when an unhandled exception occurs. The default is 1000. When set to 0 or less, all traceback information is suppressed and only the exception type and value are printed.

**sys.**version
A string containing the version number of the Python interpreter plus additional information on the build number and compiler used. This string is displayed when the interactive interpreter is started. Do not extract version information out of it, rather, use `version_info` and the functions provided by the `platform` module.

`systapi_version`

The C API version for this interpreter. Programmers may find this useful when debugging version conflicts between Python and extension modules.

`systversion_info`

A tuple containing the five components of the version number: `major`, `minor`, `micro`, `releaselevel`, and `serial`. All values except `releaselevel` are integers; the release level is 'alpha', 'beta', 'candidate', or 'final'. The `version_info` value corresponding to the Python version 2.0 is (2, 0, 0, 'final', 0). The components can also be accessed by name, so `sys.version_info[0]` is equivalent to `sys.version_info.major` and so on.

*Changed in version 3.1:* Added named component attributes.

`systwarnoptions`

This is an implementation detail of the warnings framework; do not modify this value. Refer to the `warnings` module for more information on the warnings framework.

`systwinver`

The version number used to form registry keys on Windows platforms. This is stored as string resource 1000 in the Python
DLL. The value is normally the first three characters of `version`. It is provided in the `sys` module for informational purposes; modifying this value has no effect on the registry keys used by Python. Availability: Windows.

`sys._xoptions`
A dictionary of the various implementation-specific flags passed through the `-X` command-line option. Option names are either mapped to their values, if given explicitly, or to `True`. Example:

```
$ ./python -Xa=b -Xc
Python 3.2a3+ (py3k, Oct 16 2010, 20:14:50)
[GCC 4.4.3] on linux2
Type "help", "copyright", "credits" or "license"

>>> import sys
>>> sys._xoptions
{'a': 'b', 'c': True}
```

**CPython implementation detail:** This is a CPython-specific way of accessing options passed through `-X`. Other implementations may export them through other means, or not at all.

*New in version 3.2.*

**Citations**

29.2. sysconfig — Provide access to Python’s configuration information

New in version 3.2.

Source code: Lib/sysconfig.py

The sysconfig module provides access to Python's configuration information like the list of installation paths and the configuration variables relevant for the current platform.
29.2.1. Configuration variables

A Python distribution contains a Makefile and a pyconfig.h header file that are necessary to build both the Python binary itself and third-party C extensions compiled using distutils.

sysconfig puts all variables found in these files in a dictionary that can be accessed using get_config_vars() or get_config_var().

Notice that on Windows, it's a much smaller set.

sysconfig.get_config_vars(*args)

With no arguments, return a dictionary of all configuration variables relevant for the current platform.

With arguments, return a list of values that result from looking up each argument in the configuration variable dictionary.

For each argument, if the value is not found, return None.

sysconfig.get_config_var(name)

Return the value of a single variable name. Equivalent to get_config_vars().get(name).

If name is not found, return None.

Example of usage:

```python
>>> import sysconfig
>>> sysconfig.get_config_var('Py_ENABLE_SHARED')
0
>>> sysconfig.get_config_var('LIBDIR')
```
29.2.2. Installation paths

Python uses an installation scheme that differs depending on the platform and on the installation options. These schemes are stored in `sysconfig` under unique identifiers based on the value returned by `os.name`.

Every new component that is installed using `distutils` or a Distutils-based system will follow the same scheme to copy its file in the right places.

Python currently supports seven schemes:

- **posix_prefix**: scheme for Posix platforms like Linux or Mac OS X. This is the default scheme used when Python or a component is installed.
- **posix_home**: scheme for Posix platforms used when a `home` option is used upon installation. This scheme is used when a component is installed through Distutils with a specific home prefix.
- **posix_user**: scheme for Posix platforms used when a component is installed through Distutils and the `user` option is used. This scheme defines paths located under the user home directory.
- **nt**: scheme for NT platforms like Windows.
- **nt_user**: scheme for NT platforms, when the `user` option is used.

Each scheme is itself composed of a series of paths and each path has a unique identifier. Python currently uses eight paths:

- **stdlib**: directory containing the standard Python library files that are not platform-specific.
- **platstdlib**: directory containing the standard Python library files that are platform-specific.
- **platlib**: directory for site-specific, platform-specific files.
- **purelib**: directory for site-specific, non-platform-specific files.
- **include**: directory for non-platform-specific header files.
- **platinclude**: directory for platform-specific header files.
- **scripts**: directory for script files.
- **data**: directory for data files.

**sysconfig** provides some functions to determine these paths.

**sysconfig.\texttt{get\_scheme\_names()}**
Return a tuple containing all schemes currently supported in **sysconfig**.

**sysconfig.\texttt{get\_path\_names()}**
Return a tuple containing all path names currently supported in **sysconfig**.

**sysconfig.\texttt{get\_path(name[, scheme[, vars[, expand]]])}**
Return an installation path corresponding to the path \texttt{name}, from the install scheme named \texttt{scheme}.

\texttt{name} has to be a value from the list returned by \texttt{get\_path\_names()}.

**sysconfig** stores installation paths corresponding to each path name, for each platform, with variables to be expanded. For instance the \texttt{stdlib} path for the \texttt{nt} scheme is: \texttt{\{base\}/Lib}.

\texttt{get\_path()} will use the variables returned by \texttt{get\_config\_vars()} to expand the path. All variables have default values for each platform so one may call this function and get the default value.
If `scheme` is provided, it must be a value from the list returned by `get_scheme_names()`. Otherwise, the default scheme for the current platform is used.

If `vars` is provided, it must be a dictionary of variables that will update the dictionary return by `get_config_vars()`.

If `expand` is set to `False`, the path will not be expanded using the variables.

If `name` is not found, return `None`.

```
sysconfig.get_paths([scheme, vars, expand])
```

Return a dictionary containing all installation paths corresponding to an installation scheme. See `get_path()` for more information.

If `scheme` is not provided, will use the default scheme for the current platform.

If `vars` is provided, it must be a dictionary of variables that will update the dictionary used to expand the paths.

If `expand` is set to false, the paths will not be expanded.

If `scheme` is not an existing scheme, `get_paths()` will raise a `KeyError`.
29.2.3. Other functions

sysconfig.get_python_version()

Return the MAJOR.MINOR Python version number as a string. Similar to '%d.%d' % sys.version_info[:2].

sysconfig.get_platform()

Return a string that identifies the current platform.

This is used mainly to distinguish platform-specific build directories and platform-specific built distributions. Typically includes the OS name and version and the architecture (as supplied by os.uname()), although the exact information included depends on the OS; e.g. for IRIX the architecture isn’t particularly important (IRIX only runs on SGI hardware), but for Linux the kernel version isn’t particularly important.

Examples of returned values:

- linux-i586
- linux-alpha (?)
- solaris-2.6-sun4u
- irix-5.3
- irix64-6.2

Windows will return one of:

- win-amd64 (64bit Windows on AMD64 (aka x86_64, Intel64, EM64T, etc)
- win-ia64 (64bit Windows on Itanium)
- win32 (all others - specifically, sys.platform is returned)

Mac OS X can return:
- macosx-10.6-ppc
- macosx-10.4-ppc64
- macosx-10.3-i386
- macosx-10.4-fat

For other non-POSIX platforms, currently just returns `sys.platform`.

**sysconfig.is_python_build()**

Return `True` if the running Python interpreter was built from source and is being run from its built location, and not from a location resulting from e.g. running `make install` or installing via a binary installer.

**sysconfig.parse_config_h(fp[, vars])**

Parse a `config.h`-style file.

`fp` is a file-like object pointing to the `config.h`-like file.

A dictionary containing name/value pairs is returned. If an optional dictionary is passed in as the second argument, it is used instead of a new dictionary, and updated with the values read in the file.

**sysconfig.get_config_h_filename()**

Return the path of `pyconfig.h`.

**sysconfig.get_makefile_filename()**

Return the path of `Makefile`. 
29.2.4. Using `sysconfig` as a script

You can use `sysconfig` as a script with Python's `-m` option:

```
$ python -m sysconfig
Platform: "macosx-10.4-i386"
Python version: "3.2"
Current installation scheme: "posix_prefix"

Paths:
  data = "/usr/local"
  include = "/Users/tarek/Dev/svn.python.org/py3k/Include"
  platininclude = "."
  platlib = "/usr/local/lib/python3.2/site-packages"
  platstdlib = "/usr/local/lib/python3.2"
  purelib = "/usr/local/lib/python3.2/site-packages"
  scripts = "/usr/local/bin"
  stdlib = "/usr/local/lib/python3.2"

Variables:
  AC_APPLE_UNIVERSAL_BUILD = "0"
  AIX_GENUINE_CPLUSPLUS = "0"
  AR = "ar"
  ARFLAGS = "rc"
  ...
```

This call will print in the standard output the information returned by `get_platform()`, `get_python_version()`, `get_path()` and `get_config_vars()`.
29.3. **builtins** — Built-in objects

This module provides direct access to all ‘built-in’ identifiers of Python; for example, `builtins.open` is the full name for the built-in function `open()`. See **Built-in Functions** and **Built-in Constants** for documentation.

This module is not normally accessed explicitly by most applications, but can be useful in modules that provide objects with the same name as a built-in value, but in which the built-in of that name is also needed. For example, in a module that wants to implement an `open()` function that wraps the built-in `open()`, this module can be used directly:

```python
import builtins

def open(path):
    f = builtins.open(path, 'r')
    return UpperCaser(f)

class UpperCaser:
    '''Wrapper around a file that converts output to upper-case.'''

    def __init__(self, f):
        self._f = f

    def read(self, count=-1):
        return self._f.read(count).upper()

    # ...
```

As an implementation detail, most modules have the name...
__builtins__ made available as part of their globals. The value of __builtins__ is normally either this module or the value of this module's __dict__ attribute. Since this is an implementation detail, it may not be used by alternate implementations of Python.
29.4. __main__ — Top-level script environment

'__main__' is the name of the scope in which top-level code executes. A module's __name__ is set equal to '__main__' when read from standard input, a script, or from an interactive prompt.

A module can discover whether or not it is running in the main scope by checking its own __name__, which allows a common idiom for conditionally executing code in a module when it is run as a script or with python -m but not when it is imported:

```python
if __name__ == '__main__':
    # execute only if run as a script
    main()
```

For a package, the same effect can be achieved by including a __main__.py module, the contents of which will be executed when the module is run with -m.
29.5. `warnings` — Warning control

**Source code:** `Lib/warnings.py`

Warning messages are typically issued in situations where it is useful to alert the user of some condition in a program, where that condition (normally) doesn't warrant raising an exception and terminating the program. For example, one might want to issue a warning when a program uses an obsolete module.

Python programmers issue warnings by calling the `warn()` function defined in this module. (C programmers use `PyErr_WarnEx()`, see `Exception Handling` for details).

Warning messages are normally written to `sys.stderr`, but their disposition can be changed flexibly, from ignoring all warnings to turning them into exceptions. The disposition of warnings can vary based on the warning category (see below), the text of the warning message, and the source location where it is issued. Repetitions of a particular warning for the same source location are typically suppressed.

There are two stages in warning control: first, each time a warning is issued, a determination is made whether a message should be issued or not; next, if a message is to be issued, it is formatted and printed using a user-settable hook.

The determination whether to issue a warning message is controlled by the warning filter, which is a sequence of matching rules and
actions. Rules can be added to the filter by calling `filterwarnings()` and reset to its default state by calling `resetwarnings()`.

The printing of warning messages is done by calling `showwarning()`, which may be overridden; the default implementation of this function formats the message by calling `formatwarning()`, which is also available for use by custom implementations.

**See also:** `logging.captureWarnings()` allows you to handle all warnings with the standard logging infrastructure.
29.5.1. Warning Categories

There are a number of built-in exceptions that represent warning categories. This categorization is useful to be able to filter out groups of warnings. The following warnings category classes are currently defined:

<table>
<thead>
<tr>
<th>Class</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Warning</td>
<td>This is the base class of all warning category classes. It is a subclass of Exception.</td>
</tr>
<tr>
<td>UserWarning</td>
<td>The default category for warn().</td>
</tr>
<tr>
<td>DeprecationWarning</td>
<td>Base category for warnings about deprecated features (ignored by default).</td>
</tr>
<tr>
<td>SyntaxWarning</td>
<td>Base category for warnings about dubious syntactic features.</td>
</tr>
<tr>
<td>RuntimeWarning</td>
<td>Base category for warnings about dubious runtime features.</td>
</tr>
<tr>
<td>FutureWarning</td>
<td>Base category for warnings about constructs that will change semantically in the future.</td>
</tr>
<tr>
<td>PendingDeprecationWarning</td>
<td>Base category for warnings about features that will be deprecated in the future (ignored by default).</td>
</tr>
<tr>
<td>ImportWarning</td>
<td>Base category for warnings triggered during the process of importing a module (ignored by</td>
</tr>
</tbody>
</table>
While these are technically built-in exceptions, they are documented here, because conceptually they belong to the warnings mechanism.

User code can define additional warning categories by subclassing one of the standard warning categories. A warning category must always be a subclass of the `Warning` class.

<table>
<thead>
<tr>
<th>Warning Category</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>UnicodeWarning</code></td>
<td>Base category for warnings related to Unicode.</td>
</tr>
<tr>
<td><code>BytesWarning</code></td>
<td>Base category for warnings related to <code>bytes</code> and <code>bytearray</code>.</td>
</tr>
<tr>
<td><code>ResourceWarning</code></td>
<td>Base category for warnings related to resource usage.</td>
</tr>
</tbody>
</table>
### 29.5.2. The Warnings Filter

The warnings filter controls whether warnings are ignored, displayed, or turned into errors (raising an exception).

Conceptually, the warnings filter maintains an ordered list of filter specifications; any specific warning is matched against each filter specification in the list in turn until a match is found; the match determines the disposition of the match. Each entry is a tuple of the form (action, message, category, module, lineno), where:

- **action** is one of the following strings:

<table>
<thead>
<tr>
<th>Value</th>
<th>Disposition</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;error&quot;</td>
<td>turn matching warnings into exceptions</td>
</tr>
<tr>
<td>&quot;ignore&quot;</td>
<td>never print matching warnings</td>
</tr>
<tr>
<td>&quot;always&quot;</td>
<td>always print matching warnings</td>
</tr>
<tr>
<td>&quot;default&quot;</td>
<td>print the first occurrence of matching warnings for each location where the warning is issued</td>
</tr>
<tr>
<td>&quot;module&quot;</td>
<td>print the first occurrence of matching warnings for each module where the warning is issued</td>
</tr>
<tr>
<td>&quot;once&quot;</td>
<td>print only the first occurrence of matching warnings, regardless of location</td>
</tr>
</tbody>
</table>

- **message** is a string containing a regular expression that the start of the warning message must match. The expression is compiled to always be case-insensitive.

- **category** is a class (a subclass of `Warning`) of which the warning category must be a subclass in order to match.
- **module** is a string containing a regular expression that the module name must match. The expression is compiled to be case-sensitive.

- **lineno** is an integer that the line number where the warning occurred must match, or 0 to match all line numbers.

Since the **Warning** class is derived from the built-in **Exception** class, to turn a warning into an error we simply raise `category(message)`.

The warnings filter is initialized by `-W` options passed to the Python interpreter command line. The interpreter saves the arguments for all `-W` options without interpretation in `sys.warnoptions`; the `warnings` module parses these when it is first imported (invalid options are ignored, after printing a message to `sys.stderr`).

### 29.5.2.1. Default Warning Filters

By default, Python installs several warning filters, which can be overridden by the command-line options passed to `-W` and calls to `filterwarnings()`.

- **DeprecationWarning** and **PendingDeprecationWarning**, and **ImportWarning** are ignored.
- **BytesWarning** is ignored unless the `-b` option is given once or twice; in this case this warning is either printed (`-b`) or turned into an exception (`-bb`).
- **ResourceWarning** is ignored unless Python was built in debug mode.

*Changed in version 3.2:* **DeprecationWarning** is now ignored by
default in addition to PendingDeprecationWarning.
29.5.3. Temporarily Suppressing Warnings

If you are using code that you know will raise a warning, such as a deprecated function, but do not want to see the warning, then it is possible to suppress the warning using the `catch_warnings` context manager:

```python
import warnings
def fxn():
    warnings.warn("deprecated", DeprecationWarning)
with warnings.catch_warnings():
    warnings.simplefilter("ignore")
    fxn()
```

While within the context manager all warnings will simply be ignored. This allows you to use known-deprecated code without having to see the warning while not suppressing the warning for other code that might not be aware of its use of deprecated code. Note: this can only be guaranteed in a single-threaded application. If two or more threads use the `catch_warnings` context manager at the same time, the behavior is undefined.
29.5.4. Testing Warnings

To test warnings raised by code, use the `catch_warnings` context manager. With it you can temporarily mutate the warnings filter to facilitate your testing. For instance, do the following to capture all raised warnings to check:

```python
import warnings

def fxn():
    warnings.warn("deprecated", DeprecationWarning)

with warnings.catch_warnings(record=True) as w:
    # Cause all warnings to always be triggered.
    warnings.simplefilter("always")
    # Trigger a warning.
    fxn()
    # Verify some things
    assert len(w) == 1
    assert issubclass(w[-1].category, DeprecationWarning)
    assert "deprecated" in str(w[-1].message)
```

One can also cause all warnings to be exceptions by using `error` instead of `always`. One thing to be aware of is that if a warning has already been raised because of a `once/default` rule, then no matter what filters are set the warning will not be seen again unless the warnings registry related to the warning has been cleared.

Once the context manager exits, the warnings filter is restored to its state when the context was entered. This prevents tests from changing the warnings filter in unexpected ways between tests and leading to indeterminate test results. The `showwarning()` function in the
module is also restored to its original value. Note: this can only be
guaranteed in a single-threaded application. If two or more threads
use the `catch_warnings` context manager at the same time, the
behavior is undefined.

When testing multiple operations that raise the same kind of warning,
it is important to test them in a manner that confirms each operation is
raising a new warning (e.g. set warnings to be raised as exceptions
and check the operations raise exceptions, check that the length of the
warning list continues to increase after each operation, or else delete
the previous entries from the warnings list before each new operation).
29.5.5. Updating Code For New Versions of Python

Warnings that are only of interest to the developer are ignored by default. As such you should make sure to test your code with typically ignored warnings made visible. You can do this from the command-line by passing -Wd to the interpreter (this is shorthand for -W default). This enables default handling for all warnings, including those that are ignored by default. To change what action is taken for encountered warnings you simply change what argument is passed to -W, e.g. -W error. See the -W flag for more details on what is possible.

To programmatically do the same as -Wd, use:

```
warnings.simplefilter('default')
```

Make sure to execute this code as soon as possible. This prevents the registering of what warnings have been raised from unexpectedly influencing how future warnings are treated.

Having certain warnings ignored by default is done to prevent a user from seeing warnings that are only of interest to the developer. As you do not necessarily have control over what interpreter a user uses to run their code, it is possible that a new version of Python will be released between your release cycles. The new interpreter release could trigger new warnings in your code that were not there in an older interpreter, e.g. DeprecationWarning for a module that you are using. While you as a developer want to be notified that your code is using a deprecated module, to a user this information is essentially noise and provides no benefit to them.
The `unittest` module has been also updated to use the 'default' filter while running tests.
29.5.6. Available Functions

```
warnings.warn(message, category=None, stacklevel=1, source=None)
```

Issue a warning, or maybe ignore it or raise an exception. The `category` argument, if given, must be a warning category class (see above); it defaults to `UserWarning`. Alternatively `message` can be a `Warning` instance, in which case `category` will be ignored and `message.__class__` will be used. In this case the message text will be `str(message)`. This function raises an exception if the particular warning issued is changed into an error by the `warnings` filter see above. The `stacklevel` argument can be used by wrapper functions written in Python, like this:

```
def deprecation(message):
    warnings.warn(message, DeprecationWarning, stacklevel=2)
```

This makes the warning refer to `deprecation()`’s caller, rather than to the source of `deprecation()` itself (since the latter would defeat the purpose of the warning message).

`source`, if supplied, is the destroyed object which emitted a `ResourceWarning`.

*Changed in version 3.6:* Added `source` parameter.

```
warnings.warn_explicit(message, category, filename, lineno, module=None, registry=None, module_globals=None, source=None)
```

This is a low-level interface to the functionality of `warn()`, passing in explicitly the message, category, filename and line number, and optionally the module name and the registry (which should be the
_warningregistry_ dictionary of the module). The module name defaults to the filename with .py stripped; if no registry is passed, the warning is never suppressed. message must be a string and category a subclass of Warning or message may be a Warning instance, in which case category will be ignored.

module_globals, if supplied, should be the global namespace in use by the code for which the warning is issued. (This argument is used to support displaying source for modules found in zipfiles or other non-filesystem import sources).

source, if supplied, is the destroyed object which emitted a ResourceWarning.

Changed in version 3.6: Add the source parameter.

warnings.showwarning(message, category, filename, lineno, file=None, line=None)

Write a warning to a file. The default implementation calls formatwarning(message, category, filename, lineno, line) and writes the resulting string to file, which defaults to sys.stderr. You may replace this function with any callable by assigning to warnings.showwarning. line is a line of source code to be included in the warning message; if line is not supplied, showwarning() will try to read the line specified by filename and lineno.

warnings.formatwarning(message, category, filename, lineno, line=None)

Format a warning the standard way. This returns a string which may contain embedded newlines and ends in a newline. line is a line of source code to be included in the warning message; if line is
not supplied, `formatwarning()` will try to read the line specified by `filename` and `lineno`.

```
warnings.filterwarnings(action=",", category="Warning", module=",", lineno=0, append=False)
```

Insert an entry into the list of `warnings` filter specifications. The entry is inserted at the front by default; if `append` is true, it is inserted at the end. This checks the types of the arguments, compiles the `message` and `module` regular expressions, and inserts them as a tuple in the list of `warnings` filters. Entries closer to the front of the list override entries later in the list, if both match a particular warning. Omitted arguments default to a value that matches everything.

```
warnings.simplefilter(action=",", category="Warning", lineno=0, append=False)
```

Insert a simple entry into the list of `warnings` filter specifications. The meaning of the function parameters is as for `filterwarnings()`, but regular expressions are not needed as the filter inserted always matches any message in any module as long as the category and line number match.

```
warnings.resetwarnings()
```

Reset the `warnings` filter. This discards the effect of all previous calls to `filterwarnings()`, including that of the `-W` command line options and calls to `simplefilter()`.
29.5.7. Available Context Managers

class warnings.catch_warnings(*, record=False, module=None)

A context manager that copies and, upon exit, restores the warnings filter and the `showwarning()` function. If the `record` argument is `False` (the default) the context manager returns `None` on entry. If `record` is `True`, a list is returned that is progressively populated with objects as seen by a custom `showwarning()` function (which also suppresses output to `sys.stdout`). Each object in the list has attributes with the same names as the arguments to `showwarning()`.

The `module` argument takes a module that will be used instead of the module returned when you import `warnings` whose filter will be protected. This argument exists primarily for testing the `warnings` module itself.

**Note:** The `catch_warnings` manager works by replacing and then later restoring the module's `showwarning()` function and internal list of filter specifications. This means the context manager is modifying global state and therefore is not thread-safe.
29.6. `contextlib` — Utilities for `with`-statement contexts

Source code: `Lib/contextlib.py`

This module provides utilities for common tasks involving the `with` statement. For more information see also Context Manager Types and With Statement Context Managers.
29.6.1. Utilities

Functions and classes provided:

class contextlib.AbstractContextManager
   An abstract base class for classes that implement object.__enter__() and object.__exit__(). A default implementation for object.__enter__() is provided which returns self while object.__exit__() is an abstract method which by default returns None. See also the definition of Context Manager Types.

   New in version 3.6.

@contextlib.contextmanager
   This function is a decorator that can be used to define a factory function for with statement context managers, without needing to create a class or separate __enter__() and __exit__() methods.

   A simple example (this is not recommended as a real way of generating HTML!):

```
from contextlib import contextmanager

def tag(name):
    print("<%s>")
    yield
    print("</%s>" % name)

>>> with tag("h1"):
    ...     print("foo")
```
The function being decorated must return a **generator**-iterator when called. This iterator must yield exactly one value, which will be bound to the targets in the `with` statement’s `as` clause, if any.

At the point where the generator yields, the block nested in the `with` statement is executed. The generator is then resumed after the block is exited. If an unhandled exception occurs in the block, it is reraised inside the generator at the point where the yield occurred. Thus, you can use a `try...except...finally` statement to trap the error (if any), or ensure that some cleanup takes place. If an exception is trapped merely in order to log it or to perform some action (rather than to suppress it entirely), the generator must reraise that exception. Otherwise the generator context manager will indicate to the `with` statement that the exception has been handled, and execution will resume with the statement immediately following the `with` statement.

`contextmanager()` uses **ContextDecorator** so the context managers it creates can be used as decorators as well as in `with` statements. When used as a decorator, a new generator instance is implicitly created on each function call (this allows the otherwise “one-shot” context managers created by `contextmanager()` to meet the requirement that context managers support multiple invocations in order to be used as decorators).

*Changed in version 3.2:* Use of **ContextDecorator**.

`contextlib.closing(thing)`
Return a context manager that closes `thing` upon completion of the block. This is basically equivalent to:

```python
from contextlib import contextmanager
@contextmanager
def closing(thing):
    try:
        yield thing
    finally:
        thing.close()
```

And lets you write code like this:

```python
from contextlib import closing
from urllib.request import urlopen

with closing(urlopen('http://www.python.org')) as page:
    for line in page:
        print(line)
```

without needing to explicitly close `page`. Even if an error occurs, `page.close()` will be called when the `with` block is exited.

---

**contextlib.suppress(**`*exceptions*`**)

Return a context manager that suppresses any of the specified exceptions if they occur in the body of a `with` statement and then resumes execution with the first statement following the end of the `with` statement.

As with any other mechanism that completely suppresses exceptions, this context manager should be used only to cover very specific errors where silently continuing with program execution is known to be the right thing to do.
For example:

```python
from contextlib import suppress

with suppress(FileNotFoundError):
    os.remove('somefile.tmp')

with suppress(FileNotFoundError):
    os.remove('someotherfile.tmp')
```

This code is equivalent to:

```python
try:
    os.remove('somefile.tmp')
except FileNotFoundError:
    pass

try:
    os.remove('someotherfile.tmp')
except FileNotFoundError:
    pass
```

This context manager is reentrant.

*New in version 3.4.*

`contextlib.redirect_stdout(new_target)`

Context manager for temporarily redirecting `sys.stdout` to another file or file-like object.

This tool adds flexibility to existing functions or classes whose output is hardwired to stdout.

For example, the output of `help()` normally is sent to `sys.stdout`. You can capture that output in a string by redirecting the output to
an `io.StringIO` object:

```python
def f = io.StringIO()
with redirect_stdout(f):
    help(pow)
s = f.getvalue()
```

To send the output of `help()` to a file on disk, redirect the output to a regular file:

```python
with open('help.txt', 'w') as f:
    with redirect_stdout(f):
        help(pow)
```

To send the output of `help()` to `sys.stderr`:

```python
with redirect_stdout(sys.stderr):
    help(pow)
```

Note that the global side effect on `sys.stdout` means that this context manager is not suitable for use in library code and most threaded applications. It also has no effect on the output of subprocesses. However, it is still a useful approach for many utility scripts.

This context manager is `reentrant`.

*New in version 3.4.*

`contextlib.redirect_stderr(new_target)`

Similar to `redirect_stdout()` but redirecting `sys.stderr` to another file or file-like object.

This context manager is `reentrant`. 
New in version 3.5.

class contextlib.ContextDecorator
A base class that enables a context manager to also be used as a decorator.

Context managers inheriting from ContextDecorator have to implement __enter__ and __exit__ as normal. __exit__ retains its optional exception handling even when used as a decorator.

ContextDecorator is used by contextmanager(), so you get this functionality automatically.

Example of ContextDecorator:

```python
from contextlib import ContextDecorator

class mycontext(ContextDecorator):
    def __enter__(self):
        print('Starting')
        return self

    def __exit__(self, *exc):
        print('Finishing')
        return False

>>> @mycontext()
... def function():
...     print('The bit in the middle')
... >>> function()
Starting
The bit in the middle
Finishing
```
>>> with mycontext():
...     print('The bit in the middle')
... 
Starting
The bit in the middle
Finishing

This change is just syntactic sugar for any construct of the following form:

```python
def f():
    with cm():
        # Do stuff
```

ContextDecorator lets you instead write:

```python
@cm()
def f():
    # Do stuff
```

It makes it clear that the `cm` applies to the whole function, rather than just a piece of it (and saving an indentation level is nice, too).

Existing context managers that already have a base class can be extended by using `ContextDecorator` as a mixin class:

```python
from contextlib import ContextDecorator
class mycontext(ContextBaseClass, ContextDecorator):
    def __enter__(self):
        return self

    def __exit__(self, *exc):
        return False
```
**Note:** As the decorated function must be able to be called multiple times, the underlying context manager must support use in multiple `with` statements. If this is not the case, then the original construct with the explicit `with` statement inside the function should be used.

*New in version 3.2.*

class `contextlib.ExitStack`

A context manager that is designed to make it easy to programmatically combine other context managers and cleanup functions, especially those that are optional or otherwise driven by input data.

For example, a set of files may easily be handled in a single `with` statement as follows:

```python
with ExitStack() as stack:
    files = [stack.enter_context(open(fname)) for
# All opened files will automatically be closed
# the with statement, even if attempts to open
# in the list raise an exception
```

Each instance maintains a stack of registered callbacks that are called in reverse order when the instance is closed (either explicitly or implicitly at the end of a `with` statement). Note that callbacks are not invoked implicitly when the context stack instance is garbage collected.

This stack model is used so that context managers that acquire their resources in their `__init__` method (such as file objects) can be handled correctly.
Since registered callbacks are invoked in the reverse order of registration, this ends up behaving as if multiple nested `with` statements had been used with the registered set of callbacks. This even extends to exception handling - if an inner callback suppresses or replaces an exception, then outer callbacks will be passed arguments based on that updated state.

This is a relatively low level API that takes care of the details of correctly unwinding the stack of exit callbacks. It provides a suitable foundation for higher level context managers that manipulate the exit stack in application specific ways.

*New in version 3.3.*

**enter_context**(*cm*)

Enters a new context manager and adds its `__exit__()` method to the callback stack. The return value is the result of the context manager’s own `__enter__()` method.

These context managers may suppress exceptions just as they normally would if used directly as part of a `with` statement.

**push**(*exit*)

Adds a context manager’s `__exit__()` method to the callback stack.

As `__enter__` is *not* invoked, this method can be used to cover part of an `__enter__()` implementation with a context manager’s own `__exit__()` method.

If passed an object that is not a context manager, this method assumes it is a callback with the same signature as a context manager’s `__exit__()` method and adds it directly to the...
callback stack.

By returning true values, these callbacks can suppress exceptions the same way context manager \_\_exit\__() methods can.

The passed in object is returned from the function, allowing this method to be used as a function decorator.

**callback**(callback, *args, **kwds)
Accepts an arbitrary callback function and arguments and adds it to the callback stack.

Unlike the other methods, callbacks added this way cannot suppress exceptions (as they are never passed the exception details).

The passed in callback is returned from the function, allowing this method to be used as a function decorator.

**pop_all()**
Transfers the callback stack to a fresh ExitStack instance and returns it. No callbacks are invoked by this operation - instead, they will now be invoked when the new stack is closed (either explicitly or implicitly at the end of a with statement).

For example, a group of files can be opened as an “all or nothing” operation as follows:

```python
with ExitStack() as stack:
    files = [stack.enter_context(open(fname)) for # Hold onto the close method, but don't call]
close_files = stack.pop_all().close # If opening any file fails, all previously
```
# closed automatically. If all files are opened successfully, they will remain open even after the with statement ends. close_files() can then be invoked explicitly.

close()

Immediately unwinds the callback stack, invoking callbacks in the reverse order of registration. For any context managers and exit callbacks registered, the arguments passed in will indicate that no exception occurred.
29.6.2. Examples and Recipes

This section describes some examples and recipes for making effective use of the tools provided by `contextlib`.

29.6.2.1. Supporting a variable number of context managers

The primary use case for `ExitStack` is the one given in the class documentation: supporting a variable number of context managers and other cleanup operations in a single `with` statement. The variability may come from the number of context managers needed being driven by user input (such as opening a user specified collection of files), or from some of the context managers being optional:

```python
with ExitStack() as stack:
    for resource in resources:
        stack.enter_context(resource)
    if need_special_resource():
        special = acquire_special_resource()
        stack.callback(release_special_resource, special)
        # Perform operations that use the acquired resource
```

As shown, `ExitStack` also makes it quite easy to use `with` statements to manage arbitrary resources that don’t natively support the context management protocol.

29.6.2.2. Simplifying support for single optional context managers
In the specific case of a single optional context manager, `ExitStack` instances can be used as a “do nothing” context manager, allowing a context manager to easily be omitted without affecting the overall structure of the source code:

```python
def debug_trace(details):
    if __debug__:
        return TraceContext(details)
    # Don't do anything special with the context in
    return ExitStack()

with debug_trace():
    # Suite is traced in debug mode, but runs normal
```

29.6.2.3. Catching exceptions from `__enter__` methods

It is occasionally desirable to catch exceptions from an `__enter__` method implementation, *without* inadvertently catching exceptions from the `with` statement body or the context manager’s `__exit__` method. By using `ExitStack` the steps in the context management protocol can be separated slightly in order to allow this:

```python
stack = ExitStack()
try:
    x = stack.enter_context(cm)
except Exception:
    # handle __enter__ exception
else:
    with stack:
        # Handle normal case
```

Actually needing to do this is likely to indicate that the underlying API
should be providing a direct resource management interface for use with `try/except/finally` statements, but not all APIs are well designed in that regard. When a context manager is the only resource management API provided, then `ExitStack` can make it easier to handle various situations that can't be handled directly in a `with` statement.

29.6.2.4. Cleaning up in an `__enter__` implementation

As noted in the documentation of `ExitStack.push()`, this method can be useful in cleaning up an already allocated resource if later steps in the `__enter__()` implementation fail.

Here's an example of doing this for a context manager that accepts resource acquisition and release functions, along with an optional validation function, and maps them to the context management protocol:

```python
from contextlib import contextmanager, AbstractContextManager

class ResourceManager(AbstractContextManager):
    def __init__(self, acquire_resource, release_resource):
        self.acquire_resource = acquire_resource
        self.release_resource = release_resource
        if check_resource_ok is None:
            def check_resource_ok(resource):
                return True
            self.check_resource_ok = check_resource_ok

@contextmanager
def _cleanup_on_error(self):
```
with ExitStack() as stack:
    stack.push(self)
    yield
    # The validation check passed and didn't raise an exception.
    # Accordingly, we want to keep the resource and pass it back to our caller.
    stack.pop_all()

def __enter__(self):
    resource = self.acquire_resource()
    with self._cleanup_on_error():
        if not self.check_resource_ok(resource):
            msg = "Failed validation for {!r}".format(resource)
            raise RuntimeError(msg)
    return resource

def __exit__(self, *exc_details):
    # We don't need to duplicate any of our resource release logic.
    self.release_resource()

29.6.2.5. Replacing any use of try-finally and flag variables

A pattern you will sometimes see is a try-finally statement with a flag variable to indicate whether or not the body of the finally clause should be executed. In its simplest form (that can't already be handled just by using an except clause instead), it looks something like this:

cleanup_needed = True
try:
    result = perform_operation()
    if result:
        cleanup_needed = False
finally:
    if cleanup_needed:
        cleanup_resources()

As with any `try` statement based code, this can cause problems for development and review, because the setup code and the cleanup code can end up being separated by arbitrarily long sections of code.

`ExitStack` makes it possible to instead register a callback for execution at the end of a `with` statement, and then later decide to skip executing that callback:

```python
from contextlib import ExitStack

with ExitStack() as stack:
    stack.callback(cleanup_resources)
    result = perform_operation()
    if result:
        stack.pop_all()
```

This allows the intended cleanup up behaviour to be made explicit up front, rather than requiring a separate flag variable.

If a particular application uses this pattern a lot, it can be simplified even further by means of a small helper class:

```python
from contextlib import ExitStack

class Callback(ExitStack):
    def __init__(self, callback, *args, **kwds):
        super(Callback, self).__init__()
        self.callback(callback, *args, **kwds)

    def cancel(self):
        self.pop_all()
```
```
with Callback(cleanup_resources) as cb:
    result = perform_operation()
    if result:
        cb.cancel()
```

If the resource cleanup isn't already neatly bundled into a standalone function, then it is still possible to use the decorator form of `ExitStack.callback()` to declare the resource cleanup in advance:

```
from contextlib import ExitStack

with ExitStack() as stack:
    @stack.callback
def cleanup_resources():
        ...  
        result = perform_operation()
        if result:
            stack.pop_all()
```

Due to the way the decorator protocol works, a callback function declared this way cannot take any parameters. Instead, any resources to be released must be accessed as closure variables.

### 29.6.2.6. Using a context manager as a function decorator

`ContextDecorator` makes it possible to use a context manager in both an ordinary `with` statement and also as a function decorator.

For example, it is sometimes useful to wrap functions or groups of statements with a logger that can track the time of entry and time of exit. Rather than writing both a function decorator and a context
manager for the task, inheriting from `ContextDecorator` provides both capabilities in a single definition:

```python
from contextlib import ContextDecorator
import logging

logging.basicConfig(level=logging.INFO)

class track_entry_and_exit(ContextDecorator):
    def __init__(self, name):
        self.name = name

    def __enter__(self):
        logging.info('Entering: %s', self.name)

    def __exit__(self, exc_type, exc, exc_tb):
        logging.info('Exiting: %s', self.name)

Instances of this class can be used as both a context manager:

```python
with track_entry_and_exit('widget loader'):
    print('Some time consuming activity goes here')
load_widget()
```

And also as a function decorator:

```python
@track_entry_and_exit('widget loader')
def activity():
    print('Some time consuming activity goes here')
load_widget()
```

Note that there is one additional limitation when using context managers as function decorators: there's no way to access the return value of `__enter__()` if that value is needed, then it is still necessary to use an explicit `with` statement.
See also:

**PEP 343 - The “with” statement**  
The specification, background, and examples for the Python `with` statement.
29.6.3. Single use, reusable and reentrant context managers

Most context managers are written in a way that means they can only be used effectively in a `with` statement once. These single use context managers must be created afresh each time they're used - attempting to use them a second time will trigger an exception or otherwise not work correctly.

This common limitation means that it is generally advisable to create context managers directly in the header of the `with` statement where they are used (as shown in all of the usage examples above).

Files are an example of effectively single use context managers, since the first `with` statement will close the file, preventing any further IO operations using that file object.

Context managers created using `contextmanager()` are also single use context managers, and will complain about the underlying generator failing to yield if an attempt is made to use them a second time:

```python
>>> from contextlib import contextmanager
>>> @contextmanager
...     def singleuse():
...         print("Before")
...         yield
...         print("After")
...
>>> cm = singleuse()
>>> with cm:
...     pass
...```
29.6.3.1. Reentrant context managers

More sophisticated context managers may be “reentrant”. These context managers can not only be used in multiple `with` statements, but may also be used `inside` a `with` statement that is already using the same context manager.

`threading.RLock` is an example of a reentrant context manager, as are `suppress()` and `redirect_stdout()`. Here’s a very simple example of reentrant use:

```python
>>> from contextlib import redirect_stdout
>>> from io import StringIO
>>> stream = StringIO()
>>> write_to_stream = redirect_stdout(stream)
>>> with write_to_stream:
...    print("This is written to the stream rather than stdout")
...    with write_to_stream:
...        print("This is also written to the stream")
...
>>> print("This is written directly to stdout")
This is written directly to stdout
```

This is written to the stream rather than stdout
This is also written to the stream
Real world examples of reentrancy are more likely to involve multiple functions calling each other and hence be far more complicated than this example.

Note also that being reentrant is not the same thing as being thread safe. redirect_stdout(), for example, is definitely not thread safe, as it makes a global modification to the system state by binding sys.stdout to a different stream.

29.6.3.2. Reusable context managers

Distinct from both single use and reentrant context managers are “reusable” context managers (or, to be completely explicit, “reusable, but not reentrant” context managers, since reentrant context managers are also reusable). These context managers support being used multiple times, but will fail (or otherwise not work correctly) if the specific context manager instance has already been used in a containing with statement.

threading.Lock is an example of a reusable, but not reentrant, context manager (for a reentrant lock, it is necessary to use threading.RLock instead).

Another example of a reusable, but not reentrant, context manager is ExitStack, as it invokes all currently registered callbacks when leaving any with statement, regardless of where those callbacks were added:

```python
>>> from contextlib import ExitStack
>>> stack = ExitStack()
>>> with stack:
...     stack.callback(print, "Callback: from first context")
...     print("Leaving first context")
```
As the output from the example shows, reusing a single stack object across multiple with statements works correctly, but attempting to nest them will cause the stack to be cleared at the end of the innermost with statement, which is unlikely to be desirable behaviour.

Using separate `ExitStack` instances instead of reusing a single instance avoids that problem:

```python
>>> from contextlib import ExitStack
>>> with ExitStack() as outer_stack:
...    outer_stack.callback(print, "Callback: from first context")
...    print("Leaving first context")
...    Callback: from second context
>>> with ExitStack() as inner_stack:
...    inner_stack.callback(print, "Callback: from inner context")
...    print("Leaving inner context")
...    Callback: from outer context
...    print("Leaving outer context")
...    Callback: from first context
```
... print("Leaving outer context") ...

Leaving inner context
Callback: from inner context
Leaving outer context
Callback: from outer context
29.7. abc — Abstract Base Classes

Source code: Lib/abc.py

This module provides the infrastructure for defining abstract base classes (ABCs) in Python, as outlined in PEP 3119; see the PEP for why this was added to Python. (See also PEP 3141 and the numbers module regarding a type hierarchy for numbers based on ABCs.)

The collections module has some concrete classes that derive from ABCs; these can, of course, be further derived. In addition the collections.abc submodule has some ABCs that can be used to test whether a class or instance provides a particular interface, for example, is it hashable or a mapping.

This module provides the metaclass ABCMeta for defining ABCs and a helper class ABC to alternatively define ABCs through inheritance:

class abc.ABC
    A helper class that has ABCMeta as its metaclass. With this class, an abstract base class can be created by simply deriving from ABC avoiding sometimes confusing metaclass usage, for example:

    from abc import ABC

    class MyABC(ABC):
        pass

    Note that the type of ABC is still ABCMeta, therefore inheriting from
ABC requires the usual precautions regarding metaclass usage, as multiple inheritance may lead to metaclass conflicts. One may also define an abstract base class by passing the metaclass keyword and using ABCMeta directly, for example:

```python
from abc import ABCMeta
class MyABC(metaclass=ABCMeta):
    pass
```

New in version 3.4.

class abc.ABCMeta

Metaclass for defining Abstract Base Classes (ABCs).

Use this metaclass to create an ABC. An ABC can be subclassed directly, and then acts as a mix-in class. You can also register unrelated concrete classes (even built-in classes) and unrelated ABCs as "virtual subclasses" – these and their descendants will be considered subclasses of the registering ABC by the built-in issubclass() function, but the registering ABC won’t show up in their MRO (Method Resolution Order) nor will method implementations defined by the registering ABC be callable (not even via super()). [1]

Classes created with a metaclass of ABCMeta have the following method:

```
register(subclass)
```

Register subclass as a “virtual subclass” of this ABC. For example:

```python
from abc import ABC
```
class MyABC(ABC):
    pass

MyABC.register(tuple)

assert issubclass(tuple, MyABC)
assert isinstance((), MyABC)

*Changed in version 3.3:* Returns the registered subclass, to allow usage as a class decorator.

*Changed in version 3.4:* To detect calls to `register()`, you can use the `get_cache_token()` function.

You can also override this method in an abstract base class:

```python
__subclasshook__(subclass)
```
(Must be defined as a class method.)

Check whether `subclass` is considered a subclass of this ABC. This means that you can customize the behavior of `issubclass` further without the need to call `register()` on every class you want to consider a subclass of the ABC. (This class method is called from the `__subclasscheck__()` method of the ABC.)

This method should return `True`, `False` or `NotImplemented`. If it returns `True`, the `subclass` is considered a subclass of this ABC. If it returns `False`, the `subclass` is not considered a subclass of this ABC, even if it would normally be one. If it returns `NotImplemented`, the subclass check is continued with the usual mechanism.
For a demonstration of these concepts, look at this example ABC definition:

```python
class Foo:
    def __getitem__(self, index):
        ...
    def __len__(self):
        ...
    def get_iterator(self):
        return iter(self)

class MyIterable(ABC):
    @abstractmethod
    def __iter__(self):
        while False:
            yield None

    def get_iterator(self):
        return self.__iter__()

    @classmethod
    def __subclasshook__(cls, C):
        if cls is MyIterable:
            if any("__iter__" in B.__dict__ for B
               return True
        return NotImplemented

MyIterable.register(Foo)
```

The ABC `MyIterable` defines the standard iterable method, `__iter__()`, as an abstract method. The implementation given here can still be called from subclasses. The `get_iterator()` method is also part of the `MyIterable` abstract base class, but it does not have to be overridden in non-abstract derived classes.
The `__subclasshook__()` class method defined here says that any class that has an `__iter__()` method in its `__dict__` (or in that of one of its base classes, accessed via the `__mro__` list) is considered a `MyIterable` too.

Finally, the last line makes `Foo` a virtual subclass of `MyIterable`, even though it does not define an `__iter__()` method (it uses the old-style iterable protocol, defined in terms of `__len__()` and `__getitem__()`). Note that this will not make `get_iterator` available as a method of `Foo`, so it is provided separately.

The `abc` module also provides the following decorators:

@`abc.abstractmethod`

A decorator indicating abstract methods.

Using this decorator requires that the class’s metaclass is `ABCMeta` or is derived from it. A class that has a metaclass derived from `ABCMeta` cannot be instantiated unless all of its abstract methods and properties are overridden. The abstract methods can be called using any of the normal ‘super’ call mechanisms. `abstractmethod()` may be used to declare abstract methods for properties and descriptors.

Dynamically adding abstract methods to a class, or attempting to modify the abstraction status of a method or class once it is created, are not supported. The `abstractmethod()` only affects subclasses derived using regular inheritance; “virtual subclasses” registered with the ABC’s `register()` method are not affected.

When `abstractmethod()` is applied in combination with other method descriptors, it should be applied as the innermost
decorator, as shown in the following usage examples:

```python
class C(ABC):
    @abstractmethod
    def my_abstract_method(self, ...):
        ...

    @classmethod
    @abstractmethod
    def my_abstract_classmethod(cls, ...):
        ...

    @staticmethod
    @abstractmethod
    def my_abstract_staticmethod(...):
        ...

    @property
    @abstractmethod
    def my_abstract_property(self):
        ...

    @my_abstract_property.setter
    @abstractmethod
    def my_abstract_property(self, val):
        ...

    @abstractmethod
    def _get_x(self):
        ...

    @abstractmethod
    def _set_x(self, val):
        ...

    x = property(_get_x, _set_x)
```

In order to correctly interoperate with the abstract base class machinery, the descriptor must identify itself as abstract using `__isabstractmethod__`. In general, this attribute should be `True` if any of the methods used to compose the descriptor are
abstract. For example, Python’s built-in property does the equivalent of:

```python
class Descriptor:
    ...
    @property
def __isabstractmethod__(self):
    return any(getattr(f, '__isabstractmethod__')
                f in (self._fget, self._fset,
```

**Note:** Unlike Java abstract methods, these abstract methods may have an implementation. This implementation can be called via the `super()` mechanism from the class that overrides it. This could be useful as an end-point for a super-call in a framework that uses cooperative multiple-inheritance.

```
@abc.abstractclassmethod
A subclass of the built-in `classmethod()`, indicating an abstract classmethod. Otherwise it is similar to `abstractmethod()`. This special case is deprecated, as the `classmethod()` decorator is now correctly identified as abstract when applied to an abstract method:

```python
class C(ABC):
    @classmethod
    @abstractmethod
def my_abstract_classmethod(cls, ...):
    ...
```

*New in version 3.2.*

*Deprecated since version 3.3:* It is now possible to use
classmethod with abstractmethod(), making this decorator redundant.

@abc.abstractstaticmethod
A subclass of the built-in staticmethod(), indicating an abstract staticmethod. Otherwise it is similar to abstractmethod().

This special case is deprecated, as the staticmethod() decorator is now correctly identified as abstract when applied to an abstract method:

```python
class C(ABC):
    @staticmethod
    @abstractmethod
    def my_abstract_staticmethod(...):
        ...
```

New in version 3.2.

Deprecated since version 3.3: It is now possible to use staticmethod with abstractmethod(), making this decorator redundant.

@abc.abstractproperty(fget=None, fset=None, fdel=None, doc=None)
A subclass of the built-in property(), indicating an abstract property.

Using this function requires that the class's metaclass is ABCMeta or is derived from it. A class that has a metaclass derived from ABCMeta cannot be instantiated unless all of its abstract methods and properties are overridden. The abstract properties can be called using any of the normal ‘super’ call mechanisms.
This special case is deprecated, as the `property()` decorator is now correctly identified as abstract when applied to an abstract method:

```python
class C(ABC):
    @property
    @abstractmethod
    def my_abstract_property(self):
        ...
```

The above example defines a read-only property; you can also define a read-write abstract property by appropriately marking one or more of the underlying methods as abstract:

```python
class C(ABC):
    @property
def x(self):
        ...

    @x.setter
    @abstractmethod
def x(self, val):
        ...
```

If only some components are abstract, only those components need to be updated to create a concrete property in a subclass:

```python
class D(C):
    @C.x.setter
    def x(self, val):
        ...
```

*Deprecated since version 3.3:* It is now possible to use `property`, `property.getter()`, `property.setter()` and
property.deleter() with abstractmethod(), making this decorator redundant.

The abc module also provides the following functions:

abc.get_cache_token()

Returns the current abstract base class cache token.

The token is an opaque object (that supports equality testing) identifying the current version of the abstract base class cache for virtual subclasses. The token changes with every call to ABCMeta.register() on any ABC.

New in version 3.4.

Footnotes

[1] C++ programmers should note that Python’s virtual base class concept is not the same as C++’s.
29.8. `atexit` — Exit handlers

The `atexit` module defines functions to register and unregister cleanup functions. Functions thus registered are automatically executed upon normal interpreter termination. `atexit` runs these functions in the reverse order in which they were registered; if you register A, B, and C, at interpreter termination time they will be run in the order C, B, A.

**Note:** The functions registered via this module are not called when the program is killed by a signal not handled by Python, when a Python fatal internal error is detected, or when `os._exit()` is called.

```python
atexit.register(func, *args, **kargs)
```

Register `func` as a function to be executed at termination. Any optional arguments that are to be passed to `func` must be passed as arguments to `register()`. It is possible to register the same function and arguments more than once.

At normal program termination (for instance, if `sys.exit()` is called or the main module's execution completes), all functions registered are called in last in, first out order. The assumption is that lower level modules will normally be imported before higher level modules and thus must be cleaned up later.

If an exception is raised during execution of the exit handlers, a traceback is printed (unless `SystemExit` is raised) and the exception information is saved. After all exit handlers have had a chance to run the last exception to be raised is re-raised.

This function returns `func`, which makes it possible to use it as a
decorator.

\texttt{atexit.unregister(func)}

Remove \textit{func} from the list of functions to be run at interpreter shutdown. After calling \texttt{unregister()}, \textit{func} is guaranteed not to be called when the interpreter shuts down, even if it was registered more than once. \texttt{unregister()} silently does nothing if \textit{func} was not previously registered.

\begin{quote}
See also:
\end{quote}

\textbf{Module \textit{readline}}

Useful example of \texttt{atexit} to read and write \texttt{readline} history files.
29.8.1. **atexit** Example

The following simple example demonstrates how a module can initialize a counter from a file when it is imported and save the counter’s updated value automatically when the program terminates without relying on the application making an explicit call into this module at termination.

```python
try:
    with open("counterfile") as infile:
        _count = int(infile.read())
except FileNotFoundError:
    _count = 0

def incrcounter(n):
    global _count
    _count = _count + n

def savecounter():
    with open("counterfile", "w") as outfile:
        outfile.write("%d" % _count)

import atexit
atexit.register(savecounter)
```

Positional and keyword arguments may also be passed to `register()` to be passed along to the registered function when it is called:

```python
def goodbye(name, adjective):
    print('Goodbye, %s, it was %s to meet you.' % (name, adjective))

import atexit
atexit.register(goodbye, 'Donny', 'nice')
```
Usage as a **decorator**:

```python
import atexit
def goodbye():
    print("You are now leaving the Python sector.")
```

This only works with functions that can be called without arguments.
29.9. traceback — Print or retrieve a stack traceback

Source code: Lib/tracback.py

This module provides a standard interface to extract, format and print stack traces of Python programs. It exactly mimics the behavior of the Python interpreter when it prints a stack trace. This is useful when you want to print stack traces under program control, such as in a “wrapper” around the interpreter.

The module uses traceback objects — this is the object type that is stored in the sys.last_traceback variable and returned as the third item from sys.exc_info().

The module defines the following functions:

traceback.print_tb(tb, limit=None, file=None)

Print up to limit stack trace entries from traceback object tb (starting from the caller's frame) if limit is positive. Otherwise, print the last abs(limit) entries. If limit is omitted or None, all entries are printed. If file is omitted or None, the output goes to sys.stderr; otherwise it should be an open file or file-like object to receive the output.

Changed in version 3.5: Added negative limit support.

traceback.print_exception(etype, value, tb, limit=None, file=None, chain=True)

Print exception information and stack trace entries from traceback
object *tb* to *file*. This differs from `print_tb()` in the following ways:

- if *tb* is not *None*, it prints a header `Traceback (most recent call last)`:  
  - it prints the exception *etype* and *value* after the stack trace
  - if `type(value)` is `SyntaxError` and *value* has the appropriate format, it prints the line where the syntax error occurred with a caret indicating the approximate position of the error.

The optional *limit* argument has the same meaning as for `print_tb()`. If *chain* is true (the default), then chained exceptions (the `__cause__` or `__context__` attributes of the exception) will be printed as well, like the interpreter itself does when printing an unhandled exception.

*Changed in version 3.5:* The *etype* argument is ignored and inferred from the type of *value*.

traceback.**print_exc**(limit=None, file=None, chain=True)

This is a shorthand for `print_exception(*sys.exc_info(), limit, file, chain)`.

traceback.**print_last**(limit=None, file=None, chain=True)

This is a shorthand for `print_exception(sys.last_type, sys.last_value, sys.last_traceback, limit, file, chain)`. In general it will work only after an exception has reached an interactive prompt (see `sys.last_type`).

traceback.**print_stack**(f=None, limit=None, file=None)

Print up to *limit* stack trace entries (starting from the invocation point) if *limit* is positive. Otherwise, print the last `abs(limit)` entries. If *limit* is omitted or *None*, all entries are printed. The
optional \textit{f} argument can be used to specify an alternate stack frame to start. The optional \textit{file} argument has the same meaning as for \texttt{print\_tb()}. 

\textit{Changed in version 3.5: Added negative limit support.}

\texttt{traceback.extract\_tb}(tb, limit=None)

Return a list of “pre-processed” stack trace entries extracted from the traceback object \textit{tb}. It is useful for alternate formatting of stack traces. The optional \textit{limit} argument has the same meaning as for \texttt{print\_tb()}. A “pre-processed” stack trace entry is a 4-tuple (\textit{filename}, \textit{line number}, \textit{function name}, \textit{text}) representing the information that is usually printed for a stack trace. The \textit{text} is a string with leading and trailing whitespace stripped; if the source is not available it is None.

\texttt{traceback.extract\_stack}(f=None, limit=None)

Extract the raw traceback from the current stack frame. The return value has the same format as for \texttt{extract\_tb()}. The optional \textit{f} and \textit{limit} arguments have the same meaning as for \texttt{print\_stack()}

\texttt{traceback.format\_list}(extracted\_list)

Given a list of tuples as returned by \texttt{extract\_tb()} or \texttt{extract\_stack()}, return a list of strings ready for printing. Each string in the resulting list corresponds to the item with the same index in the argument list. Each string ends in a newline; the strings may contain internal newlines as well, for those items whose source text line is not None.

\texttt{traceback.format\_exception\_only}(etype, value)

Format the exception part of a traceback. The arguments are the
exception type and value such as given by `sys.last_type` and `sys.last_value`. The return value is a list of strings, each ending in a newline. Normally, the list contains a single string; however, for `SyntaxError` exceptions, it contains several lines that (when printed) display detailed information about where the syntax error occurred. The message indicating which exception occurred is the always last string in the list.

```python
traceback.format_exception(etype, value, tb, limit=None, chain=True)
```

Format a stack trace and the exception information. The arguments have the same meaning as the corresponding arguments to `print_exception()`. The return value is a list of strings, each ending in a newline and some containing internal newlines. When these lines are concatenated and printed, exactly the same text is printed as does `print_exception()`.

*Changed in version 3.5:* The `etype` argument is ignored and inferred from the type of `value`.

```python
traceback.format_exc(limit=None, chain=True)
```

This is like `print_exc(limit)` but returns a string instead of printing to a file.

```python
traceback.format_tb(tb, limit=None)
```

A shorthand for `format_list(extract_tb(tb, limit))`.

```python
traceback.format_stack(f=None, limit=None)
```

A shorthand for `format_list(extract_stack(f, limit))`.

```python
clear_frames(tb)
```

Clears the local variables of all the stack frames in a traceback `tb`
by calling the clear() method of each frame object.

*New in version 3.4.*

`traceback.walk_stack(f)`

Walk a stack following `f.f_back` from the given frame, yielding the frame and line number for each frame. If `f` is `None`, the current stack is used. This helper is used with `StackSummary.extract()`.

*New in version 3.5.*

`traceback.walk_tb(tb)`

Walk a traceback following `tb_next` yielding the frame and line number for each frame. This helper is used with `StackSummary.extract()`.

*New in version 3.5.*

The module also defines the following classes:
29.9.1. **TracebackException** Objects

*New in version 3.5.*

**TracebackException** objects are created from actual exceptions to capture data for later printing in a lightweight fashion.

class traceback.TracebackException(exc_type, exc_value, exc_traceback, *, limit=None, lookup_lines=True, capture_locals=False)

Capture an exception for later rendering. *limit*, *lookup_lines* and *capture_locals* are as for the **StackSummary** class.

Note that when locals are captured, they are also shown in the traceback.

**__cause__**

A **TracebackException** of the original **__cause__**.

**__context__**

A **TracebackException** of the original **__context__**.

**__suppress_context__**

The **__suppress_context__** value from the original exception.

**stack**

A **StackSummary** representing the traceback.

**exc_type**

The class of the original traceback.

**filename**
For syntax errors - the file name where the error occurred.

**lineno**
For syntax errors - the line number where the error occurred.

**text**
For syntax errors - the text where the error occurred.

**offset**
For syntax errors - the offset into the text where the error occurred.

**msg**
For syntax errors - the compiler error message.

```python
classmethod from_exception(exc, *, limit=None, lookup_lines=True, capture_locals=False)
```
Capture an exception for later rendering. *limit*, *lookup_lines* and *capture_locals* are as for the `StackSummary` class.

Note that when locals are captured, they are also shown in the traceback.

```python
format(*, chain=True)
```
Format the exception.

If *chain* is not `True`, `__cause__` and `__context__` will not be formatted.

The return value is a generator of strings, each ending in a newline and some containing internal newlines. `print_exception()` is a wrapper around this method which just prints the lines to a file.
The message indicating which exception occurred is always the last string in the output.

**format_exception_only()**

Format the exception part of the traceback.

The return value is a generator of strings, each ending in a newline.

Normally, the generator emits a single string; however, for `SyntaxError` exceptions, it emits several lines that (when printed) display detailed information about where the syntax error occurred.

The message indicating which exception occurred is always the last string in the output.
29.9.2. **StackSummary** Objects

*New in version 3.5.*

*StackSummary* objects represent a call stack ready for formatting.

```python
class traceback.StackSummary
    @classmethod
    def extract(cls, frame_gen, *, limit=None, lookup_lines=True, capture_locals=False)
        Construct a *StackSummary* object from a frame generator
        (such as is returned by *walk_stack()* or *walk_tb()*).

        If *limit* is supplied, only this many frames are taken from
        *frame_gen*. If *lookup_lines* is False, the returned
        *FrameSummary* objects will not have read their lines in yet,
        making the cost of creating the *StackSummary* cheaper (which
        may be valuable if it may not actually get formatted). If
        *capture_locals* is True the local variables in each
        *FrameSummary* are captured as object representations.

    @classmethod
    def from_list(cls, a_list)
        Construct a *StackSummary* object from a supplied old-style list
        of tuples. Each tuple should be a 4-tuple with filename, lineno,
        name, line as the elements.

    def format(self)
        Returns a list of strings ready for printing. Each string in the
        resulting list corresponds to a single frame from the stack. Each
        string ends in a newline; the strings may contain internal
        newlines as well, for those items with source text lines.
```
For long sequences of the same frame and line, the first few repetitions are shown, followed by a summary line stating the exact number of further repetitions.

*Changed in version 3.6:* Long sequences of repeated frames are now abbreviated.
29.9.3. **FrameSummary** Objects

*New in version 3.5.*

**FrameSummary** objects represent a single frame in a traceback.

```python
class traceback.FrameSummary(filename, lineno, name,
lookup_line=True, locals=None, line=None)
```

Represent a single frame in the traceback or stack that is being formatted or printed. It may optionally have a stringified version of the frames locals included in it. If `lookup_line` is `False`, the source code is not looked up until the **FrameSummary** has the `line` attribute accessed (which also happens when casting it to a tuple). `line` may be directly provided, and will prevent line lookups happening at all. `locals` is an optional local variable dictionary, and if supplied the variable representations are stored in the summary for later display.
This simple example implements a basic read-eval-print loop, similar to (but less useful than) the standard Python interactive interpreter loop. For a more complete implementation of the interpreter loop, refer to the code module.

```python
import sys, traceback

def run_user_code(envdir):
    source = input(">>> ")
    try:
        exec(source, envdir)
    except Exception:
        print("Exception in user code:")
        print("-" * 60)
        traceback.print_exc(file=sys.stdout)
        print("-" * 60)

envdir = {}
while True:
    run_user_code(envdir)
```

The following example demonstrates the different ways to print and format the exception and traceback:

```python
import sys, traceback

def lumberjack():
    bright_side_of_death()

def bright_side_of_death():
    return tuple()[0]
```
```python
try:
    lumberjack()
except IndexError:
    exc_type, exc_value, exc_traceback = sys.exc_info()
    print("*** print_tb:")
    traceback.print_tb(exc_traceback, limit=1, file=sys.stdout)
    print("*** print_exception:")
    # exc_type below is ignored on 3.5 and later
    traceback.print_exception(exc_type, exc_value, exc_traceback, limit=2, file=sys.stdout)
    print("*** print_exc:")
    traceback.print_exc(limit=2, file=sys.stdout)
    print("*** format_exc,
    first and last line:")
    formatted_lines = traceback.format_exc().splitlines()
    print(formatted_lines[0])
    print(formatted_lines[-1])
    print("*** format_exception:")
    # exc_type below is ignored on 3.5 and later
    print(repr(traceback.format_exception(exc_type, exc_traceback)))
    print("*** extract_tb:")
    print(repr(traceback.extract_tb(exc_traceback)))
    print("*** format_tb:")
    print(repr(traceback.format_tb(exc_traceback)))
    print("*** tb_lineno:")
    exc_traceback.tb_lineno
```

The output for the example would look similar to this:

```
*** print_tb:
   File "<doctest...>", line 10, in <module>
      lumberjack()
*** print_exception:
Traceback (most recent call last):
   File "<doctest...>", line 10, in <module>
      lumberjack()
   File "<doctest...>", line 4, in lumberjack
```
The following example shows the different ways to print and format the stack:

```python
>>> import traceback
>>> def another_function():
...     lumberstack()
...     
>>> def lumberstack():
```
>>> another_function()
    File "<doctest>", line 10, in <module>
        another_function()
    File "<doctest>", line 3, in another_function
        lumberstack()
    File "<doctest>", line 6, in lumberstack
        traceback.print_stack()
[(
    '<doctest>', 10, '<module>', 'another_function()
    ('<doctest>', 3, 'another_function', 'lumberstack()
    ('<doctest>', 7, 'lumberstack', 'print(repr(traceback.extract_stack()))

    File "<doctest>", line 10, in <module>
    File "<doctest>", line 3, in another_function
    File "<doctest>", line 8, in lumberstack

This last example demonstrates the final few formatting functions:

>>> import traceback
>>> traceback.format_list([('spam.py', 3, '<module>',
    ('eggs.py', 42, 'eggs',
    ['File "spam.py", line 3, in <module>
    File "eggs.py", line 42, in eggs
    File "eggs.py", line 42, in eggs

>>> an_error = IndexError('tuple index out of range')
>>> traceback.format_exception_only(type(an_error),
    ['IndexError: tuple index out of range

29.10. __future__ — Future statement definitions

Source code: Lib/__future__.py

__future__ is a real module, and serves three purposes:

- To avoid confusing existing tools that analyze import statements and expect to find the modules they’re importing.
- To ensure that future statements run under releases prior to 2.1 at least yield runtime exceptions (the import of __future__ will fail, because there was no module of that name prior to 2.1).
- To document when incompatible changes were introduced, and when they will be — or were — made mandatory. This is a form of executable documentation, and can be inspected programmatically via importing __future__ and examining its contents.

Each statement in __future__.py is of the form:

```
FeatureName = _Feature(OptionalRelease, MandatoryRelease, CompilerFlag)
```

where, normally, OptionalRelease is less than MandatoryRelease, and both are 5-tuples of the same form as sys.version_info:

```
(PY_MAJOR_VERSION,  # the 2 in 2.1.0a3; an int
 PY_MINOR_VERSION,  # the 1; an int
 PY_MICRO_VERSION,  # the 0; an int
 PY_RELEASE_LEVEL,  # "alpha", "beta", "candidate" or
 PY_RELEASE_SERIAL # the 3; an int
```
OptionalRelease records the first release in which the feature was accepted.

In the case of a MandatoryRelease that has not yet occurred, MandatoryRelease predicts the release in which the feature will become part of the language.

Else MandatoryRelease records when the feature became part of the language; in releases at or after that, modules no longer need a future statement to use the feature in question, but may continue to use such imports.

MandatoryRelease may also be None, meaning that a planned feature got dropped.

Instances of class _Feature have two corresponding methods, getOptionalRelease() and getMandatoryRelease().

CompilerFlag is the (bitfield) flag that should be passed in the fourth argument to the built-in function compile() to enable the feature in dynamically compiled code. This flag is stored in the compiler_flag attribute on _Feature instances.

No feature description will ever be deleted from __future__. Since its introduction in Python 2.1 the following features have found their way into the language using this mechanism:

<table>
<thead>

How the compiler treats future imports.
29.11. gc — Garbage Collector interface

This module provides an interface to the optional garbage collector. It provides the ability to disable the collector, tune the collection frequency, and set debugging options. It also provides access to unreachable objects that the collector found but cannot free. Since the collector supplements the reference counting already used in Python, you can disable the collector if you are sure your program does not create reference cycles. Automatic collection can be disabled by calling `gc.disable()`. To debug a leaking program call `gc.set_debug(gc.DEBUG_LEAK)`. Notice that this includes `gc.DEBUG_SAVEALL`, causing garbage-collected objects to be saved in `gc.garbage` for inspection.

The `gc` module provides the following functions:

- **gc.enable()**
  - Enable automatic garbage collection.

- **gc.disable()**
  - Disable automatic garbage collection.

- **gc.isenabled()**
  - Returns true if automatic collection is enabled.

- **gc.collect(generation=2)**
  - With no arguments, run a full collection. The optional argument `generation` may be an integer specifying which generation to collect (from 0 to 2). A `ValueError` is raised if the generation number is
invalid. The number of unreachable objects found is returned.

The free lists maintained for a number of built-in types are cleared whenever a full collection or collection of the highest generation (2) is run. Not all items in some free lists may be freed due to the particular implementation, in particular float.

\texttt{gc.set_debug(flags)}

Set the garbage collection debugging flags. Debugging information will be written to \texttt{sys.stderr}. See below for a list of debugging flags which can be combined using bit operations to control debugging.

\texttt{gc.get_debug()}

Return the debugging flags currently set.

\texttt{gc.get_objects()}

Returns a list of all objects tracked by the collector, excluding the list returned.

\texttt{gc.get_stats()}

Return a list of three per-generation dictionaries containing collection statistics since interpreter start. The number of keys may change in the future, but currently each dictionary will contain the following items:

- \texttt{collections} is the number of times this generation was collected;
- \texttt{collected} is the total number of objects collected inside this generation;
- \texttt{uncollectable} is the total number of objects which were found to be uncollectable (and were therefore moved to the garbage list) inside this generation.
New in version 3.4.

```python
gc.set_threshold(threshold0[, threshold1[, threshold2]])
```
Set the garbage collection thresholds (the collection frequency). Setting `threshold0` to zero disables collection.

The GC classifies objects into three generations depending on how many collection sweeps they have survived. New objects are placed in the youngest generation (generation 0). If an object survives a collection it is moved into the next older generation. Since generation 2 is the oldest generation, objects in that generation remain there after a collection. In order to decide when to run, the collector keeps track of the number object allocations and deallocations since the last collection. When the number of allocations minus the number of deallocations exceeds `threshold0`, collection starts. Initially only generation 0 is examined. If generation 0 has been examined more than `threshold1` times since generation 1 has been examined, then generation 1 is examined as well. Similarly, `threshold2` controls the number of collections of generation 1 before collecting generation 2.

```python
gc.get_count()
```
Return the current collection counts as a tuple of `(count0, count1, count2)`.

```python
gc.get_threshold()
```
Return the current collection thresholds as a tuple of `(threshold0, threshold1, threshold2)`.

```python
gc.get_referrers(*objs)
```
Return the list of objects that directly refer to any of `objs`. This function will only locate those containers which support garbage
collection; extension types which do refer to other objects but do not support garbage collection will not be found.

Note that objects which have already been dereferenced, but which live in cycles and have not yet been collected by the garbage collector can be listed among the resulting referrers. To get only currently live objects, call `collect()` before calling `get_referrers()`.

Care must be taken when using objects returned by `get_referrers()` because some of them could still be under construction and hence in a temporarily invalid state. Avoid using `get_referrers()` for any purpose other than debugging.

```
gc.get_referents(*objs)
```

Return a list of objects directly referred to by any of the arguments. The referents returned are those objects visited by the arguments’ C-level `tp_traverse` methods (if any), and may not be all objects actually directly reachable. `tp_traverse` methods are supported only by objects that support garbage collection, and are only required to visit objects that may be involved in a cycle. So, for example, if an integer is directly reachable from an argument, that integer object may or may not appear in the result list.

```
gc.is_tracked(obj)
```

Returns `True` if the object is currently tracked by the garbage collector, `False` otherwise. As a general rule, instances of atomic types aren’t tracked and instances of non-atomic types (containers, user-defined objects...) are. However, some type-specific optimizations can be present in order to suppress the garbage collector footprint of simple instances (e.g. dicts containing only atomic keys and values):
New in version 3.1.

The following variables are provided for read-only access (you can mutate the values but should not rebind them):

`gc.garbage`

A list of objects which the collector found to be unreachable but could not be freed (uncollectable objects). Starting with Python 3.4, this list should be empty most of the time, except when using instances of C extension types with a non-NULL `tp_del` slot.

If `DEBUG_SAVEALL` is set, then all unreachable objects will be added to this list rather than freed.

Changed in version 3.2: If this list is non-empty at interpreter shutdown, a `ResourceWarning` is emitted, which is silent by default. If `DEBUG_UNCOLLECTABLE` is set, in addition all uncollectable objects are printed.

Changed in version 3.4: Following `PEP 442`, objects with a `__del__()` method don’t end up in `gc.garbage` anymore.
**gc/callbacks**

A list of callbacks that will be invoked by the garbage collector before and after collection. The callbacks will be called with two arguments, *phase* and *info*.

*phase* can be one of two values:

- “start”: The garbage collection is about to start.
- “stop”: The garbage collection has finished.

*info* is a dict providing more information for the callback. The following keys are currently defined:

- “generation”: The oldest generation being collected.
- “collected”: When *phase* is “stop”, the number of objects successfully collected.
- “uncollectable”: When *phase* is “stop”, the number of objects that could not be collected and were put in garbage.

Applications can add their own callbacks to this list. The primary use cases are:

- Gathering statistics about garbage collection, such as how often various generations are collected, and how long the collection takes.
- Allowing applications to identify and clear their own uncollectable types when they appear in garbage.

*New in version 3.3.*

The following constants are provided for use with `set_debug()`:
gc. `DEBUG_STATS`
Print statistics during collection. This information can be useful when tuning the collection frequency.

gc. `DEBUG_COLLECTABLE`
Print information on collectable objects found.

gc. `DEBUG_UNCOLLECTABLE`
Print information of uncollectable objects found (objects which are not reachable but cannot be freed by the collector). These objects will be added to the garbage list.

*Changed in version 3.2:* Also print the contents of the garbage list at interpreter shutdown, if it isn't empty.

gc. `DEBUG_SAVEALL`
When set, all unreachable objects found will be appended to garbage rather than being freed. This can be useful for debugging a leaking program.

gc. `DEBUG_LEAK`
The debugging flags necessary for the collector to print information about a leaking program (equal to `DEBUG_COLLECTABLE | DEBUG_UNCOLLECTABLE | DEBUG_SAVEALL`).
29.12. inspect — Inspect live objects

Source code: Lib/inspect.py

The inspect module provides several useful functions to help get information about live objects such as modules, classes, methods, functions, tracebacks, frame objects, and code objects. For example, it can help you examine the contents of a class, retrieve the source code of a method, extract and format the argument list for a function, or get all the information you need to display a detailed traceback.

There are four main kinds of services provided by this module: type checking, getting source code, inspecting classes and functions, and examining the interpreter stack.
29.12.1. Types and members

The `getmembers()` function retrieves the members of an object such as a class or module. The functions whose names begin with “is” are mainly provided as convenient choices for the second argument to `getmembers()`. They also help you determine when you can expect to find the following special attributes:

<table>
<thead>
<tr>
<th>Type</th>
<th>Attribute</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>module</td>
<td><strong>doc</strong></td>
<td>documentation string</td>

</tr>
</tbody>
</table>

*Changed in version 3.5:* Add `__qualname__` and `gi_yieldfrom` attributes to generators.

The `__name__` attribute of generators is now set from the function name, instead of the code name, and it can now be modified.

**inspect.getmembers(object[, predicate])**

Return all the members of an object in a list of (name, value) pairs sorted by name. If the optional `predicate` argument is supplied, only members for which the predicate returns a true value are included.

**Note:** `getmembers()` will only return class attributes defined in the metaclass when the argument is a class and those attributes have been listed in the metaclass’ custom `__dir__()`.

**inspect.getmodulename(path)**

Return the name of the module named by the file `path`, without including the names of enclosing packages. The file extension is checked against all of the entries in `importlib.machinery.all_suffixes()`. If it matches, the final path component is returned with the extension removed. Otherwise, `None` is returned.

Note that this function *only* returns a meaningful name for actual
Python modules - paths that potentially refer to Python packages will still return None.

*Changed in version 3.3:* The function is based directly on `importlib`.

`inspect.ismodule(object)`
Return true if the object is a module.

`inspect.isclass(object)`
Return true if the object is a class, whether built-in or created in Python code.

`inspect.ismethod(object)`
Return true if the object is a bound method written in Python.

`inspect.isfunction(object)`
Return true if the object is a Python function, which includes functions created by a `lambda` expression.

`inspect.isgeneratorfunction(object)`
Return true if the object is a Python generator function.

`inspect.isgenerator(object)`
Return true if the object is a generator.

`inspect.iscoroutinefunction(object)`
Return true if the object is a coroutine function (a function defined with an `async def` syntax).

*New in version 3.5.*

`inspect.iscoroutine(object)`
Return true if the object is a coroutine created by an async def function.

*New in version 3.5.*

`inspect.isawaitable(object)`

Return true if the object can be used in `await` expression.

Can also be used to distinguish generator-based coroutines from regular generators:

```python
def gen():
    yield
@types.coroutine
def gen_coro():
    yield

assert not isawaitable(gen())
assert isawaitable(gen_coro())
```

*New in version 3.5.*

`inspect.isasyncgenfunction(object)`

Return true if the object is an asynchronous generator function, for example:

```python
>>> async def agen():
...    yield 1
...
>>> inspect.isasyncgenfunction(agen)
True
```

*New in version 3.6.*

`inspect.isasyncgen(object)`
Return true if the object is an asynchronous generator iterator created by an asynchronous generator function.

*New in version 3.6.*

```
inspect.istraceback(object)
```
Return true if the object is a traceback.

```
inspect.isframe(object)
```
Return true if the object is a frame.

```
inspect.iscode(object)
```
Return true if the object is a code.

```
inspect.isbuiltin(object)
```
Return true if the object is a built-in function or a bound built-in method.

```
inspect.isroutine(object)
```
Return true if the object is a user-defined or built-in function or method.

```
inspect.isabstract(object)
```
Return true if the object is an abstract base class.

```
inspect.ismethoddescriptor(object)
```
Return true if the object is a method descriptor, but not if ismethod(), isclass(), isfunction() or isbuiltin() are true.

This, for example, is true of `int.__add__`. An object passing this test has a `__get__() method but not a `__set__() method, but beyond that the set of attributes varies. A `__name__ attribute is
usually sensible, and __doc__ often is.

Methods implemented via descriptors that also pass one of the other tests return false from the ismethoddescriptor() test, simply because the other tests promise more – you can, e.g., count on having the __func__ attribute (etc) when an object passes ismethod().

inspect.isdatadescriptor(object)
Return true if the object is a data descriptor.

Data descriptors have both a __get__ and a __set__ method. Examples are properties (defined in Python), getsets, and members. The latter two are defined in C and there are more specific tests available for those types, which is robust across Python implementations. Typically, data descriptors will also have __name__ and __doc__ attributes (properties, getsets, and members have both of these attributes), but this is not guaranteed.

inspect.isgetsetdescriptor(object)
Return true if the object is a getset descriptor.

**CPython implementation detail:** getsets are attributes defined in extension modules via PyGetSetDef structures. For Python implementations without such types, this method will always return False.

inspect.ismemberdescriptor(object)
Return true if the object is a member descriptor.

**CPython implementation detail:** Member descriptors are attributes defined in extension modules via PyMemberDef structures. For Python implementations without such types, this
method will always return False.
29.12.2. Retrieving source code

**inspect.getdoc(object)**

Get the documentation string for an object, cleaned up with `cleandoc()`. If the documentation string for an object is not provided and the object is a class, a method, a property or a descriptor, retrieve the documentation string from the inheritance hierarchy.

*Changed in version 3.5:* Documentation strings are now inherited if not overridden.

**inspect.getcomments(object)**

Return in a single string any lines of comments immediately preceding the object’s source code (for a class, function, or method), or at the top of the Python source file (if the object is a module). If the object’s source code is unavailable, return `None`. This could happen if the object has been defined in C or the interactive shell.

**inspect.getfile(object)**

Return the name of the (text or binary) file in which an object was defined. This will fail with a `TypeError` if the object is a built-in module, class, or function.

**inspect.getmodule(object)**

Try to guess which module an object was defined in.

**inspect.getsourcefile(object)**

Return the name of the Python source file in which an object was defined. This will fail with a `TypeError` if the object is a built-in
module, class, or function.

inspect. `getsourcecode(object)`
Return a list of source lines and starting line number for an object. The argument may be a module, class, method, function, traceback, frame, or code object. The source code is returned as a list of the lines corresponding to the object and the line number indicates where in the original source file the first line of code was found. An `OSError` is raised if the source code cannot be retrieved.

*Changed in version 3.3:* `OSError` is raised instead of `IOError`, now an alias of the former.

inspect. `getsource(object)`
Return the text of the source code for an object. The argument may be a module, class, method, function, traceback, frame, or code object. The source code is returned as a single string. An `OSError` is raised if the source code cannot be retrieved.

*Changed in version 3.3:* `OSError` is raised instead of `IOError`, now an alias of the former.

inspect. `cleandoc(doc)`
Clean up indentation from docstrings that are indented to line up with blocks of code.

All leading whitespace is removed from the first line. Any leading whitespace that can be uniformly removed from the second line onwards is removed. Empty lines at the beginning and end are subsequently removed. Also, all tabs are expanded to spaces.
29.12.3. Introspecting callables with the Signature object

New in version 3.3.

The Signature object represents the call signature of a callable object and its return annotation. To retrieve a Signature object, use the `signature()` function.

```
inspect.signature(callable, *, follow_wrapped=True)
```

Return a `Signature` object for the given callable:

```python
>>> from inspect import signature
>>> def foo(a, *, b:int, **kwargs):
...     pass

>>> sig = signature(foo)

>>> str(sig)
'(a, *, b:int, **kwargs)'

>>> str(sig.parameters['b'])
'b:int'

>>> sig.parameters['b'].annotation
<class 'int'>
```

Accepts a wide range of python callables, from plain functions and classes to `functools.partial()` objects.

Raises `ValueError` if no signature can be provided, and `TypeError` if that type of object is not supported.
New in version 3.5: follow_wrapped parameter. Pass False to get a signature of callable specifically (callable.__wrapped__ will not be used to unwrap decorated callables.)

Note: Some callables may not be introspectable in certain implementations of Python. For example, in CPython, some built-in functions defined in C provide no metadata about their arguments.

```python
class inspect.Signature(parameters=None, *, return_annotation=Signature.empty)
```

A Signature object represents the call signature of a function and its return annotation. For each parameter accepted by the function it stores a Parameter object in its parameters collection.

The optional parameters argument is a sequence of Parameter objects, which is validated to check that there are no parameters with duplicate names, and that the parameters are in the right order, i.e. positional-only first, then positional-or-keyword, and that parameters with defaults follow parameters without defaults.

The optional return_annotation argument, can be an arbitrary Python object, is the “return” annotation of the callable.

Signature objects are immutable. Use Signature.replace() to make a modified copy.

Changed in version 3.5: Signature objects are picklable and hashable.

empty
A special class-level marker to specify absence of a return annotation.

**parameters**

An ordered mapping of parameters’ names to the corresponding Parameter objects.

**return_annotation**

The “return” annotation for the callable. If the callable has no “return” annotation, this attribute is set to Signature.empty.

**`bind`(**`*args`, **`**kwargs`**)**

Create a mapping from positional and keyword arguments to parameters. Returns BoundArguments if *args and **kwargs match the signature, or raises a TypeError.

**`bind_partial`(**`*args`, **`**kwargs`**)**

Works the same way as Signature.bind(), but allows the omission of some required arguments (mimics functools.partial() behavior.) Returns BoundArguments, or raises a TypeError if the passed arguments do not match the signature.

**`replace`(**`[*`, **parameters][`, return_annotation]**)**

Create a new Signature instance based on the instance replace was invoked on. It is possible to pass different parameters and/or return_annotation to override the corresponding properties of the base signature. To remove return_annotation from the copied Signature, pass in Signature.empty.

```python
>>> def test(a, b):
...    pass
```
```python
>>> sig = signature(test)
>>> new_sig = sig.replace(return_annotation="new")
>>> str(new_sig)
"(a, b) -> 'new return anno'"
```

classmethod `from_callable(obj, *, follow_wrapped=True)`

Return a `Signature` (or its subclass) object for a given callable `obj`. Pass `follow_wrapped=False` to get a signature of `obj` without unwrapping its `__wrapped__` chain.

This method simplifies subclassing of `Signature`:

```python
class MySignature(Signature):
    pass

sig = MySignature.from_callable(min)
assert isinstance(sig, MySignature)
```

*New in version 3.5.*

class `inspect.Parameter(name, kind, *,
default=Parameter.empty, annotation=Parameter.empty)`

Parameter objects are immutable. Instead of modifying a Parameter object, you can use `Parameter.replace()` to create a modified copy.

*Changed in version 3.5:* Parameter objects are picklable and hashable.

`empty`

A special class-level marker to specify absence of default values and annotations.

`name`
The name of the parameter as a string. The name must be a valid Python identifier.

**CPython implementation detail:** CPython generates implicit parameter names of the form `.0` on the code objects used to implement comprehensions and generator expressions. *Changed in version 3.6:* These parameter names are exposed by this module as names like `implicit0`.

**default**

The default value for the parameter. If the parameter has no default value, this attribute is set to `Parameter.empty`.

**annotation**

The annotation for the parameter. If the parameter has no annotation, this attribute is set to `Parameter.empty`.

**kind**

Describes how argument values are bound to the parameter. Possible values (accessible via `Parameter`, like `Parameter.KEYWORD_ONLY`):

<table>
<thead>
<tr>
<th>Name</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>POSITIONAL_ONLY</strong></td>
<td>Value must be supplied as a positional argument.</td>
</tr>
<tr>
<td></td>
<td>Python has no explicit syntax for defining positional-only parameters,</td>
</tr>
<tr>
<td></td>
<td>but many built-in and extension module functions (especially those that</td>
</tr>
<tr>
<td><strong>POSITIONAL_OR_KEYWORD</strong></td>
<td>accept only one or two parameters) accept them.</td>
</tr>
<tr>
<td>--------------------------</td>
<td>--------------------------------------------------</td>
</tr>
<tr>
<td><strong>VAR_POSITIONAL</strong></td>
<td>Value may be supplied as either a keyword or positional argument (this is the standard binding behaviour for functions implemented in Python.)</td>
</tr>
<tr>
<td><strong>KEYWORD_ONLY</strong></td>
<td>A tuple of positional arguments that aren’t bound to any other parameter. This corresponds to a *args parameter in a Python function definition.</td>
</tr>
<tr>
<td><strong>VAR_KEYWORD</strong></td>
<td>Value must be supplied as a keyword argument. Keyword only parameters are those which appear after a * or *args entry in a Python function definition.</td>
</tr>
<tr>
<td></td>
<td>A dict of keyword arguments that aren’t bound to any other parameter. This corresponds to a **kwargs parameter in a Python function definition.</td>
</tr>
</tbody>
</table>

Example: print all keyword-only arguments without default values:

```python
>>> def foo(a, b, *, c, d=10):
    ...    pass
```
replace(*[, name][, kind][, default][, annotation])

Create a new Parameter instance based on the instance replaced was invoked on. To override a Parameter attribute, pass the corresponding argument. To remove a default value or/and an annotation from a Parameter, pass Parameter.empty.

Changed in version 3.4: In Python 3.3 Parameter objects were allowed to have name set to None if their kind was set to POSITIONAL_ONLY. This is no longer permitted.

class inspect.BoundArguments
Result of a Signature.bind() or Signature.bind_partial() call. Holds the mapping of
arguments to the function's parameters.

**arguments**

An ordered, mutable mapping (`collections.OrderedDict`) of parameters' names to arguments' values. Contains only explicitly bound arguments. Changes in `arguments` will reflect in `args` and `kwargs`.

Should be used in conjunction with `Signature.parameters` for any argument processing purposes.

**Note:** Arguments for which `Signature.bind()` or `Signature.bind_partial()` relied on a default value are skipped. However, if needed, use `BoundArguments.apply_defaults()` to add them.

**args**

A tuple of positional arguments values. Dynamically computed from the `arguments` attribute.

**kwargs**

A dict of keyword arguments values. Dynamically computed from the `arguments` attribute.

**signature**

A reference to the parent `Signature` object.

**apply_defaults()**

Set default values for missing arguments.

For variable-positional arguments (`*args`) the default is an empty tuple.
For variable-keyword arguments (**kwargs) the default is an empty dict.

```python
def foo(a, b='ham', *args):
    pass
>>> ba = inspect.signature(foo).bind('spam')
>>> ba.apply_defaults()
>>> ba.arguments
OrderedDict([('a', 'spam'), ('b', 'ham'), ('args', ())])
```

New in version 3.5.

The `args` and `kwargs` properties can be used to invoke functions:

```python
def test(a, *, b):
    ...

sig = signature(test)
ba = sig.bind(10, b=20)
test(*ba.args, **ba.kwvars)
```

See also:

**PEP 362 - Function Signature Object.**
The detailed specification, implementation details and examples.
29.12.4. Classes and functions

`inspect.getclasstree(classes, unique=False)`

Arrange the given list of classes into a hierarchy of nested lists. Where a nested list appears, it contains classes derived from the class whose entry immediately precedes the list. Each entry is a 2-tuple containing a class and a tuple of its base classes. If the `unique` argument is true, exactly one entry appears in the returned structure for each class in the given list. Otherwise, classes using multiple inheritance and their descendants will appear multiple times.

`inspect.getargspec(func)`

Get the names and default values of a Python function's parameters. A named tuple `ArgSpec(args, varargs, keywords, defaults)` is returned. `args` is a list of the parameter names. `varargs` and `keywords` are the names of the `*` and `**` parameters or `None`. `defaults` is a tuple of default argument values or `None` if there are no default arguments; if this tuple has `n` elements, they correspond to the last `n` elements listed in `args`.

*Deprecated since version 3.0:* Use `getfullargspec()` for an updated API that is usually a drop-in replacement, but also correctly handles function annotations and keyword-only parameters.

Alternatively, use `signature()` and `Signature Object`, which provide a more structured introspection API for callables.

`inspect.getfullargspec(func)`

Get the names and default values of a Python function's
parameters. A **named tuple** is returned:

```
FullArgSpec(args, varargs, varkw, defaults, kwonlyargs, kwonlydefaults, annotations)
```

*args* is a list of the positional parameter names. *varargs* is the name of the * parameter or None if arbitrary positional arguments are not accepted. *varkw* is the name of the ** parameter or None if arbitrary keyword arguments are not accepted. *defaults* is an \( n \)-tuple of default argument values corresponding to the last \( n \) positional parameters, or None if there are no such defaults defined. *kwonlyargs* is a list of keyword-only parameter names. *kwonlydefaults* is a dictionary mapping parameter names from *kwonlyargs* to the default values used if no argument is supplied. *annotations* is a dictionary mapping parameter names to annotations. The special key "return" is used to report the function return value annotation (if any).

Note that *signature()* and *Signature Object* provide the recommended API for callable introspection, and support additional behaviours (like positional-only arguments) that are sometimes encountered in extension module APIs. This function is retained primarily for use in code that needs to maintain compatibility with the Python 2 *inspect* module API.

*Changed in version 3.4:* This function is now based on *signature()* , but still ignores \_\_wrapped\_ attributes and includes the already bound first parameter in the signature output for bound methods.

*Changed in version 3.6:* This method was previously documented as deprecated in favour of *signature()* in Python 3.5, but that decision has been reversed in order to restore a clearly supported
standard interface for single-source Python 2/3 code migrating away from the legacy `getargspec()` API.

`inspect.getargvalues(frame)`

Get information about arguments passed into a particular frame. A named tuple `ArgInfo(args, varargs, keywords, locals)` is returned. `args` is a list of the argument names. `varargs` and `keywords` are the names of the `*` and `**` arguments or `None`. `locals` is the locals dictionary of the given frame.

**Note:** This function was inadvertently marked as deprecated in Python 3.5.

`inspect.formatargspec(args[, varargs, varkw, defaults, kwonlyargs, kwonlydefaults, annotations[, formatarg, formatvarargs, formatvarkw, formatvalue, formatreturns, formatannotations]]))` Format a pretty argument spec from the values returned by `getfullargspec()`.

The first seven arguments are `(args, varargs, varkw, defaults, kwonlyargs, kwonlydefaults, annotations)`.

The other six arguments are functions that are called to turn argument names, `*` argument name, `**` argument name, default values, return annotation and individual annotations into strings, respectively.

For example:

```python
>>> from inspect import formatargspec, getfullarg
>>> def f(a: int, b: float):
...     pass
```
... formatargspec(*getfullargspec(f))
'(a: int, b: float)'

*Deprecated since version 3.5:* Use `signature()` and **Signature Object**, which provide a better introspecting API for callables.

inspect.formatargvalues(args[, varargs, varkw, locals, formatarg, formatvarargs, formatvarkw, formatvalue])

Format a pretty argument spec from the four values returned by `getargvalues()`. The `format*` arguments are the corresponding optional formatting functions that are called to turn names and values into strings.

**Note:** This function was inadvertently marked as deprecated in Python 3.5.

inspect.getmro(cls)

Return a tuple of class cls's base classes, including cls, in method resolution order. No class appears more than once in this tuple. Note that the method resolution order depends on cls's type. Unless a very peculiar user-defined metatype is in use, cls will be the first element of the tuple.

inspect.getcallargs(func, *args, **kwds)

Bind the `args` and `kwds` to the argument names of the Python function or method `func`, as if it was called with them. For bound methods, bind also the first argument (typically named `self`) to the associated instance. A dict is returned, mapping the argument names (including the names of the * and ** arguments, if any) to their values from `args` and `kwds`. In case of invoking `func`
incorrectly, i.e. whenever \texttt{func(*args, **kwds)} would raise an exception because of incompatible signature, an exception of the same type and the same or similar message is raised. For example:

\begin{verbatim}
>>> from inspect import getcallargs
>>> def f(a, b=1, *pos, **named):
...     pass
>>> getcallargs(f, 1, 2, 3) == {'a': 1, 'named': []}
True
>>> getcallargs(f, a=2, x=4) == {'a': 2, 'named': []}
True
>>> getcallargs(f)
Traceback (most recent call last):
  ... TypeError: f() missing 1 required positional argument:
\end{verbatim}

\textit{New in version 3.2.}

\textit{Deprecated since version 3.5:} Use \texttt{Signature.bind()} and \texttt{Signature.bind_partial()} instead.

\texttt{inspect.getclosurevars}(\textit{func})

Get the mapping of external name references in a Python function or method \textit{func} to their current values. A named tuple \texttt{ClosureVars(nonlocals, globals, builtins, unbound)} is returned. \texttt{nonlocals} maps referenced names to lexical closure variables, \texttt{globals} to the function’s module globals and \texttt{builtins} to the builtins visible from the function body. \texttt{unbound} is the set of names referenced in the function that could not be resolved at all given the current module globals and builtins.

\texttt{TypeError} is raised if \textit{func} is not a Python function or method.
New in version 3.3.

`inspect.unwrap(func, *, stop=None)`

Get the object wrapped by `func`. It follows the chain of `__wrapped__` attributes returning the last object in the chain.

`stop` is an optional callback accepting an object in the wrapper chain as its sole argument that allows the unwrapping to be terminated early if the callback returns a true value. If the callback never returns a true value, the last object in the chain is returned as usual. For example, `signature()` uses this to stop unwrapping if any object in the chain has a `__signature__` attribute defined.

`ValueError` is raised if a cycle is encountered.

New in version 3.4.
29.12.5. The interpreter stack

When the following functions return “frame records,” each record is a named tuple `FrameInfo(frame, filename, lineno, function, code_context, index)`. The tuple contains the frame object, the filename, the line number of the current line, the function name, a list of lines of context from the source code, and the index of the current line within that list.

*Changed in version 3.5:* Return a named tuple instead of a tuple.

**Note:** Keeping references to frame objects, as found in the first element of the frame records these functions return, can cause your program to create reference cycles. Once a reference cycle has been created, the lifespan of all objects which can be accessed from the objects which form the cycle can become much longer even if Python’s optional cycle detector is enabled. If such cycles must be created, it is important to ensure they are explicitly broken to avoid the delayed destruction of objects and increased memory consumption which occurs.

Though the cycle detector will catch these, destruction of the frames (and local variables) can be made deterministic by removing the cycle in a `finally` clause. This is also important if the cycle detector was disabled when Python was compiled or using `gc.disable()`. For example:

```python
def handle_stackframe_without_leak():
    frame = inspect.currentframe()
    try:
        # do something with the frame
    finally:
```
If you want to keep the frame around (for example to print a traceback later), you can also break reference cycles by using the `frame.clear()` method.

The optional `context` argument supported by most of these functions specifies the number of lines of context to return, which are centered around the current line.

```
inspect.getframeinfo(frame, context=1)
```

Get information about a frame or traceback object. A named tuple `Traceback(filename, lineno, function, code_context, index)` is returned.

```
inspect.getouterframes(frame, context=1)
```

Get a list of frame records for a frame and all outer frames. These frames represent the calls that lead to the creation of `frame`. The first entry in the returned list represents `frame`; the last entry represents the outermost call on `frame`'s stack.

*Changed in version 3.5:* A list of named tuples `FrameInfo(frame, filename, lineno, function, code_context, index)` is returned.

```
inspect.getinnerframes(traceback, context=1)
```

Get a list of frame records for a traceback’s frame and all inner frames. These frames represent calls made as a consequence of `frame`. The first entry in the list represents `traceback`; the last entry represents where the exception was raised.

*Changed in version 3.5:* A list of named tuples
FrameInfo(frame, filename, lineno, function, code_context, index) is returned.

inspect.currentframe()

Return the frame object for the caller’s stack frame.

**CPython implementation detail:** This function relies on Python stack frame support in the interpreter, which isn’t guaranteed to exist in all implementations of Python. If running in an implementation without Python stack frame support this function returns None.

inspect.stack(context=1)

Return a list of frame records for the caller’s stack. The first entry in the returned list represents the caller; the last entry represents the outermost call on the stack.

*Changed in version 3.5:* A list of named tuples FrameInfo(frame, filename, lineno, function, code_context, index) is returned.

inspect.trace(context=1)

Return a list of frame records for the stack between the current frame and the frame in which an exception currently being handled was raised in. The first entry in the list represents the caller; the last entry represents where the exception was raised.

*Changed in version 3.5:* A list of named tuples FrameInfo(frame, filename, lineno, function, code_context, index) is returned.
29.12.6. Fetching attributes statically

Both `getattr()` and `hasattr()` can trigger code execution when fetching or checking for the existence of attributes. Descriptors, like properties, will be invoked and `__getattr__()` and `__getattribute__()` may be called.

For cases where you want passive introspection, like documentation tools, this can be inconvenient. `getattr_static()` has the same signature as `getattr()` but avoids executing code when it fetches attributes.

```python
inspect.getattr_static(obj, attr, default=None)
```

Retrieve attributes without triggering dynamic lookup via the descriptor protocol, `__getattr__()` or `__getattribute__()`. Note: this function may not be able to retrieve all attributes that `getattr` can fetch (like dynamically created attributes) and may find attributes that `getattr` can’t (like descriptors that raise AttributeError). It can also return descriptors objects instead of instance members.

If the instance `__dict__` is shadowed by another member (for example a property) then this function will be unable to find instance members.

*New in version 3.2.*

`getattr_static()` does not resolve descriptors, for example slot descriptors or getset descriptors on objects implemented in C. The descriptor object is returned instead of the underlying attribute.
You can handle these with code like the following. Note that for arbitrary getset descriptors invoking these may trigger code execution:

```python
# example code for resolving the built-in descriptor
class _foo:
    __slots__ = ['foo']

slot_descriptor = type(_foo.foo)
getset_descriptor = type(type(open(__file__)).name)
wrapper_descriptor = type(str.__dict__['__add__'])
descriptor_types = (slot_descriptor, getset_descriptor)

result = getattr_static(some_object, 'foo')
if type(result) in descriptor_types:
    try:
        result = result.__get__()
    except AttributeError:
        # descriptors can raise AttributeError to
        # indicate there is no underlying value
        # in which case the descriptor itself will
        # have to do
        pass
```
29.12.7. Current State of Generators and Coroutines

When implementing coroutine schedulers and for other advanced uses of generators, it is useful to determine whether a generator is currently executing, is waiting to start or resume or execution, or has already terminated. `getgeneratorstate()` allows the current state of a generator to be determined easily.

```
inspect.getgeneratorstate(generator)
```
Get current state of a generator-iterator.

Possible states are:
- GEN_CREATED: Waiting to start execution.
- GEN_RUNNING: Currently being executed by the interpreter.
- GEN_SUSPENDED: Currently suspended at a yield expression.
- GEN_CLOSED: Execution has completed.

*New in version 3.2.*

```
inspect.getcoroutinestate(coroutine)
```
Get current state of a coroutine object. The function is intended to be used with coroutine objects created by `async def` functions, but will accept any coroutine-like object that has `cr_running` and `cr_frame` attributes.

Possible states are:
- CORO_CREATED: Waiting to start execution.
- CORO_RUNNING: Currently being executed by the interpreter.
- CORO_SUSPENDED: Currently suspended at an await expression.
- CORO_CLOSED: Execution has completed.

New in version 3.5.

The current internal state of the generator can also be queried. This is mostly useful for testing purposes, to ensure that internal state is being updated as expected:

```python
inspect.getgeneratorlocals(generator)
```

Get the mapping of live local variables in `generator` to their current values. A dictionary is returned that maps from variable names to values. This is the equivalent of calling `locals()` in the body of the generator, and all the same caveats apply.

If `generator` is a generator with no currently associated frame, then an empty dictionary is returned. `TypeError` is raised if `generator` is not a Python generator object.

**CPython implementation detail:** This function relies on the generator exposing a Python stack frame for introspection, which isn’t guaranteed to be the case in all implementations of Python. In such cases, this function will always return an empty dictionary.

New in version 3.3.

```python
inspect.getcoroutinelocals(coroutine)
```

This function is analogous to `getgeneratorlocals()`, but works for coroutine objects created by `async def` functions.

New in version 3.5.
29.12.8. Code Objects Bit Flags

Python code objects have a `co_flags` attribute, which is a bitmap of the following flags:

inspect.**CO_OPTIMIZED**

The code object is optimized, using fast locals.

inspect.**CO_NEWLOCALS**

If set, a new dict will be created for the frame's `f_locals` when the code object is executed.

inspect.**CO_VARARGS**

The code object has a variable positional parameter (`*args`-like).

inspect.**CO_VARKEYWORDS**

The code object has a variable keyword parameter (`**kwargs`-like).

inspect.**CO_NESTED**

The flag is set when the code object is a nested function.

inspect.**CO_GENERATOR**

The flag is set when the code object is a generator function, i.e. a generator object is returned when the code object is executed.

inspect.**CO_NOFREE**

The flag is set if there are no free or cell variables.

inspect.**CO_COROUTINE**

The flag is set when the code object is a coroutine function. When the code object is executed it returns a coroutine object. See PEP
for more details.

New in version 3.5.

inspect.CO_ITERABLE_COROUTINE

The flag is used to transform generators into generator-based coroutines. Generator objects with this flag can be used in `await` expression, and can `yield from` coroutine objects. See PEP 492 for more details.

New in version 3.5.

inspect.CO_ASYNC_GENERATOR

The flag is set when the code object is an asynchronous generator function. When the code object is executed it returns an asynchronous generator object. See PEP 525 for more details.

New in version 3.6.

Note: The flags are specific to CPython, and may not be defined in other Python implementations. Furthermore, the flags are an implementation detail, and can be removed or deprecated in future Python releases. It’s recommended to use public APIs from the inspect module for any introspection needs.
29.12.9. Command Line Interface

The `inspect` module also provides a basic introspection capability from the command line.

By default, accepts the name of a module and prints the source of that module. A class or function within the module can be printed instead by appended a colon and the qualified name of the target object.

`--details`

Print information about the specified object rather than the source code
29.13. `site` — Site-specific configuration hook

**Source code:** Lib/site.py

This module is automatically imported during initialization. The automatic import can be suppressed using the interpreter’s `-S` option.

Importing this module will append site-specific paths to the module search path and add a few builtins, unless `-S` was used. In that case, this module can be safely imported with no automatic modifications to the module search path or additions to the builtins. To explicitly trigger the usual site-specific additions, call the `site.main()` function.

*Changed in version 3.3:* Importing the module used to trigger paths manipulation even when using `-S`.

It starts by constructing up to four directories from a head and a tail part. For the head part, it uses `sys.prefix` and `sys.exec_prefix`; empty heads are skipped. For the tail part, it uses the empty string and then `lib/site-packages` (on Windows) or `lib/pythonX.Y/site-packages` (on Unix and Macintosh). For each of the distinct head-tail combinations, it sees if it refers to an existing directory, and if so, adds it to `sys.path` and also inspects the newly added path for configuration files.

*Changed in version 3.5:* Support for the “site-python” directory has been removed.

If a file named “pyvenv.cfg” exists one directory above `sys.executable`,
sys.prefix and sys.exec_prefix are set to that directory and it is also checked for site-packages (sys.base_prefix and sys.base_exec_prefix will always be the “real” prefixes of the Python installation). If “pyvenv.cfg” (a bootstrap configuration file) contains the key “include-system-site-packages” set to anything other than “false” (case-insensitive), the system-level prefixes will still also be searched for site-packages; otherwise they won’t.

A path configuration file is a file whose name has the form `name.pth` and exists in one of the four directories mentioned above; its contents are additional items (one per line) to be added to `sys.path`. Non-existing items are never added to `sys.path`, and no check is made that the item refers to a directory rather than a file. No item is added to `sys.path` more than once. Blank lines and lines beginning with `#` are skipped. Lines starting with `import` (followed by space or tab) are executed.

For example, suppose `sys.prefix` and `sys.exec_prefix` are set to `/usr/local`. The Python X.Y library is then installed in `/usr/local/lib/pythonX.Y`. Suppose this has a subdirectory `/usr/local/lib/pythonX.Y/site-packages` with three subsubdirectories, `foo`, `bar` and `spam`, and two path configuration files, `foo.pth` and `bar.pth`. Assume `foo.pth` contains the following:

```plaintext
# foo package configuration
foo
bar
bletch
```

and `bar.pth` contains:
Then the following version-specific directories are added to `sys.path`, in this order:

```
/usr/local/lib/pythonX.Y/site-packages/bar
/usr/local/lib/pythonX.Y/site-packages/foo
```

Note that `bletch` is omitted because it doesn’t exist; the `bar` directory precedes the `foo` directory because `bar.pth` comes alphabetically before `foo.pth`; and `spam` is omitted because it is not mentioned in either path configuration file.

After these path manipulations, an attempt is made to import a module named `sitecustomize`, which can perform arbitrary site-specific customizations. It is typically created by a system administrator in the `site-packages` directory. If this import fails with an `ImportError` exception, it is silently ignored. If Python is started without output streams available, as with `pythonw.exe` on Windows (which is used by default to start IDLE), attempted output from `sitecustomize` is ignored. Any exception other than `ImportError` causes a silent and perhaps mysterious failure of the process.

After this, an attempt is made to import a module named `usercustomize`, which can perform arbitrary user-specific customizations, if `ENABLE_USER_SITE` is true. This file is intended to be created in the user `site-packages` directory (see below), which is part of `sys.path` unless disabled by `-s`. An `ImportError` will be silently ignored.
Note that for some non-Unix systems, `sys.prefix` and `sys.exec_prefix` are empty, and the path manipulations are skipped; however the import of `sitecustomize` and `usercustomize` is still attempted.
29.13.1. Readline configuration

On systems that support `readline`, this module will also import and configure the `rlcompleter` module, if Python is started in interactive mode and without the `-S` option. The default behavior is to enable tab-completion and to use `~/.python_history` as the history save file. To disable it, delete (or override) the `sys.__interactivehook__` attribute in your `sitecustomize` or `usercustomize` module or your `PYTHONSTARTUP` file.

*Changed in version 3.4:* Activation of rlcompleter and history was made automatic.
29.13.2. Module contents

site.**PREFIXES**

A list of prefixes for site-packages directories.

site.**ENABLE_USER_SITE**

Flag showing the status of the user site-packages directory. **True** means that it is enabled and was added to `sys.path`. **False** means that it was disabled by user request (with `-s` or `PYTHONNOUSERSITE`). **None** means it was disabled for security reasons (mismatch between user or group id and effective id) or by an administrator.

site.**USER_SITE**

Path to the user site-packages for the running Python. Can be **None** if `getusersitepackages()` hasn't been called yet. Default value is `~/.local/lib/pythonX.Y/site-packages` for UNIX and non-framework Mac OS X builds, `~/Library/Python/X.Y/lib/python/site-packages` for Mac framework builds, and `%APPDATA%\Python\PythonXY\site-packages` on Windows. This directory is a site directory, which means that `.pth` files in it will be processed.

site.**USER_BASE**

Path to the base directory for the user site-packages. Can be **None** if `getuserbase()` hasn't been called yet. Default value is `~/.local` for UNIX and Mac OS X non-framework builds, `~/Library/Python/X.Y` for Mac framework builds, and `%APPDATA%\Python` for Windows. This value is used by Distutils.
to compute the installation directories for scripts, data files, Python modules, etc. for the user installation scheme. See also PYTHONUSERBASE.

**site.main()**

Adds all the standard site-specific directories to the module search path. This function is called automatically when this module is imported, unless the Python interpreter was started with the `-S` flag.

*Changed in version 3.3:* This function used to be called unconditionally.

**site.addsitedir(sitedir, known_paths=None)**

Add a directory to sys.path and process its `.pth` files. Typically used in sitecustomize or usercustomize (see above).

**site.getsitepackages()**

Return a list containing all global site-packages directories.

*New in version 3.2.*

**site.getuserbase()**

Return the path of the user base directory, `USER_BASE`. If it is not initialized yet, this function will also set it, respecting PYTHONUSERBASE.

*New in version 3.2.*

**site.getusersitepackages()**

Return the path of the user-specific site-packages directory, `USER_SITE`. If it is not initialized yet, this function will also set it, respecting PYTHONNOUSERSITE and USER_BASE.
New in version 3.2.

The `site` module also provides a way to get the user directories from the command line:

```
$ python3 -m site --user-site /home/user/.local/lib/python3.3/site-packages
```

If it is called without arguments, it will print the contents of `sys.path` on the standard output, followed by the value of `USER_BASE` and whether the directory exists, then the same thing for `USER_SITE`, and finally the value of `ENABLE_USER_SITE`.

---

**--user-base**

Print the path to the user base directory.

**--user-site**

Print the path to the user site-packages directory.

If both options are given, user base and user site will be printed (always in this order), separated by `os.pathsep`.

If any option is given, the script will exit with one of these values: 0 if the user site-packages directory is enabled, 1 if it was disabled by the user, 2 if it is disabled for security reasons or by an administrator, and a value greater than 2 if there is an error.

---

**See also:** PEP 370 – Per user site-packages directory
29.14. \texttt{fpectl} — Floating point exception control

\textbf{Note:} The \texttt{fpectl} module is not built by default, and its usage is discouraged and may be dangerous except in the hands of experts. See also the section \textit{Limitations and other considerations} on limitations for more details.

Most computers carry out floating point operations in conformance with the so-called IEEE-754 standard. On any real computer, some floating point operations produce results that cannot be expressed as a normal floating point value. For example, try

\begin{verbatim}
>>> import math
>>> math.exp(1000)
inf
>>> math.exp(1000) / math.exp(1000)
nan
\end{verbatim}

(The example above will work on many platforms. DEC Alpha may be one exception.) “Inf” is a special, non-numeric value in IEEE-754 that stands for “infinity”, and “nan” means “not a number.” Note that, other than the non-numeric results, nothing special happened when you asked Python to carry out those calculations. That is in fact the default behaviour prescribed in the IEEE-754 standard, and if it works for you, stop reading now.

In some circumstances, it would be better to raise an exception and stop processing at the point where the faulty operation was attempted. The \texttt{fpectl} module is for use in that situation. It provides control over
floating point units from several hardware manufacturers, allowing the user to turn on the generation of SIGFPE whenever any of the IEEE-754 exceptions Division by Zero, Overflow, or Invalid Operation occurs. In tandem with a pair of wrapper macros that are inserted into the C code comprising your python system, SIGFPE is trapped and converted into the Python `FloatingPointError` exception.

The `fpectl` module defines the following functions and may raise the given exception:

`fpectl.turnon_sigfpe()`

Turn on the generation of SIGFPE, and set up an appropriate signal handler.

`fpectl.turnoff_sigfpe()`

Reset default handling of floating point exceptions.

`exception fpectl.FloatingPointError`

After `turnon_sigfpe()` has been executed, a floating point operation that raises one of the IEEE-754 exceptions Division by Zero, Overflow, or Invalid operation will in turn raise this standard Python exception.
29.14.1. Example

The following example demonstrates how to start up and test operation of the `fpectl` module.

```python
>>> import fpectl
>>> import fpetest
>>> fpectl.turnon_sigfpe()
>>> fpetest.test()
overflow        PASS
FloatingPointError: Overflow
div by 0        PASS
FloatingPointError: Division by zero
    [ more output from test elided ]
>>> import math
>>> math.exp(1000)
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
FloatingPointError: in math_1
```
29.14.2. Limitations and other considerations

Setting up a given processor to trap IEEE-754 floating point errors currently requires custom code on a per-architecture basis. You may have to modify `fpectl` to control your particular hardware.

Conversion of an IEEE-754 exception to a Python exception requires that the wrapper macros `PyFPE_START_PROTECT` and `PyFPE_END_PROTECT` be inserted into your code in an appropriate fashion. Python itself has been modified to support the `fpectl` module, but many other codes of interest to numerical analysts have not.

The `fpectl` module is not thread-safe.

See also: Some files in the source distribution may be interesting in learning more about how this module operates. The include file `Include/pyfpe.h` discusses the implementation of this module at some length. `Modules/fpetestmodule.c` gives several examples of use. Many additional examples can be found in `Objects/floatobject.c`. 
30. Custom Python Interpreters

The modules described in this chapter allow writing interfaces similar to Python's interactive interpreter. If you want a Python interpreter that supports some special feature in addition to the Python language, you should look at the `code` module. (The `codeop` module is lower-level, used to support compiling a possibly-incomplete chunk of Python code.)

The full list of modules described in this chapter is:

- **30.1. code — Interpreter base classes**
  - 30.1.1. Interactive Interpreter Objects
  - 30.1.2. Interactive Console Objects
- **30.2. codeop — Compile Python code**
30.1. **code** — Interpreter base classes

**Source code:** Lib/code.py

The `code` module provides facilities to implement read-eval-print loops in Python. Two classes and convenience functions are included which can be used to build applications which provide an interactive interpreter prompt.

```python
class code.InteractiveInterpreter(locals=None)
    This class deals with parsing and interpreter state (the user's namespace); it does not deal with input buffering or prompting or input file naming (the filename is always passed in explicitly). The optional `locals` argument specifies the dictionary in which code will be executed; it defaults to a newly created dictionary with key '__name__' set to '__console__' and key '__doc__' set to None.

class code.InteractiveConsole(locals=None, filename="<console>")
    Closely emulate the behavior of the interactive Python interpreter. This class builds on InteractiveInterpreter and adds prompting using the familiar sys.ps1 and sys.ps2, and input buffering.
```

```python
code.interact(banner=None, readfunc=None, local=None, exitmsg=None)
    Convenience function to run a read-eval-print loop. This creates a
new instance of `InteractiveConsole` and sets `readfunc` to be used as the `InteractiveConsole.raw_input()` method, if provided. If `local` is provided, it is passed to the `InteractiveConsole` constructor for use as the default namespace for the interpreter loop. The `interact()` method of the instance is then run with `banner` and `exitmsg` passed as the banner and exit message to use, if provided. The console object is discarded after use.

*Changed in version 3.6: Added `exitmsg` parameter.*

code.**compile_command**(source, filename="<input>", symbol="single")

This function is useful for programs that want to emulate Python's interpreter main loop (a.k.a. the read-eval-print loop). The tricky part is to determine when the user has entered an incomplete command that can be completed by entering more text (as opposed to a complete command or a syntax error). This function *almost* always makes the same decision as the real interpreter main loop.

`source` is the source string; `filename` is the optional filename from which source was read, defaulting to `'<input>'`; and `symbol` is the optional grammar start symbol, which should be either 'single' (the default) or 'eval'.

Returns a code object (the same as `compile(source, filename, symbol)`) if the command is complete and valid; `None` if the command is incomplete; raises `SyntaxError` if the command is complete and contains a syntax error, or raises `OverflowError` or `ValueError` if the command contains an invalid literal.
30.1.1. Interactive Interpreter Objects

InteractiveInterpreter.runsource(source, filename="<input>", symbol="single")

Compile and run some source in the interpreter. Arguments are the same as for compile_command(); the default for filename is '<input>', and for symbol is 'single'. One several things can happen:

- The input is incorrect; compile_command() raised an exception (SyntaxError or OverflowError). A syntax traceback will be printed by calling the showsyntaxerror() method. runsource() returns False.
- The input is incomplete, and more input is required; compile_command() returned None. runsource() returns True.
- The input is complete; compile_command() returned a code object. The code is executed by calling the runcode() (which also handles run-time exceptions, except for SystemExit). runsource() returns False.

The return value can be used to decide whether to use sys.ps1 or sys.ps2 to prompt the next line.

InteractiveInterpreter.runcode(code)

Execute a code object. When an exception occurs, showtraceback() is called to display a traceback. All exceptions are caught except SystemExit, which is allowed to propagate.

A note about KeyboardInterrupt: this exception may occur elsewhere in this code, and may not always be caught. The caller should be prepared to deal with it.
InteractiveInterpreter. `showsyntaxerror(filename=\None)`

Display the syntax error that just occurred. This does not display a stack trace because there isn’t one for syntax errors. If `filename` is given, it is stuffed into the exception instead of the default filename provided by Python’s parser, because it always uses `<string>` when reading from a string. The output is written by the `write()` method.

InteractiveInterpreter. `showtraceback()`

Display the exception that just occurred. We remove the first stack item because it is within the interpreter object implementation. The output is written by the `write()` method.

*Changed in version 3.5:* The full chained traceback is displayed instead of just the primary traceback.

InteractiveInterpreter. `write(data)`

Write a string to the standard error stream (`sys.stderr`). Derived classes should override this to provide the appropriate output handling as needed.
30.1.2. Interactive Console Objects

The `InteractiveConsole` class is a subclass of `InteractiveInterpreter`, and so offers all the methods of the interpreter objects as well as the following additions.

`InteractiveConsole.interact(banner=None, exitmsg=None)`

Closely emulate the interactive Python console. The optional `banner` argument specify the banner to print before the first interaction; by default it prints a banner similar to the one printed by the standard Python interpreter, followed by the class name of the console object in parentheses (so as not to confuse this with the real interpreter – since it’s so close!).

The optional `exitmsg` argument specifies an exit message printed when exiting. Pass the empty string to suppress the exit message. If `exitmsg` is not given or `None`, a default message is printed.

*Changed in version 3.4:* To suppress printing any banner, pass an empty string.

*Changed in version 3.6:* Print an exit message when exiting.

`InteractiveConsole.push(line)`

Push a line of source text to the interpreter. The line should not have a trailing newline; it may have internal newlines. The line is appended to a buffer and the interpreter’s `runsource()` method is called with the concatenated contents of the buffer as source. If this indicates that the command was executed or invalid, the buffer is reset; otherwise, the command is incomplete, and the buffer is left as it was after the line was appended. The return value is `True` if more input is required, `False` if the line was dealt with in some
way (this is the same as runsource()).

InteractiveConsole.**resetbuffer**
Remove any unhandled source text from the input buffer.

InteractiveConsole.**raw_input**(prompt="")
Write a prompt and read a line. The returned line does not include
the trailing newline. When the user enters the EOF key sequence,
**EOFError** is raised. The base implementation reads from
**sys.stdin**; a subclass may replace this with a different
implementation.
30.2. codeop — Compile Python code

Source code: Lib/codeop.py

The codeop module provides utilities upon which the Python read-eval-print loop can be emulated, as is done in the code module. As a result, you probably don’t want to use the module directly; if you want to include such a loop in your program you probably want to use the code module instead.

There are two parts to this job:

1. Being able to tell if a line of input completes a Python statement: in short, telling whether to print ‘>>>’ or ‘...’ next.
2. Remembering which future statements the user has entered, so subsequent input can be compiled with these in effect.

The codeop module provides a way of doing each of these things, and a way of doing them both.

To do just the former:

codeop.compile_command(source, filename="<input>", symbol="single")

Tries to compile source, which should be a string of Python code and return a code object if source is valid Python code. In that case, the filename attribute of the code object will be filename, which defaults to '<input>'. Returns None if source is not valid Python code, but is a prefix of valid Python code.
If there is a problem with `source`, an exception will be raised. `SyntaxError` is raised if there is invalid Python syntax, and `OverflowError` or `ValueError` if there is an invalid literal.

The `symbol` argument determines whether `source` is compiled as a statement ('single', the default) or as an `expression` ('eval'). Any other value will cause `ValueError` to be raised.

**Note:** It is possible (but not likely) that the parser stops parsing with a successful outcome before reaching the end of the source; in this case, trailing symbols may be ignored instead of causing an error. For example, a backslash followed by two newlines may be followed by arbitrary garbage. This will be fixed once the API for the parser is better.

*class* codeop. **Compile**

Instances of this class have `__call__()` methods identical in signature to the built-in function `compile()`, but with the difference that if the instance compiles program text containing a `__future__` statement, the instance ‘remembers’ and compiles all subsequent program texts with the statement in force.

*class* codeop. **CommandCompiler**

Instances of this class have `__call__()` methods identical in signature to `compile_command()`; the difference is that if the instance compiles program text containing a `__future__` statement, the instance ‘remembers’ and compiles all subsequent program texts with the statement in force.
31. Importing Modules

The modules described in this chapter provide new ways to import other Python modules and hooks for customizing the import process.

The full list of modules described in this chapter is:

- **31.1. zipimport — Import modules from Zip archives**
  - 31.1.1. zipimporter Objects
  - 31.1.2. Examples
- **31.2. pkgutil — Package extension utility**
- **31.3. modulefinder — Find modules used by a script**
  - 31.3.1. Example usage of ModuleFinder
- **31.4. runpy — Locating and executing Python modules**
- **31.5. importlib — The implementation of import**
  - 31.5.1. Introduction
  - 31.5.2. Functions
  - 31.5.3. importlib.abc – Abstract base classes related to import
  - 31.5.4. importlib.machinery – Importers and path hooks
  - 31.5.5. importlib.util – Utility code for importers
  - 31.5.6. Examples
    - 31.5.6.1. Importing programmatically
    - 31.5.6.2. Checking if a module can be imported
    - 31.5.6.3. Importing a source file directly
    - 31.5.6.4. Setting up an importer
    - 31.5.6.5. Approximating `importlib.import_module()`
31.1. `zipimport` — Import modules from Zip archives

This module adds the ability to import Python modules (*.py, *.pyc) and packages from ZIP-format archives. It is usually not needed to use the `zipimport` module explicitly; it is automatically used by the built-in `import` mechanism for `sys.path` items that are paths to ZIP archives.

Typically, `sys.path` is a list of directory names as strings. This module also allows an item of `sys.path` to be a string naming a ZIP file archive. The ZIP archive can contain a subdirectory structure to support package imports, and a path within the archive can be specified to only import from a subdirectory. For example, the path `example.zip/lib/` would only import from the `lib/` subdirectory within the archive.

Any files may be present in the ZIP archive, but only files `.py` and `.pyc` are available for import. ZIP import of dynamic modules (.pyd, .so) is disallowed. Note that if an archive only contains `.py` files, Python will not attempt to modify the archive by adding the corresponding `.pyc` file, meaning that if a ZIP archive doesn’t contain `.pyc` files, importing may be rather slow.

ZIP archives with an archive comment are currently not supported.

See also:

**PKZIP Application Note**

Documentation on the ZIP file format by Phil Katz, the creator of
the format and algorithms used.

**PEP 273 - Import Modules from Zip Archives**
Written by James C. Ahlstrom, who also provided an implementation. Python 2.3 follows the specification in PEP 273, but uses an implementation written by Just van Rossum that uses the import hooks described in PEP 302.

**PEP 302 - New Import Hooks**
The PEP to add the import hooks that help this module work.

This module defines an exception:

```
exception zipimport.ZipImportError
    Exception raised by zipimporter objects. It's a subclass of ImportError, so it can be caught as ImportError, too.
```
31.1.1. zipimporter Objects

`zipimporter` is the class for importing ZIP files.

```python
class zipimport.zipimporter(archivepath)
```

Create a new zipimporter instance. `archivepath` must be a path to a ZIP file, or to a specific path within a ZIP file. For example, an `archivepath` of `foo/bar.zip/lib` will look for modules in the `lib` directory inside the ZIP file `foo/bar.zip` (provided that it exists).

`ZipImportError` is raised if `archivepath` doesn’t point to a valid ZIP archive.

```python
find_module(fullname[, path])
```

Search for a module specified by `fullname`. `fullname` must be the fully qualified (dotted) module name. It returns the zipimporter instance itself if the module was found, or `None` if it wasn’t. The optional `path` argument is ignored—it’s there for compatibility with the importer protocol.

```python
get_code(fullname)
```

Return the code object for the specified module. Raise `ZipImportError` if the module couldn’t be found.

```python
get_data(pathname)
```

Return the data associated with `pathname`. Raise `OSError` if the file wasn’t found.

*Changed in version 3.3:* `IOError` used to be raised instead of `OSError`. 
get_filename(fullname)
Return the value __file__ would be set to if the specified module was imported. Raise ZipImportError if the module couldn't be found.

New in version 3.1.

get_source(fullname)
Return the source code for the specified module. Raise ZipImportError if the module couldn’t be found, return None if the archive does contain the module, but has no source for it.

is_package(fullname)
Return True if the module specified by fullname is a package. Raise ZipImportError if the module couldn’t be found.

load_module(fullname)
Load the module specified by fullname. fullname must be the fully qualified (dotted) module name. It returns the imported module, or raises ZipImportError if it wasn’t found.

archive
The file name of the importer's associated ZIP file, without a possible subpath.

prefix
The subpath within the ZIP file where modules are searched. This is the empty string for zipimporter objects which point to the root of the ZIP file.

The archive and prefix attributes, when combined with a
slash, equal the original *archivepath* argument given to the *zipimporter* constructor.
31.1.2. Examples

Here is an example that imports a module from a ZIP archive - note that the `zipimport` module is not explicitly used.

```
$ unzip -l example.zip
Archive:  example.zip
        Length    Date       Time    Name
--------  ----  --------  --------
     8467  11-26-02  22:30  jwzthreading.py
--------  ----  --------  --------
     8467       -------

$ ./python
Python 2.3 (#1, Aug 1 2003, 19:54:32)
>>> import sys
>>> sys.path.insert(0, 'example.zip')  # Add .zip file
>>> import jwzthreading
>>> jwzthreading.__file__
'example.zip/jwzthreading.py'
```
31.2. pkgutil — Package extension utility

Source code: Lib/pkgutil.py

This module provides utilities for the import system, in particular package support.

```python
class pkgutil.ModuleInfo(module_finder, name, ispkg)
    A namedtuple that holds a brief summary of a module's info.
```

*New in version 3.6.*

```python
pkgutil.extend_path(path, name)
```

Extend the search path for the modules which comprise a package. Intended use is to place the following code in a package's `__init__.py`:

```python
from pkgutil import extend_path
__path__ = extend_path(__path__, __name__)
```

This will add to the package's `__path__` all subdirectories of directories on `sys.path` named after the package. This is useful if one wants to distribute different parts of a single logical package as multiple directories.

It also looks for `*.pkg` files beginning where `*` matches the `name` argument. This feature is similar to `*.pth` files (see the `site` module for more information), except that it doesn't special-case lines starting with `import`. A `*.pkg` file is trusted at face value:
apart from checking for duplicates, all entries found in a *.pkg file are added to the path, regardless of whether they exist on the filesystem. (This is a feature.)

If the input path is not a list (as is the case for frozen packages) it is returned unchanged. The input path is not modified; an extended copy is returned. Items are only appended to the copy at the end.

It is assumed that `sys.path` is a sequence. Items of `sys.path` that are not strings referring to existing directories are ignored. Unicode items on `sys.path` that cause errors when used as filenames may cause this function to raise an exception (in line with `os.path.isdir()` behavior).

class pkgutil.ImpImporter(\texttt{dirname=\texttt{None}})

\textbf{PEP 302} Finder that wraps Python’s “classic” import algorithm.

If \texttt{dirname} is a string, a \textbf{PEP 302} finder is created that searches that directory. If \texttt{dirname} is \texttt{None}, a \textbf{PEP 302} finder is created that searches the current `sys.path`, plus any modules that are frozen or built-in.

Note that `ImpImporter` does not currently support being used by placement on `sys.meta_path`.

\textit{Deprecated since version 3.3}: This emulation is no longer needed, as the standard import mechanism is now fully PEP 302 compliant and available in `importlib`.

class pkgutil.ImpLoader(\texttt{fullname, file, filename, etc})

\textbf{Loader} that wraps Python’s “classic” import algorithm.

\textit{Deprecated since version 3.3}: This emulation is no longer needed,
as the standard import mechanism is now fully PEP 302 compliant and available in `importlib`.

`pkgutil.find_loader(fullname)`

Retrieve a module loader for the given `fullname`.

This is a backwards compatibility wrapper around `importlib.util.find_spec()` that converts most failures to `ImportError` and only returns the loader rather than the full `ModuleSpec`.

*Changed in version 3.3:* Updated to be based directly on `importlib` rather than relying on the package internal PEP 302 import emulation.

*Changed in version 3.4:* Updated to be based on [PEP 451](https://www.python.org/dev/peps/pep-0451/)

`pkgutil.get_importer(path_item)`

Retrieve a finder for the given `path_item`.

The returned finder is cached in `sys.path_importer_cache` if it was newly created by a path hook.

The cache (or part of it) can be cleared manually if a rescan of `sys.path_hooks` is necessary.

*Changed in version 3.3:* Updated to be based directly on `importlib` rather than relying on the package internal PEP 302 import emulation.

`pkgutil.get_loader(module_or_name)`

Get a loader object for `module_or_name`.

If the module or package is accessible via the normal import
mechanism, a wrapper around the relevant part of that machinery is returned. Returns None if the module cannot be found or imported. If the named module is not already imported, its containing package (if any) is imported, in order to establish the package __path__.

*Changed in version 3.3:* Updated to be based directly on importlib rather than relying on the package internal PEP 302 import emulation.

*Changed in version 3.4:* Updated to be based on PEP 451

pkgutil.iter_importers(fullname='')

Yield finder objects for the given module name.

If fullname contains a '.', the finders will be for the package containing fullname, otherwise they will be all registered top level finders (i.e. those on both sys.meta_path and sys.path_hooks).

If the named module is in a package, that package is imported as a side effect of invoking this function.

If no module name is specified, all top level finders are produced.

*Changed in version 3.3:* Updated to be based directly on importlib rather than relying on the package internal PEP 302 import emulation.

pkgutil.iter_modules(path=None, prefix='')

Yields ModuleInfo for all submodules on path, or, if path is None, all top-level modules on sys.path.

path should be either None or a list of paths to look for modules in.
prefix is a string to output on the front of every module name on output.

**Note:** Only works for a finder which defines an `iter_modules()` method. This interface is non-standard, so the module also provides implementations for `importlib.machinery.FileFinder` and `zipimport.zipimporter`.

*Changed in version 3.3:* Updated to be based directly on `importlib` rather than relying on the package internal PEP 302 import emulation.

`pkgutil.walk_packages(path=None, prefix='', onerror=None)`

Yields `ModuleInfo` for all modules recursively on `path`, or, if `path` is `None`, all accessible modules.

- `path` should be either `None` or a list of paths to look for modules in.
- `prefix` is a string to output on the front of every module name on output.

Note that this function must import all packages (*not* all modules!) on the given `path`, in order to access the `__path__` attribute to find submodules.

- `onerror` is a function which gets called with one argument (the name of the package which was being imported) if any exception occurs while trying to import a package. If no `onerror` function is supplied, `ImportError`s are caught and ignored, while all other exceptions are propagated, terminating the search.

Examples:
# list all modules python can access
walk_packages()

# list all submodules of ctypes
walk_packages(ctypes.__path__, ctypes.__name__ +

Note: Only works for a finder which defines an iter_modules() method. This interface is non-standard, so the module also provides implementations for importlib.machinery.FileFinder and zipimport.zipimporter.

Changed in version 3.3: Updated to be based directly on importlib rather than relying on the package internal PEP 302 import emulation.

pkgutil.get_data(package, resource)

Get a resource from a package.

This is a wrapper for the loader get_data API. The package argument should be the name of a package, in standard module format (foo.bar). The resource argument should be in the form of a relative filename, using / as the path separator. The parent directory name .. is not allowed, and nor is a rooted name (starting with a /).

The function returns a binary string that is the contents of the specified resource.

For packages located in the filesystem, which have already been imported, this is the rough equivalent of:
d = os.path.dirname(sys.modules[package].__file__)
data = open(os.path.join(d, resource), 'rb').read

If the package cannot be located or loaded, or it uses a loader which does not support get_data, then None is returned. In particular, the loader for namespace packages does not support get_data.
31.3. modulefinder — Find modules used by a script

Source code: Lib/modulefinder.py

This module provides a ModuleFinder class that can be used to determine the set of modules imported by a script. modulefinder.py can also be run as a script, giving the filename of a Python script as its argument, after which a report of the imported modules will be printed.

modulefinder. AddPackagePath(pkg_name, path)
Record that the package named pkg_name can be found in the specified path.

modulefinder. ReplacePackage(oldname, newname)
Allows specifying that the module named oldname is in fact the package named newname.

class modulefinder. ModuleFinder(path=None, debug=0, excludes=[], replace_paths=[])
This class provides run_script() and report() methods to determine the set of modules imported by a script. path can be a list of directories to search for modules; if not specified, sys.path is used. debug sets the debugging level; higher values make the class print debugging messages about what it's doing. excludes is a list of module names to exclude from the analysis. replace_paths is a list of (oldpath, newpath) tuples that will be replaced in module paths.
**report()**

Print a report to standard output that lists the modules imported by the script and their paths, as well as modules that are missing or seem to be missing.

**run_script(pathname)**

Analyze the contents of the *pathname* file, which must contain Python code.

**modules**

A dictionary mapping module names to modules. See Example usage of ModuleFinder.
31.3.1. Example usage of ModuleFinder

The script that is going to get analyzed later on (bacon.py):

```python
import re, itertools

try:
    import baconhameggs
except ImportError:
    pass

try:
    import guido.python.ham
except ImportError:
    pass
```

The script that will output the report of bacon.py:

```python
from modulefinder import ModuleFinder

finder = ModuleFinder()
finder.run_script('bacon.py')

print('Loaded modules:')
for name, mod in finder.modules.items():
    print('%s: %s, end=' % (name, end=''))
    print(',', .join(list(mod.globalnames.keys()))[:3])

print('-'*50)
print('Modules not imported: ')
print('
'.join(finder.badmodules.keys()))
```

Sample output (may vary depending on the architecture):
Loaded modules:
_types:
copyreg:  _inverted_registry,_slotnames,__all__
sre_compile:  isstring,_sre,_optimize_unicode
_sre:
sre_constants:  REPEAT_ONE,makedict,AT_END_LINE
sys:
re:  __module__,__finditer,__expand
итertools:
__main__:  re,итertools,baconhameggs
sre_parse:  _PATTERNENDERS,SRE_FLAG_UNICODE
array:
types:  __module__,IntType,TypeType

Modules not imported:
guido.python.ham
baconhameggs
31.4. runpy — Locating and executing Python modules

Source code: Lib/runpy.py

The `runpy` module is used to locate and run Python modules without importing them first. Its main use is to implement the `-m` command line switch that allows scripts to be located using the Python module namespace rather than the filesystem.

Note that this is not a sandbox module - all code is executed in the current process, and any side effects (such as cached imports of other modules) will remain in place after the functions have returned.

Furthermore, any functions and classes defined by the executed code are not guaranteed to work correctly after a `runpy` function has returned. If that limitation is not acceptable for a given use case, `importlib` is likely to be a more suitable choice than this module.

The `runpy` module provides two functions:

```
runpy.run_module(mod_name, init_globals=None, run_name=None, alter_sys=False)
```

Execute the code of the specified module and return the resulting module globals dictionary. The module’s code is first located using the standard import mechanism (refer to PEP 302 for details) and then executed in a fresh module namespace.

The `mod_name` argument should be an absolute module name. If the module name refers to a package rather than a normal module,
then that package is imported and the __main__ submodule within that package is then executed and the resulting module globals dictionary returned.

The optional dictionary argument init_globals may be used to pre-populate the module's globals dictionary before the code is executed. The supplied dictionary will not be modified. If any of the special global variables below are defined in the supplied dictionary, those definitions are overridden by run_module().

The special global variables __name__, __spec__, __file__, __cached__, __loader__ and __package__ are set in the globals dictionary before the module code is executed (Note that this is a minimal set of variables - other variables may be set implicitly as an interpreter implementation detail).

__name__ is set to run_name if this optional argument is not None, to mod_name + '__main__' if the named module is a package and to the mod_name argument otherwise.

__spec__ will be set appropriately for the actually imported module (that is, __spec__.name will always be mod_name or mod_name + '__main__', never run_name).

__file__, __cached__, __loader__ and __package__ are set as normal based on the module spec.

If the argument alter_sys is supplied and evaluates to True, then sys.argv[0] is updated with the value of __file__ and sys.modules[__name__] is updated with a temporary module object for the module being executed. Both sys.argv[0] and sys.modules[__name__] are restored to their original values
before the function returns.

Note that this manipulation of sys is not thread-safe. Other threads may see the partially initialised module, as well as the altered list of arguments. It is recommended that the sys module be left alone when invoking this function from threaded code.

See also: The -m option offering equivalent functionality from the command line.

Changed in version 3.1: Added ability to execute packages by looking for a __main__ submodule.

Changed in version 3.2: Added __cached__ global variable (see PEP 3147).

Changed in version 3.4: Updated to take advantage of the module spec feature added by PEP 451. This allows __cached__ to be set correctly for modules run this way, as well as ensuring the real module name is always accessible as __spec__.name.

runpy.run_path(file_path, init_globals=None, run_name=None)

Execute the code at the named filesystem location and return the resulting module globals dictionary. As with a script name supplied to the CPython command line, the supplied path may refer to a Python source file, a compiled bytecode file or a valid sys.path entry containing a __main__ module (e.g. a zipfile containing a top-level __main__.py file).

For a simple script, the specified code is simply executed in a fresh module namespace. For a valid sys.path entry (typically a zipfile or directory), the entry is first added to the beginning of sys.path. The function then looks for and executes a __main__ module
using the updated path. Note that there is no special protection against invoking an existing __main__ entry located elsewhere on sys.path if there is no such module at the specified location.

The optional dictionary argument init_globals may be used to pre-populate the module's globals dictionary before the code is executed. The supplied dictionary will not be modified. If any of the special global variables below are defined in the supplied dictionary, those definitions are overridden by run_path().

The special global variables __name__, __spec__, __file__, __cached__, __loader__ and __package__ are set in the globals dictionary before the module code is executed (Note that this is a minimal set of variables - other variables may be set implicitly as an interpreter implementation detail).

__name__ is set to run_name if this optional argument is not None and to '<run_path>' otherwise.

If the supplied path directly references a script file (whether as source or as precompiled byte code), then __file__ will be set to the supplied path, and __spec__, __cached__, __loader__ and __package__ will all be set to None.

If the supplied path is a reference to a valid sys.path entry, then __spec__ will be set appropriately for the imported __main__ module (that is, __spec__.name will always be __main__). __file__, __cached__, __loader__ and __package__ will be set as normal based on the module spec.

A number of alterations are also made to the sys module. Firstly, sys.path may be altered as described above. sys.argv[0] is
updated with the value of `file_path` and `sys.modules[__name__]` is updated with a temporary module object for the module being executed. All modifications to items in `sys` are reverted before the function returns.

Note that, unlike `run_module()`, the alterations made to `sys` are not optional in this function as these adjustments are essential to allowing the execution of `sys.path` entries. As the thread-safety limitations still apply, use of this function in threaded code should be either serialised with the import lock or delegated to a separate process.

See also: Interface options for equivalent functionality on the command line (`python path/to/script`).

New in version 3.2.

Changed in version 3.4: Updated to take advantage of the module spec feature added by PEP 451. This allows `__cached__` to be set correctly in the case where `__main__` is imported from a valid `sys.path` entry rather than being executed directly.

The **importlib.import_module()** function
31.5. `importlib` — The implementation of `import`

New in version 3.1.

Source code: Lib/importlib/__init__.py
31.5.1. Introduction

The purpose of the `importlib` package is two-fold. One is to provide the implementation of the `import` statement (and thus, by extension, the `__import__()` function) in Python source code. This provides an implementation of `import` which is portable to any Python interpreter. This also provides an implementation which is easier to comprehend than one implemented in a programming language other than Python.

Two, the components to implement `import` are exposed in this package, making it easier for users to create their own custom objects (known generically as an `importer`) to participate in the import process.

See also:

The `import` statement
The language reference for the `import` statement.

Packages specification
Original specification of packages. Some semantics have changed since the writing of this document (e.g. redirecting based on `None` in `sys.modules`).

The `__import__()` function
The `import` statement is syntactic sugar for this function.

31.5.2. Functions

importlib.\texttt{\_\_import\_\_}(\textit{name}, \textit{globals}=\text{None}, \textit{locals}=\text{None}, \textit{fromlist}=(), \textit{level}=0)

An implementation of the built-in \texttt{\_\_import\_\_()} function.

\textbf{Note:} Programmatic importing of modules should use \texttt{import_module()} instead of this function.

importlib.\texttt{import\_module}(\textit{name}, \textit{package}=\text{None})

Import a module. The \textit{name} argument specifies what module to import in absolute or relative terms (e.g. either \texttt{pkg.mod} or \texttt{..mod}). If the name is specified in relative terms, then the \textit{package} argument must be set to the name of the package which is to act as the anchor for resolving the package name (e.g. \texttt{import\_module('..mod', 'pkg.subpkg')} will import \texttt{pkg.mod}).

The \texttt{import\_module()} function acts as a simplifying wrapper around \texttt{importlib.\_\_import\_\_()}. This means all semantics of the function are derived from \texttt{importlib.\_\_import\_\_()}. The most important difference between these two functions is that \texttt{import\_module()} returns the specified package or module (e.g. \texttt{pkg.mod}), while \texttt{\_\_import\_\_()} returns the top-level package or module (e.g. \texttt{pkg}).

If you are dynamically importing a module that was created since the interpreter began execution (e.g., created a Python source file), you may need to call \texttt{invalidate\_caches()} in order for the new module to be noticed by the import system.
Changed in version 3.3: Parent packages are automatically imported.

`importlib.find_loader(name, path=None)`

Find the loader for a module, optionally within the specified `path`. If the module is in `sys.modules`, then `sys.modules[name].__loader__` is returned (unless the loader would be `None` or is not set, in which case `ValueError` is raised). Otherwise a search using `sys.meta_path` is done. `None` is returned if no loader is found.

A dotted name does not have its parents implicitly imported as that requires loading them and that may not be desired. To properly import a submodule you will need to import all parent packages of the submodule and use the correct argument to `path`.

New in version 3.3.

Changed in version 3.4: If `__loader__` is not set, raise `ValueError`, just like when the attribute is set to `None`.

Deprecated since version 3.4: Use `importlib.util.find_spec()` instead.

`importlib.invalidate_caches()`

Invalidate the internal caches of finders stored at `sys.meta_path`. If a finder implements `invalidate_caches()` then it will be called to perform the invalidation. This function should be called if any modules are created/installed while your program is running to guarantee all finders will notice the new module's existence.

New in version 3.3.
importlib.reload(module)

Reload a previously imported module. The argument must be a module object, so it must have been successfully imported before. This is useful if you have edited the module source file using an external editor and want to try out the new version without leaving the Python interpreter. The return value is the module object (which can be different if re-importing causes a different object to be placed in sys.modules).

When reload() is executed:

- Python module's code is recompiled and the module-level code re-executed, defining a new set of objects which are bound to names in the module’s dictionary by reusing the loader which originally loaded the module. The init function of extension modules is not called a second time.
- As with all other objects in Python the old objects are only reclaimed after their reference counts drop to zero.
- The names in the module namespace are updated to point to any new or changed objects.
- Other references to the old objects (such as names external to the module) are not rebound to refer to the new objects and must be updated in each namespace where they occur if that is desired.

There are a number of other caveats:

When a module is reloaded, its dictionary (containing the module’s global variables) is retained. Redefinitions of names will override the old definitions, so this is generally not a problem. If the new version of a module does not define a name that was defined by the old version, the old definition remains. This feature can be used to the module’s advantage if it maintains a global table or cache of objects — with a try statement it can test for the table’s presence
and skip its initialization if desired:

```python
try:
    cache
except NameError:
    cache = {}
```

It is generally not very useful to reload built-in or dynamically loaded modules. Reloading `sys`, `__main__`, `builtins` and other key modules is not recommended. In many cases extension modules are not designed to be initialized more than once, and may fail in arbitrary ways when reloaded.

If a module imports objects from another module using `from ... import ...`, calling `reload()` for the other module does not redefine the objects imported from it — one way around this is to re-execute the `from` statement, another is to use `import` and qualified names (`module.name`) instead.

If a module instantiates instances of a class, reloading the module that defines the class does not affect the method definitions of the instances — they continue to use the old class definition. The same is true for derived classes.

*New in version 3.4.*
31.5.3. **importlib.abc** – Abstract base classes related to import

**Source code:** Lib/importlib/abc.py

The `importlib.abc` module contains all of the core abstract base classes used by `import`. Some subclasses of the core abstract base classes are also provided to help in implementing the core ABCs.

ABC hierarchy:

```
object
    +-- Finder (deprecated)
    |    +-- MetaPathFinder
    |    +-- PathEntryFinder
    +-- Loader
        +-- ResourceLoader
        +-- InspectLoader
            |    +-- ExecutionLoader
            |    +-- FileLoader
        +-- SourceLoader
```

**class importlib.abc.Finder**

An abstract base class representing a `finder`.

*Deprecated since version 3.3:* Use `MetaPathFinder` or `PathEntryFinder` instead.

**abstractmethod** `find_module(fullname, path=None)`

An abstract method for finding a `loader` for the specified module. Originally specified in **PEP 302**, this method was meant for use in `sys.meta_path` and in the path-based import subsystem.
Changed in version 3.4: Returns None when called instead of raising `NotImplementedError`.

class importlib.abc.MetaPathFinder

An abstract base class representing a meta path finder. For compatibility, this is a subclass of `Finder`.

New in version 3.3.

**find_spec**(fullname, path, target=None)

An abstract method for finding a spec for the specified module. If this is a top-level import, `path` will be `None`. Otherwise, this is a search for a subpackage or module and `path` will be the value of `__path__` from the parent package. If a spec cannot be found, `None` is returned. When passed in, `target` is a module object that the finder may use to make a more educated guess about what spec to return.

New in version 3.4.

**find_module**(fullname, path)

A legacy method for finding a loader for the specified module. If this is a top-level import, `path` will be `None`. Otherwise, this is a search for a subpackage or module and `path` will be the value of `__path__` from the parent package. If a loader cannot be found, `None` is returned.

If `find_spec()` is defined, backwards-compatible functionality is provided.

Changed in version 3.4: Returns `None` when called instead of raising `NotImplementedError`. Can use `find_spec()` to
provide functionality.

*Deprecated since version 3.4:* Use `find_spec()` instead.

**invalidate_caches()**
An optional method which, when called, should invalidate any internal cache used by the finder. Used by `importlib.invalidate_caches()` when invalidating the caches of all finders on `sys.meta_path`.

*Changed in version 3.4:* Returns `None` when called instead of `NotImplemented`.

**class importlib.abc.PathEntryFinder**
An abstract base class representing a *path entry finder*. Though it bears some similarities to `MetaPathFinder`, `PathEntryFinder` is meant for use only within the path-based import subsystem provided by `PathFinder`. This ABC is a subclass of `Finder` for compatibility reasons only.

*New in version 3.3.*

**find_spec(fullname, target=None)**
An abstract method for finding a *spec* for the specified module. The finder will search for the module only within the *path entry* to which it is assigned. If a spec cannot be found, `None` is returned. When passed in, `target` is a module object that the finder may use to make a more educated guess about what spec to return.

*New in version 3.4.*

**find_loader(fullname)**
A legacy method for finding a loader for the specified module. Returns a 2-tuple of (loader, portion) where portion is a sequence of file system locations contributing to part of a namespace package. The loader may be None while specifying portion to signify the contribution of the file system locations to a namespace package. An empty list can be used for portion to signify the loader is not part of a namespace package. If loader is None and portion is the empty list then no loader or location for a namespace package were found (i.e. failure to find anything for the module).

If find_spec() is defined then backwards-compatible functionality is provided.

*Changed in version 3.4:* Returns (None, []) instead of raising NotImplementedError. Uses find_spec() when available to provide functionality.

*Deprecated since version 3.4:* Use find_spec() instead.

**find_module**(fullname)

A concrete implementation of Finder.find_module() which is equivalent to self.find_loader(fullname)[0].

*Deprecated since version 3.4:* Use find_spec() instead.

**invalidate_caches()**

An optional method which, when called, should invalidate any internal cache used by the finder. Used by PathFinder.invalidate_caches() when invalidating the caches of all cached finders.
class importlib.abc.Loader

An abstract base class for a loader. See PEP 302 for the exact definition for a loader.

**create_module**(spec)

A method that returns the module object to use when importing a module. This method may return None, indicating that default module creation semantics should take place.

*New in version 3.4.*

*Changed in version 3.5:* Starting in Python 3.6, this method will not be optional when exec_module() is defined.

**exec_module**(module)

An abstract method that executes the module in its own namespace when a module is imported or reloaded. The module should already be initialized when exec_module() is called. When this method exists, create_module() must be defined.

*New in version 3.4.*

*Changed in version 3.6:* create_module() must also be defined.

**load_module**(fullname)

A legacy method for loading a module. If the module cannot be loaded, ImportError is raised, otherwise the loaded module is returned.

If the requested module already exists in sys.modules, that module should be used and reloaded. Otherwise the loader
should create a new module and insert it into `sys.modules` before any loading begins, to prevent recursion from the import. If the loader inserted a module and the load fails, it must be removed by the loader from `sys.modules`; modules already in `sys.modules` before the loader began execution should be left alone (see `importlib.util.module_for_loader()`).

The loader should set several attributes on the module. (Note that some of these attributes can change when a module is reloaded):

- `__name__`: The name of the module.
- `__file__`: The path to where the module data is stored (not set for built-in modules).
- `__cached__`: The path to where a compiled version of the module is/should be stored (not set when the attribute would be inappropriate).
- `__path__`: A list of strings specifying the search path within a package. This attribute is not set on modules.
- `__package__`: The parent package for the module/package. If the module is top-level then it has a value of the empty string. The `importlib.util.module_for_loader()` decorator can handle the details for `__package__`.
- `__loader__`
The loader used to load the module. The `importlib.util.module_for_loader()` decorator can handle the details for `__package__`.

When `exec_module()` is available then backwards-compatible functionality is provided.

*Changed in version 3.4:* Raise `ImportError` when called instead of `NotImplementedError`. Functionality provided when `exec_module()` is available.

*Deprecated since version 3.4:* The recommended API for loading a module is `exec_module()` (and `create_module()`). Loaders should implement it instead of `load_module()`. The import machinery takes care of all the other responsibilities of `load_module()` when `exec_module()` is implemented.

**module_repr(module)**

A legacy method which when implemented calculates and returns the given module's repr, as a string. The module type's default `repr()` will use the result of this method as appropriate.

*New in version 3.3.*

*Changed in version 3.4:* Made optional instead of an abstractmethod.

*Deprecated since version 3.4:* The import machinery now takes care of this automatically.

**class importlib.abc.ResourceLoader**

An abstract base class for a `loader` which implements the optional **PEP 302** protocol for loading arbitrary resources from the storage
back-end.

**abstractmethod get_data**(path)
An abstract method to return the bytes for the data located at path. Loaders that have a file-like storage back-end that allows storing arbitrary data can implement this abstract method to give direct access to the data stored. OSError is to be raised if the path cannot be found. The path is expected to be constructed using a module's __file__ attribute or an item from a package's __path__.

*Changed in version 3.4:* Raises OSError instead of NotImplementedError.

class importlib.abc.InspectLoader
An abstract base class for a loader which implements the optional PEP 302 protocol for loaders that inspect modules.

**get_code**(fullname)
Return the code object for a module, or None if the module does not have a code object (as would be the case, for example, for a built-in module). Raise an ImportError if loader cannot find the requested module.

*Note:* While the method has a default implementation, it is suggested that it be overridden if possible for performance.

*Changed in version 3.4:* No longer abstract and a concrete implementation is provided.

**abstractmethod get_source**(fullname)
An abstract method to return the source of a module. It is
returned as a text string using universal newlines, translating all recognized line separators into \n characters. Returns None if no source is available (e.g. a built-in module). Raises ImportError if the loader cannot find the module specified.

Changed in version 3.4: Raises ImportError instead of NotImplementedError.

**is_package(fullname)**

An abstract method to return a true value if the module is a package, a false value otherwise. ImportError is raised if the loader cannot find the module.

Changed in version 3.4: Raises ImportError instead of NotImplementedError.

**static source_to_code(data, path='<string>')**

Create a code object from Python source.

The data argument can be whatever the compile() function supports (i.e. string or bytes). The path argument should be the “path” to where the source code originated from, which can be an abstract concept (e.g. location in a zip file).

With the subsequent code object one can execute it in a module by running exec(code, module.__dict__).

New in version 3.4.

Changed in version 3.5: Made the method static.

**exec_module(module)**

Implementation of Loader.exec_module().
New in version 3.4.

**load_module**(*fullname*)

Implementation of `Loader.load_module()`.

*Deprecated since version 3.4:* use `exec_module()` instead.

class importlib.abc.**ExecutionLoader**

An abstract base class which inherits from `InspectLoader` that, when implemented, helps a module to be executed as a script. The ABC represents an optional **PEP 302** protocol.

abstractmethod *get_filename*(*fullname*)

An abstract method that is to return the value of `__file__` for the specified module. If no path is available, `ImportError` is raised.

If source code is available, then the method should return the path to the source file, regardless of whether a bytecode was used to load the module.

*Changed in version 3.4:* Raises `ImportError` instead of `NotImplementedError`.

class importlib.abc.**FileLoader**(*fullname*, *path*)

An abstract base class which inherits from `ResourceLoader` and `ExecutionLoader`, providing concrete implementations of `ResourceLoader.get_data()` and `ExecutionLoader.get_filename()`.

The *fullname* argument is a fully resolved name of the module the loader is to handle. The *path* argument is the path to the file for the module.
New in version 3.3.

name
The name of the module the loader can handle.

path
Path to the file of the module.

load_module(fullname)
Calls super's load_module().

Deprecated since version 3.4: Use Loader.exec_module() instead.

abstractmethod get_filename(fullname)
Returns path.

abstractmethod get_data(path)
Reads path as a binary file and returns the bytes from it.

class importlib.abc.SourceLoader
An abstract base class for implementing source (and optionally bytecode) file loading. The class inherits from both ResourceLoader and ExecutionLoader, requiring the implementation of:

- ResourceLoader.get_data()
- ExecutionLoader.get_filename()

Should only return the path to the source file; sourceless loading is not supported.

The abstract methods defined by this class are to add optional bytecode file support. Not implementing these optional methods (or
causing them to raise \texttt{NotImplementedError}) causes the loader to only work with source code. Implementing the methods allows the loader to work with source and bytecode files; it does not allow for sourceless loading where only bytecode is provided. Bytecode files are an optimization to speed up loading by removing the parsing step of Python's compiler, and so no bytecode-specific API is exposed.

\textbf{path\_stats}(\textit{path})

Optional abstract method which returns a \texttt{dict} containing metadata about the specified path. Supported dictionary keys are:

- \texttt{'mtime'} (mandatory): an integer or floating-point number representing the modification time of the source code;
- \texttt{'size'} (optional): the size in bytes of the source code.

Any other keys in the dictionary are ignored, to allow for future extensions. If the path cannot be handled, \texttt{OSError} is raised.

\textit{New in version 3.3.}

\textit{Changed in version 3.4:} Raise \texttt{OSError} instead of \texttt{NotImplementedError}.

\textbf{path\_mtime}(\textit{path})

Optional abstract method which returns the modification time for the specified path.

\textit{Deprecated since version 3.3:} This method is deprecated in favour of \texttt{path\_stats()}. You don’t have to implement it, but it is still available for compatibility purposes. Raise \texttt{OSError} if the path cannot be handled.
Changed in version 3.4: Raise OSError instead of NotImplementedError.

**set_data**(path, data)
Optional abstract method which writes the specified bytes to a file path. Any intermediate directories which do not exist are to be created automatically.

When writing to the path fails because the path is read-only (errno.EACCES/PermissionError), do not propagate the exception.

Changed in version 3.4: No longer raises NotImplementedError when called.

**get_code**(fullname)
Concrete implementation of InspectLoader.get_code().

**exec_module**(module)
Concrete implementation of Loader.exec_module().

New in version 3.4.

**load_module**(fullname)
Concrete implementation of Loader.load_module().

Deprecated since version 3.4: Use exec_module() instead.

**get_source**(fullname)
Concrete implementation of InspectLoader.get_source() .

**is_package**(fullname)
Concrete implementation of `InspectLoader.is_package()`. A module is determined to be a package if its file path (as provided by `ExecutionLoader.get_filename()`) is a file named \texttt{__init__} when the file extension is removed \textbf{and} the module name itself does not end in \texttt{__init__}. 
31.5.4. **importlib.machinery** – Importers and path hooks

**Source code:** Lib/importlib/machinery.py

This module contains the various objects that help `import` find and load modules.

*importlib.machinery.*SOURCE_SUFFIXES

A list of strings representing the recognized file suffixes for source modules.

*New in version 3.3.*

*importlib.machinery.*DEBUG_BYTECODE_SUFFIXES

A list of strings representing the file suffixes for non-optimized bytecode modules.

*New in version 3.3.*

*Deprecated since version 3.5:* Use `BYTECODE_SUFFIXES` instead.

*importlib.machinery.*OPTIMIZED_BYTECODE_SUFFIXES

A list of strings representing the file suffixes for optimized bytecode modules.

*New in version 3.3.*

*Deprecated since version 3.5:* Use `BYTECODE_SUFFIXES` instead.

*importlib.machinery.*BYTECODE_SUFFIXES

A list of strings representing the recognized file suffixes for
bytecode modules (including the leading dot).

*New in version 3.3.*

*Changed in version 3.5:* The value is no longer dependent on `__debug__`.

**importlib.machinery.EXTENSION_SUFFİXES**

A list of strings representing the recognized file suffixes for extension modules.

*New in version 3.3.*

**importlib.machinery.all_suffixes()**

Returns a combined list of strings representing all file suffixes for modules recognized by the standard import machinery. This is a helper for code which simply needs to know if a filesystem path potentially refers to a module without needing any details on the kind of module (for example, `inspect.getmodulename()`).

*New in version 3.3.*

**class importlib.machinery.BuiltinImporter**

An importer for built-in modules. All known built-in modules are listed in `sys.builtin_module_names`. This class implements the `importlib.abc.MetaPathFinder` and `importlib.abc.InspectLoader` ABCs.

Only class methods are defined by this class to alleviate the need for instantiation.

*Changed in version 3.5:* As part of [PEP 489](https://peps.python.org/pep-0489/), the builtin importer now implements `Loader.create_module()` and `Loader.exec_module()`
class importlib.machinery.FrozenImporter

An importer for frozen modules. This class implements the importlib.abc.MetaPathFinder and importlib.abc.InspectLoader ABCs.

Only class methods are defined by this class to alleviate the need for instantiation.

class importlib.machinery.WindowsRegistryFinder

Finder for modules declared in the Windows registry. This class implements the importlib.abc.Finder ABC.

Only class methods are defined by this class to alleviate the need for instantiation.

New in version 3.3.

Deprecated since version 3.6: Use site configuration instead. Future versions of Python may not enable this finder by default.

class importlib.machinery.PathFinder

A Finder for sys.path and package __path__ attributes. This class implements the importlib.abc.MetaPathFinder ABC.

Only class methods are defined by this class to alleviate the need for instantiation.

classmethod find_spec(fullname, path=None, target=None)

Class method that attempts to find a spec for the module specified by fullname on sys.path or, if defined, on path. For each path entry that is searched, sys.path_importer_cache is checked. If a non-false object
is found then it is used as the path entry finder to look for the module being searched for. If no entry is found in `sys.path_importer_cache`, then `sys.path_hooks` is searched for a finder for the path entry and, if found, is stored in `sys.path_importer_cache` along with being queried about the module. If no finder is ever found then `None` is both stored in the cache and returned.

*New in version 3.4.*

*Changed in version 3.5:* If the current working directory – represented by an empty string – is no longer valid then `None` is returned but no value is cached in `sys.path_importer_cache`.

**classmethod** `find_module(fullname, path=None)`

A legacy wrapper around `find_spec()`.

*Deprecated since version 3.4:* Use `find_spec()` instead.

**classmethod** `invalidate_caches()`

Calls

```
importlib.abc.PathEntryFinder.invalidate_caches()
```
on all finders stored in `sys.path_importer_cache`.

*Changed in version 3.4:* Calls objects in `sys.path_hooks` with the current working directory for `''` (i.e. the empty string).

**class importlib.machinery.FileFinder(path, *loader_details)**

A concrete implementation of `importlib.abc.PathEntryFinder` which caches results from
the file system.

The *path* argument is the directory for which the finder is in charge of searching.

The *loader_details* argument is a variable number of 2-item tuples each containing a loader and a sequence of file suffixes the loader recognizes. The loaders are expected to be callables which accept two arguments of the module’s name and the path to the file found.

The finder will cache the directory contents as necessary, making stat calls for each module search to verify the cache is not outdated. Because cache staleness relies upon the granularity of the operating system’s state information of the file system, there is a potential race condition of searching for a module, creating a new file, and then searching for the module the new file represents. If the operations happen fast enough to fit within the granularity of stat calls, then the module search will fail. To prevent this from happening, when you create a module dynamically, make sure to call `importlib.invalidate_caches()`.

*New in version 3.3.*

**path**

The path the finder will search in.

**find_spec**(fullname, target=None)

Attempt to find the spec to handle *fullname* within *path*.

*New in version 3.4.*

**find_loader**(fullname)

Attempt to find the loader to handle *fullname* within *path*. 
**invalidate_caches()**
Clear out the internal cache.

**classmethod path_hook(*loader_details)**
A class method which returns a closure for use on `sys.path_hooks`. An instance of `FileFinder` is returned by the closure using the path argument given to the closure directly and `loader_details` indirectly.

If the argument to the closure is not an existing directory, `ImportError` is raised.

```python
class importlib.machinery.SourceFileLoader(fullname, path)
```
A concrete implementation of `importlib.abc.SourceLoader` by subclassing `importlib.abc.FileLoader` and providing some concrete implementations of other methods.

*New in version 3.3.*

**name**
The name of the module that this loader will handle.

**path**
The path to the source file.

**is_package(fullname)**
Return true if `path` appears to be for a package.

**path_stats(path)**
Concrete implementation of `importlib.abc.SourceLoader.path_stats()`. 
**set_data**(*path*, *data*)
Concrete implementation of *importlib.abc.SourceLoader.set_data()*.  

**load_module**(*name=None*)
Concrete implementation of *importlib.abc.Loader.load_module()* where specifying the name of the module to load is optional.

*Deprecated since version 3.6:* Use *importlib.abc.Loader.exec_module()* instead.

```python
class importlib.machinery.SourcelessFileLoader(*fullname, path*)
```
A concrete implementation of *importlib.abc.FileLoader* which can import bytecode files (i.e. no source code files exist).

Please note that direct use of bytecode files (and thus not source code files) inhibits your modules from being usable by all Python implementations or new versions of Python which change the bytecode format.

*New in version 3.3.*

**name**
The name of the module the loader will handle.

**path**
The path to the bytecode file.

**is_package**(*fullname*)
Determines if the module is a package based on *path*.  

get_code(fullname)

Returns the code object for name created from path.

get_source(fullname)

Returns None as bytecode files have no source when this loader is used.

load_module(name=None)

Concrete implementation of importlib.abc.Loader.load_module() where specifying the name of the module to load is optional.

Deprecated since version 3.6: Use importlib.abc.Loader.exec_module() instead.

class importlib.machinery.ExtensionFileLoader(fullname, path)

A concrete implementation of importlib.abc.ExecutionLoader for extension modules.

The fullname argument specifies the name of the module the loader is to support. The path argument is the path to the extension module's file.

New in version 3.3.

name

Name of the module the loader supports.

path

Path to the extension module.
create_module(spec)
    Creates the module object from the given specification in accordance with PEP 489.

    New in version 3.5.

global exec_module(module)
    Initializes the given module object in accordance with PEP 489.

    New in version 3.5.

is_package(fullname)
    Returns True if the file path points to a package's __init__ module based on EXTENSION_SUFFIXES.

global get_code(fullname)
    Returns None as extension modules lack a code object.

global get_source(fullname)
    Returns None as extension modules do not have source code.

global get_filename(fullname)
    Returns path.

    New in version 3.4.

class importlib.machinery.ModuleSpec(name, loader, *, origin=None, loader_state=None, is_package=None)
    A specification for a module's import-system-related state.

    New in version 3.4.

name
(__name__)  
A string for the fully-qualified name of the module.

**loader**

(__loader__)  
The loader to use for loading. For namespace packages this should be set to `None`.

**origin**

(__file__)  
Name of the place from which the module is loaded, e.g. “builtin” for built-in modules and the filename for modules loaded from source. Normally “origin” should be set, but it may be `None` (the default) which indicates it is unspecified.

**submodule_search_locations**

(__path__)  
List of strings for where to find submodules, if a package (`None` otherwise).

**loader_state**

Container of extra module-specific data for use during loading (or `None`).

**cached**

(__cached__)
String for where the compiled module should be stored (or None).

**parent**

(`__package__`)

(Read-only) Fully-qualified name of the package to which the module belongs as a submodule (or None).

**has_location**

Boolean indicating whether or not the module’s “origin” attribute refers to a loadable location.
31.5.5. importlib.util – Utility code for importers

Source code: Lib/importlib/util.py

This module contains the various objects that help in the construction of an importer.

importlib.util.MAGIC_NUMBER
The bytes which represent the bytecode version number. If you need help with loading/writing bytecode then consider importlib.abc.SourceLoader.

New in version 3.4.

importlib.util.cache_from_source(path, debug_override=None, *, optimization=None)
Return the PEP 3147/PEP 488 path to the byte-compiled file associated with the source path. For example, if path is /foo/bar/baz.py the return value would be /foo/bar/__pycache__/baz.cpython-32.pyc for Python 3.2. The cpython-32 string comes from the current magic tag (see get_tag()); if sys.implementation.cache_tag is not defined then NotImplementedError will be raised).

The optimization parameter is used to specify the optimization level of the bytecode file. An empty string represents no optimization, so /foo/bar/baz.py with an optimization of '' will result in a bytecode path of /foo/bar/__pycache__/baz.cpython-32.pyc. None causes the interpreter’s optimization level to be used.
Any other value's string representation being used, so `/foo/bar/baz.py` with an `optimization` of 2 will lead to the bytecode path of `/foo/bar/__pycache__/baz.cpython-32.opt-2.pyc`. The string representation of `optimization` can only be alphanumeric, else `ValueError` is raised.

The `debug_override` parameter is deprecated and can be used to override the system's value for `__debug__`. A `True` value is the equivalent of setting `optimization` to the empty string. A `False` value is the same as setting `optimization` to 1. If both `debug_override` an `optimization` are not `None` then `TypeError` is raised.

*New in version 3.4.*

*Changed in version 3.5:* The `optimization` parameter was added and the `debug_override` parameter was deprecated.

*Changed in version 3.6:* Accepts a `path-like object`.

`importlib.util.source_from_cache(path)`

Given the `path` to a PEP 3147 file name, return the associated source code file path. For example, if `path` is `/foo/bar/__pycache__/baz.cpython-32.pyc` the returned path would be `/foo/bar/baz.py`. `path` need not exist, however if it does not conform to PEP 3147 or PEP 488 format, a `ValueError` is raised. If `sys.implementation.cache_tag` is not defined, `NotImplementedError` is raised.

*New in version 3.4.*

*Changed in version 3.6:* Accepts a `path-like object`. 
importlib.util.**decode_source**(source_bytes)

Decode the given bytes representing source code and return it as a string with universal newlines (as required by importlib.abc.InspectLoader.get_source()).

*New in version 3.4.*

importlib.util.**resolve_name**(name, package)

Resolve a relative module name to an absolute one.

If `name` has no leading dots, then `name` is simply returned. This allows for usage such as `importlib.util.resolve_name('sys', __package__)` without doing a check to see if the `package` argument is needed.

*ValueError* is raised if `name` is a relative module name but `package` is a false value (e.g. `None` or the empty string). *ValueError* is also raised a relative name would escape its containing package (e.g. requesting `.bacon` from within the `spam` package).

*New in version 3.3.*

importlib.util.**find_spec**(name, package=None)

Find the `spec` for a module, optionally relative to the specified `package` name. If the module is in `sys.modules`, then `sys.modules[name].__spec__` is returned (unless the spec would be `None` or is not set, in which case *ValueError* is raised). Otherwise a search using `sys.meta_path` is done. `None` is returned if no spec is found.

If `name` is for a submodule (contains a dot), the parent module is automatically imported.
name and package work the same as for import_module().

New in version 3.4.

importlib.util.module_from_spec(spec)
Create a new module based on spec and spec.loader.create_module.

If spec.loader.create_module does not return None, then any pre-existing attributes will not be reset. Also, no AttributeError will be raised if triggered while accessing spec or setting an attribute on the module.

This function is preferred over using types.ModuleType to create a new module as spec is used to set as many import-controlled attributes on the module as possible.

New in version 3.5.

@importlib.util.module_for_loader
A decorator for importlib.abc.Loader.load_module() to handle selecting the proper module object to load with. The decorated method is expected to have a call signature taking two positional arguments (e.g. load_module(self, module)) for which the second argument will be the module object to be used by the loader. Note that the decorator will not work on static methods because of the assumption of two arguments.

The decorated method will take in the name of the module to be loaded as expected for a loader. If the module is not found in sys.modules then a new one is constructed. Regardless of where the module came from, __loader__ set to self and
__package__ is set based on what importlib.abc.InspectLoader.is_package() returns (if available). These attributes are set unconditionally to support reloading.

If an exception is raised by the decorated method and a module was added to sys.modules, then the module will be removed to prevent a partially initialized module from being in left in sys.modules. If the module was already in sys.modules then it is left alone.

*Changed in version 3.3:* __loader__ and __package__ are automatically set (when possible).

*Changed in version 3.4:* Set __name__, __loader__, __package__ unconditionally to support reloading.

*Deprecated since version 3.4:* The import machinery now directly performs all the functionality provided by this function.

@importlib.util.set_loader

A decorator for importlib.abc.Loader.load_module() to set the __loader__ attribute on the returned module. If the attribute is already set the decorator does nothing. It is assumed that the first positional argument to the wrapped method (i.e. self) is what __loader__ should be set to.

*Changed in version 3.4:* Set __loader__ if set to None, as if the attribute does not exist.

*Deprecated since version 3.4:* The import machinery takes care of this automatically.
@importlib.util.{set\_package}

A **decorator** for `importlib.abc.Loader.load_module()` to set the `__package__` attribute on the returned module. If `__package__` is set and has a value other than `None` it will not be changed.

*Deprecated since version 3.4:* The import machinery takes care of this automatically.

`importlib.util.spec\_from\_loader(name, loader, *, origin=None, is\_package=None)`

A factory function for creating a `ModuleSpec` instance based on a loader. The parameters have the same meaning as they do for `ModuleSpec`. The function uses available `loader` APIs, such as `InspectLoader.is\_package()`, to fill in any missing information on the spec.

*New in version 3.4.*

`importlib.util.spec\_from\_file\_location(name, location, *, loader=None, submodule\_search\_locations=None)`

A factory function for creating a `ModuleSpec` instance based on the path to a file. Missing information will be filled in on the spec by making use of loader APIs and by the implication that the module will be file-based.

*New in version 3.4.*

*Changed in version 3.6:* Accepts a **path-like object**.

```python
class importlib.util.LazyLoader(loader)
```

A class which postpones the execution of the loader of a module until the module has an attribute accessed.
This class **only** works with loaders that define `exec_module()` as control over what module type is used for the module is required. For those same reasons, the loader’s `create_module()` method must return `None` or a type for which its `__class__` attribute can be mutated along with not using `slots`. Finally, modules which substitute the object placed into `sys.modules` will not work as there is no way to properly replace the module references throughout the interpreter safely; `ValueError` is raised if such a substitution is detected.

**Note:** For projects where startup time is critical, this class allows for potentially minimizing the cost of loading a module if it is never used. For projects where startup time is not essential then use of this class is **heavily** discouraged due to error messages created during loading being postponed and thus occurring out of context.

*New in version 3.5.*

*Changed in version 3.6:* Began calling `create_module()`, removing the compatibility warning for `importlib.machinery.BuiltinImporter` and `importlib.machinery.ExtensionFileLoader`.

**classmethod factory(loader)**

A static method which returns a callable that creates a lazy loader. This is meant to be used in situations where the loader is passed by class instead of by instance.

```python
suffixes = importlib.machinery.SOURCE_SUFFIXES
loader = importlib.machinery.SourceFileLoader
lazy_loader = importlib.util.LazyLoader.factory
finder = importlib.machinery.FileFinder(path, (
```
31.5.6. Examples

31.5.6.1. Importing programmatically

To programmatically import a module, use `importlib.import_module()`.

```python
import importlib

importlib.import_module('itertools')
```

31.5.6.2. Checking if a module can be imported

If you need to find out if a module can be imported without actually doing the import, then you should use `importlib.util.find_spec()`.

```python
import importlib.util
import sys

# For illustrative purposes.
name = 'itertools'

spec = importlib.util.find_spec(name)
if spec is None:
    print("can't find the itertools module")
else:
    # If you chose to perform the actual import ...
    module = importlib.util.module_from_spec(spec)
    spec.loader.exec_module(module)
    # Adding the module to sys.modules is optional.
    sys.modules[name] = module
```
31.5.6.3. Importing a source file directly

To import a Python source file directly, use the following recipe (Python 3.4 and newer only):

```python
import importlib.util
import sys

# For illustrative purposes.
import tokenize
file_path = tokenize.__file__
module_name = tokenize.__name__

spec = importlib.util.spec_from_file_location(module_name, file_path)
module = importlib.util.module_from_spec(spec)
spec.loader.exec_module(module)

# Optional; only necessary if you want to be able to import by name later.
sys.modules[module_name] = module
```

31.5.6.4. Setting up an importer

For deep customizations of import, you typically want to implement an importer. This means managing both the finder and loader side of things. For finders there are two flavours to choose from depending on your needs: a meta path finder or a path entry finder. The former is what you would put on `sys.meta_path` while the latter is what you create using a path entry hook on `sys.path_hooks` which works with `sys.path` entries to potentially create a finder. This example will show you how to register your own importers so that import will use them (for creating an importer for yourself, read the documentation for the appropriate classes defined within this package):
31.5.6.5. Approximating \texttt{importlib.import_module()}

Import itself is implemented in Python code, making it possible to expose most of the import machinery through importlib. The following helps illustrate the various APIs that importlib exposes by providing an approximate implementation of \texttt{importlib.import_module()} (Python 3.4 and newer for the importlib usage, Python 3.6 and newer for other parts of the code).

```python
import importlib.util
import sys

def import_module(name, package=None):
    """An approximate implementation of import.""
```
```python
absolute_name = importlib.util.resolve_name(name)
try:
    return sys.modules[absolute_name]
except KeyError:
    pass

path = None
if '.' in absolute_name:
    parent_name, _, child_name = absolute_name.rpartition('.
parent_module = import_module(parent_name)
    path = parent_module.spec.submodule_search_locations
for finder in sys.meta_path:
    spec = finder.find_spec(absolute_name, path)
    if spec is not None:
        break
else:
    raise ImportError(f'No module named {absolute_name}
module = importlib.util.module_from_spec(spec)
    spec.loader.exec_module(module)
sys.modules[absolute_name] = module
if path is not None:
    setattr(parent_module, child_name, module)
return module
```

Created using Sphinx 1.6.3.
32. Python Language Services

Python provides a number of modules to assist in working with the Python language. These modules support tokenizing, parsing, syntax analysis, bytecode disassembly, and various other facilities.

These modules include:

- **32.1. parser — Access Python parse trees**
  - 32.1.1. Creating ST Objects
  - 32.1.2. Converting ST Objects
  - 32.1.3. Queries on ST Objects
  - 32.1.4. Exceptions and Error Handling
  - 32.1.5. ST Objects
  - 32.1.6. Example: Emulation of compile()

- **32.2. ast — Abstract Syntax Trees**
  - 32.2.1. Node classes
  - 32.2.2. Abstract Grammar
  - 32.2.3. ast Helpers

- **32.3. symtable — Access to the compiler's symbol tables**
  - 32.3.1. Generating Symbol Tables
  - 32.3.2. Examining Symbol Tables

- **32.4. symbol — Constants used with Python parse trees**
- **32.5. token — Constants used with Python parse trees**

32.1. **parser** — Access Python parse trees

The **parser** module provides an interface to Python’s internal parser and byte-code compiler. The primary purpose for this interface is to allow Python code to edit the parse tree of a Python expression and create executable code from this. This is better than trying to parse and modify an arbitrary Python code fragment as a string because parsing is performed in a manner identical to the code forming the application. It is also faster.

**Note:** From Python 2.5 onward, it’s much more convenient to cut in at the Abstract Syntax Tree (AST) generation and compilation stage, using the **ast** module.

There are a few things to note about this module which are important to making use of the data structures created. This is not a tutorial on editing the parse trees for Python code, but some examples of using the **parser** module are presented.

Most importantly, a good understanding of the Python grammar processed by the internal parser is required. For full information on the language syntax, refer to The Python Language Reference. The parser itself is created from a grammar specification defined in the file Grammar/Grammar in the standard Python distribution. The parse trees stored in the ST objects created by this module are the actual output from the internal parser when created by the `expr()` or `suite()` functions, described below. The ST objects created by `sequence2st()` faithfully simulate those structures. Be aware that
the values of the sequences which are considered “correct” will vary from one version of Python to another as the formal grammar for the language is revised. However, transporting code from one Python version to another as source text will always allow correct parse trees to be created in the target version, with the only restriction being that migrating to an older version of the interpreter will not support more recent language constructs. The parse trees are not typically compatible from one version to another, whereas source code has always been forward-compatible.

Each element of the sequences returned by \texttt{st2list()} or \texttt{st2tuple()} has a simple form. Sequences representing non-terminal elements in the grammar always have a length greater than one. The first element is an integer which identifies a production in the grammar. These integers are given symbolic names in the C header file \texttt{Include/graminit.h} and the Python module \texttt{symbol}. Each additional element of the sequence represents a component of the production as recognized in the input string: these are always sequences which have the same form as the parent. An important aspect of this structure which should be noted is that keywords used to identify the parent node type, such as the keyword \texttt{if} in an \texttt{if_stmt}, are included in the node tree without any special treatment. For example, the \texttt{if} keyword is represented by the tuple \texttt{(1, 'if')}, where \texttt{1} is the numeric value associated with all \texttt{NAME} tokens, including variable and function names defined by the user. In an alternate form returned when line number information is requested, the same token might be represented as \texttt{(1, 'if', 12)}, where the \texttt{12} represents the line number at which the terminal symbol was found.

Terminal elements are represented in much the same way, but without any child elements and the addition of the source text which was identified. The example of the \texttt{if} keyword above is representative.
The various types of terminal symbols are defined in the C header file `Include/token.h` and the Python module `token`.

The ST objects are not required to support the functionality of this module, but are provided for three purposes: to allow an application to amortize the cost of processing complex parse trees, to provide a parse tree representation which conserves memory space when compared to the Python list or tuple representation, and to ease the creation of additional modules in C which manipulate parse trees. A simple “wrapper” class may be created in Python to hide the use of ST objects.

The `parser` module defines functions for a few distinct purposes. The most important purposes are to create ST objects and to convert ST objects to other representations such as parse trees and compiled code objects, but there are also functions which serve to query the type of parse tree represented by an ST object.

**See also:**

**Module symbol**

Useful constants representing internal nodes of the parse tree.

**Module token**

Useful constants representing leaf nodes of the parse tree and functions for testing node values.
32.1.1. Creating ST Objects

ST objects may be created from source code or from a parse tree. When creating an ST object from source, different functions are used to create the 'eval' and 'exec' forms.

parser.\texttt{expr}(source)

The \texttt{expr()} function parses the parameter \texttt{source} as if it were an input to \texttt{compile(source, 'file.py', 'eval')} . If the parse succeeds, an ST object is created to hold the internal parse tree representation, otherwise an appropriate exception is raised.

parser.\texttt{suite}(source)

The \texttt{suite()} function parses the parameter \texttt{source} as if it were an input to \texttt{compile(source, 'file.py', 'exec')} . If the parse succeeds, an ST object is created to hold the internal parse tree representation, otherwise an appropriate exception is raised.

parser.\texttt{sequence2st}(sequence)

This function accepts a parse tree represented as a sequence and builds an internal representation if possible. If it can validate that the tree conforms to the Python grammar and all nodes are valid node types in the host version of Python, an ST object is created from the internal representation and returned to the called. If there is a problem creating the internal representation, or if the tree cannot be validated, a \texttt{ParserError} exception is raised. An ST object created this way should not be assumed to compile correctly; normal exceptions raised by compilation may still be initiated when the ST object is passed to \texttt{compilest()}. This may indicate problems not related to syntax (such as a \texttt{MemoryError} exception), but may also be due to constructs such as the result of
parsing \texttt{del f(0)}, which escapes the Python parser but is checked by the bytecode compiler.

Sequences representing terminal tokens may be represented as either two-element lists of the form \((1, \text{'name'})\) or as three-element lists of the form \((1, \text{'name'}, 56)\). If the third element is present, it is assumed to be a valid line number. The line number may be specified for any subset of the terminal symbols in the input tree.

\begin{verbatim}
parser.tuple2st(sequence)
\end{verbatim}

This is the same function as \texttt{sequence2st()}. This entry point is maintained for backward compatibility.
32.1.2. Converting ST Objects

ST objects, regardless of the input used to create them, may be converted to parse trees represented as list- or tuple- trees, or may be compiled into executable code objects. Parse trees may be extracted with or without line numbering information.

\[ \text{parser} . \text{st2list}(st, \text{line_info} = \text{False}, \text{col_info} = \text{False}) \]

This function accepts an ST object from the caller in \( st \) and returns a Python list representing the equivalent parse tree. The resulting list representation can be used for inspection or the creation of a new parse tree in list form. This function does not fail so long as memory is available to build the list representation. If the parse tree will only be used for inspection, \( \text{st2tuple()} \) should be used instead to reduce memory consumption and fragmentation. When the list representation is required, this function is significantly faster than retrieving a tuple representation and converting that to nested lists.

If \( \text{line_info} \) is true, line number information will be included for all terminal tokens as a third element of the list representing the token. Note that the line number provided specifies the line on which the token \textit{ends}. This information is omitted if the flag is false or omitted.

\[ \text{parser} . \text{st2tuple}(st, \text{line_info} = \text{False}, \text{col_info} = \text{False}) \]

This function accepts an ST object from the caller in \( st \) and returns a Python tuple representing the equivalent parse tree. Other than returning a tuple instead of a list, this function is identical to \( \text{st2list()} \).

If \( \text{line_info} \) is true, line number information will be included for all
terminal tokens as a third element of the list representing the token. This information is omitted if the flag is false or omitted.

```
parser.compilest(st, filename='<syntax-tree>')
```

The Python byte compiler can be invoked on an ST object to produce code objects which can be used as part of a call to the built-in `exec()` or `eval()` functions. This function provides the interface to the compiler, passing the internal parse tree from `st` to the parser, using the source file name specified by the `filename` parameter. The default value supplied for `filename` indicates that the source was an ST object.

Compiling an ST object may result in exceptions related to compilation; an example would be a `SyntaxError` caused by the parse tree for `del f(0)`: this statement is considered legal within the formal grammar for Python but is not a legal language construct. The `SyntaxError` raised for this condition is actually generated by the Python byte-compiler normally, which is why it can be raised at this point by the `parser` module. Most causes of compilation failure can be diagnosed programmatically by inspection of the parse tree.
32.1.3. Queries on ST Objects

Two functions are provided which allow an application to determine if an ST was created as an expression or a suite. Neither of these functions can be used to determine if an ST was created from source code via `expr()` or `suite()` or from a parse tree via `sequence2st()`.

**`parser.isexpr(st)`**

When `st` represents an `'eval'` form, this function returns true, otherwise it returns false. This is useful, since code objects normally cannot be queried for this information using existing built-in functions. Note that the code objects created by `compilest()` cannot be queried like this either, and are identical to those created by the built-in `compile()` function.

**`parser.issuite(st)`**

This function mirrors `isexpr()` in that it reports whether an ST object represents an `'exec'` form, commonly known as a “suite.” It is not safe to assume that this function is equivalent to `not isexpr(st)`, as additional syntactic fragments may be supported in the future.
32.1.4. Exceptions and Error Handling

The parser module defines a single exception, but may also pass other built-in exceptions from other portions of the Python runtime environment. See each function for information about the exceptions it can raise.

*exception* `parser.ParserError`

Exception raised when a failure occurs within the parser module. This is generally produced for validation failures rather than the built-in *SyntaxError* raised during normal parsing. The exception argument is either a string describing the reason of the failure or a tuple containing a sequence causing the failure from a parse tree passed to `sequence2st()` and an explanatory string. Calls to `sequence2st()` need to be able to handle either type of exception, while calls to other functions in the module will only need to be aware of the simple string values.

Note that the functions `compilest()`, `expr()`, and `suite()` may raise exceptions which are normally raised by the parsing and compilation process. These include the built in exceptions *MemoryError*, *OverflowError*, *SyntaxError*, and *SystemError*. In these cases, these exceptions carry all the meaning normally associated with them. Refer to the descriptions of each function for detailed information.
32.1.5. ST Objects

Ordered and equality comparisons are supported between ST objects. Pickling of ST objects (using the `pickle` module) is also supported.

**parser.STType**

The type of the objects returned by `expr()`, `suite()` and `sequence2st()`.

ST objects have the following methods:

**ST.compile(filename='<syntax-tree>')**

Same as `compilest(st, filename)`.

**ST.isexpr()**

Same as `isexpr(st)`.

**ST.isuite()**

Same as `issuite(st)`.

**ST.tolist(line_info=False, col_info=False)**

Same as `st2list(st, line_info, col_info)`.

**ST.totuple(line_info=False, col_info=False)**

Same as `st2tuple(st, line_info, col_info)`.
32.1.6. Example: Emulation of `compile()`

While many useful operations may take place between parsing and bytecode generation, the simplest operation is to do nothing. For this purpose, using the `parser` module to produce an intermediate data structure is equivalent to the code

```python
>>> code = compile('a + 5', 'file.py', 'eval')
>>> a = 5
>>> eval(code)
10
```

The equivalent operation using the `parser` module is somewhat longer, and allows the intermediate internal parse tree to be retained as an ST object:

```python
>>> import parser
>>> st = parser.expr('a + 5')
>>> code = st.compile('file.py')
>>> a = 5
>>> eval(code)
10
```

An application which needs both ST and code objects can package this code into readily available functions:

```python
import parser
def load_suite(source_string):
    st = parser.suite(source_string)
    return st, st.compile()
```
def load_expression(source_string):
    st = parser.expr(source_string)
    return st, st.compile()
32.2. **ast — Abstract Syntax Trees**

**Source code:** Lib/ast.py

The `ast` module helps Python applications to process trees of the Python abstract syntax grammar. The abstract syntax itself might change with each Python release; this module helps to find out programmatically what the current grammar looks like.

An abstract syntax tree can be generated by passing `ast.PyCF_ONLY_AST` as a flag to the `compile()` built-in function, or using the `parse()` helper provided in this module. The result will be a tree of objects whose classes all inherit from `ast.AST`. An abstract syntax tree can be compiled into a Python code object using the built-in `compile()` function.
32.2.1. Node classes

```
class ast.AST
```

This is the base of all AST node classes. The actual node classes are derived from the `Parser/Python.asdl` file, which is reproduced below. They are defined in the `_ast` C module and re-exported in `ast`.

There is one class defined for each left-hand side symbol in the abstract grammar (for example, `ast.stmt` or `ast.expr`). In addition, there is one class defined for each constructor on the right-hand side; these classes inherit from the classes for the left-hand side trees. For example, `ast.BinOp` inherits from `ast.expr`. For production rules with alternatives (aka “sums”), the left-hand side class is abstract: only instances of specific constructor nodes are ever created.

```
_fields
```

Each concrete class has an attribute `_fields` which gives the names of all child nodes.

Each instance of a concrete class has one attribute for each child node, of the type as defined in the grammar. For example, `ast.BinOp` instances have an attribute `left` of type `ast.expr`.

If these attributes are marked as optional in the grammar (using a question mark), the value might be `None`. If the attributes can have zero-or-more values (marked with an asterisk), the values are represented as Python lists. All possible attributes must be present and have valid values when compiling an AST with
Instances of ast.expr and ast.stmt subclasses have `lineno` and `col_offset` attributes. The `lineno` is the line number of source text (1-indexed so the first line is line 1) and the `col_offset` is the UTF-8 byte offset of the first token that generated the node. The UTF-8 offset is recorded because the parser uses UTF-8 internally.

The constructor of a class `ast.T` parses its arguments as follows:

- If there are positional arguments, there must be as many as there are items in `T._fields`; they will be assigned as attributes of these names.
- If there are keyword arguments, they will set the attributes of the same names to the given values.

For example, to create and populate an `ast.UnaryOp` node, you could use

```python
node = ast.UnaryOp()
node.op = ast.USub()
node.operand = ast.Num()
node.operand.n = 5
node.operand.linenos = 0
node.operand.col_offset = 0
node.linenos = 0
node.col_offset = 0
```

or the more compact

```python
node = ast.UnaryOp(ast.USub(), ast.Num(5, lineno=0, col_offset=0))
```
32.2.2. Abstract Grammar

The abstract grammar is currently defined as follows:

```
module Python {
    mod = Module(stmt* body)
        | Interactive(stmt* body)
        | Expression(expr body)

    stmt = FunctionDef(identifier name, arguments args, stmt* body, expr* decorator_list)
        | AsyncFunctionDef(identifier name, arguments args, stmt* body, expr* decorator_list)
        | ClassDef(identifier name, expr* bases, keyword* keywords, stmt* body, expr* decorator_list)
        | Return(expr? value)

    | Delete(expr* targets)
    | Assign(expr* targets, expr value)
    | AugAssign(expr target, operator op, expr value)
```

-- ASDL's 7 builtin types are:
-- identifier, int, string, bytes, object, singleton
-- singleton: None, True or False
-- constant can be None, whereas None means "no value"

-- 'simple' indicates that we annotate simple name without parens
AnnAssign(expr target, expr annotation, ...)

-- use 'orelse' because else is a keyword
| For(expr target, expr iter, stmt* body, ...
| AsyncFor(expr target, expr iter, stmt* body, ...
| While(expr test, stmt* body, stmt* orelse)
| If(expr test, stmt* body, stmt* orelse)
| With(withitem* items, stmt* body)
| AsyncWith(withitem* items, stmt* body)

| Raise(expr? exc, expr? cause)
| Try(stmt* body, excepthandler* handlers, ...
| Assert(expr test, expr? msg)

| Import(alias* names)
| ImportFrom(identifier? module, alias* names)

| Global(identifier* names)
| Nonlocal(identifier* names)
| Expr(expr value)
| Pass | Break | Continue

-- XXX Jython will be different
-- col_offset is the byte offset in the utf8 string the parser uses
attributes (int lineno, int col_offset)

-- BoolOp() can use left & right?
expr = BoolOp(boolop op, expr* values)
| BinOp(expr left, operator op, expr right)
| UnaryOp(unaryop op, expr operand)
| Lambda(arguments args, expr body)
| IfExp(expr test, expr body, expr orelse)
| Dict(expr* keys, expr* values)
| Set(expr* elts)
| ListComp(expr elt, comprehension* generators)
| SetComp(expr elt, comprehension* generators)
| DictComp(expr key, expr value, comprehension* generators)
GeneratorExp(expr elt, comprehension* generators)
-- the grammar constrains where yield expressions can occur
| Await(expr value)
| Yield(expr? value)
| YieldFrom(expr value)
-- need sequences for compare to distinguish
-- x < 4 < 3 and (x < 4) < 3
| Compare(expr left, cmpop* ops, expr* comparators)
| Call(expr func, expr* args, keyword* keywords)
| Num(object n) -- a number as a PyObject.
| Str(string s) -- need to specify raw, unicode?
| FormattedValue(expr value, int? conversion,
| JoinedStr(expr* values)
| Bytes(bytes s)
| NameConstant(singleton value)
| Ellipsis

comprehension = (expr target, expr iter, expr* ifs, int is_async)

excepthandler = ExceptHandler(expr? type, identifier? name, stmt* body)

attributes = (int lineno, int col_offset)

arguments = (arg* args, arg? vararg, arg* kwonly |
              arg? kwarg, expr* defaults)

arg = (identifier arg, expr? annotation)

attributes = (int lineno, int col_offset)

-- keyword arguments supplied to call (NULL identifier for **kwargs)

keyword = (identifier? arg, expr value)

-- import name with optional 'as' alias.

alias = (identifier name, identifier? asname)

withitem = (expr context_expr, expr? optional_vars)
32.2.3. ast Helpers

Apart from the node classes, the `ast` module defines these utility functions and classes for traversing abstract syntax trees:

```python
class ast

ast.parse(source, filename='<unknown>', mode='exec')
    Parse the source into an AST node. Equivalent to
    compile(source, filename, mode, ast.PyCF_ONLY_AST).

ast.literal_eval(node_or_string)
    Safely evaluate an expression node or a string containing a Python
    literal or container display. The string or node provided may only
    consist of the following Python literal structures: strings, bytes,
    numbers, tuples, lists, dicts, sets, booleans, and None.
    
    This can be used for safely evaluating strings containing Python
    values from untrusted sources without the need to parse the values
    oneself. It is not capable of evaluating arbitrarily complex
    expressions, for example involving operators or indexing.
    
    Changed in version 3.2: Now allows bytes and set literals.

ast.get_docstring(node, clean=True)
    Return the docstring of the given node (which must be a
    FunctionDef, ClassDef or Module node), or None if it has no
    docstring. If clean is true, clean up the docstring’s indentation with
    inspect.cleandoc().

ast.fix_missing_locations(node)
    When you compile a node tree with compile(), the compiler
```
expects lineno and col_offset attributes for every node that supports them. This is rather tedious to fill in for generated nodes, so this helper adds these attributes recursively where not already set, by setting them to the values of the parent node. It works recursively starting at node.

```python
ast.increment_lineno(node, n=1)
```
Increment the line number of each node in the tree starting at node by $n$. This is useful to “move code” to a different location in a file.

```python
ast.copy_location(new_node, old_node)
```
Copy source location (lineno and col_offset) from old_node to new_node if possible, and return new_node.

```python
ast.iter_fields(node)
```
Yield a tuple of (fieldname, value) for each field in node._fields that is present on node.

```python
ast.iter_child_nodes(node)
```
Yield all direct child nodes of node, that is, all fields that are nodes and all items of fields that are lists of nodes.

```python
ast.walk(node)
```
Recursively yield all descendant nodes in the tree starting at node (including node itself), in no specified order. This is useful if you only want to modify nodes in place and don’t care about the context.

```python
class ast.NodeVisitor
```
A node visitor base class that walks the abstract syntax tree and calls a visitor function for every node found. This function may return a value which is forwarded by the visit() method.
This class is meant to be subclassed, with the subclass adding visitor methods.

**visit(node)**

Visit a node. The default implementation calls the method called `self.visit_classname` where `classname` is the name of the node class, or `generic_visit()` if that method doesn’t exist.

**generic_visit(node)**

This visitor calls `visit()` on all children of the node.

Note that child nodes of nodes that have a custom visitor method won’t be visited unless the visitor calls `generic_visit()` or visits them itself.

Don’t use the `NodeVisitor` if you want to apply changes to nodes during traversal. For this a special visitor exists (`NodeTransformer`) that allows modifications.

**class ast.NodeTransformer**

A `NodeVisitor` subclass that walks the abstract syntax tree and allows modification of nodes.

The `NodeTransformer` will walk the AST and use the return value of the visitor methods to replace or remove the old node. If the return value of the visitor method is `None`, the node will be removed from its location, otherwise it is replaced with the return value. The return value may be the original node in which case no replacement takes place.

Here is an example transformer that rewrites all occurrences of name lookups (`foo`) to `data['foo']`:
class RewriteName(NodeTransformer):

def visit_Name(self, node):
    return copy_location(Subscript(
        value=Name(id='data', ctx=Load()),
        slice=Index(value=Str(s=node.id)),
        ctx=node.ctx
    ), node)

Keep in mind that if the node you're operating on has child nodes you must either transform the child nodes yourself or call the generic_visit() method for the node first.

For nodes that were part of a collection of statements (that applies to all statement nodes), the visitor may also return a list of nodes rather than just a single node.

Usually you use the transformer like this:

    node = YourTransformer().visit(node)

ast.dump(node, annotate_fields=True, include_attributes=False)

Return a formatted dump of the tree in node. This is mainly useful for debugging purposes. The returned string will show the names and the values for fields. This makes the code impossible to evaluate, so if evaluation is wanted annotate_fields must be set to False. Attributes such as line numbers and column offsets are not dumped by default. If this is wanted, include_attributes can be set to True.

See also: Green Tree Snakes, an external documentation resource, has good details on working with Python ASTs.
32.3. symtable — Access to the compiler’s symbol tables

Source code: Lib/symtable.py

Symbol tables are generated by the compiler from AST just before bytecode is generated. The symbol table is responsible for calculating the scope of every identifier in the code. symtable provides an interface to examine these tables.
32.3.1. Generating Symbol Tables

```python
def symtable(code, filename, compile_type):
    Return the toplevel SymbolTable for the Python source code. filename is the name of the file containing the code. compile_type is like the mode argument to compile().
```
32.3.2. Examining Symbol Tables

class symtable.SymbolTable

A namespace table for a block. The constructor is not public.

get_type()

Return the type of the symbol table. Possible values are 'class', 'module', and 'function'.

get_id()

Return the table's identifier.

get_name()

Return the table's name. This is the name of the class if the table is for a class, the name of the function if the table is for a function, or 'top' if the table is global (get_type() returns 'module').

get_lineno()

Return the number of the first line in the block this table represents.

is_optimized()

Return True if the locals in this table can be optimized.

is_nested()

Return True if the block is a nested class or function.

has_children()

Return True if the block has nested namespaces within it. These can be obtained with get_children().
has_exec()
   Return True if the block uses exec.

get_identifiers()
   Return a list of names of symbols in this table.

lookup(name)
   Lookup name in the table and return a Symbol instance.

get_symbols()
   Return a list of Symbol instances for names in the table.

get_children()
   Return a list of the nested symbol tables.

class symtable.Function
   A namespace for a function or method. This class inherits SymbolTable.

get_parameters()
   Return a tuple containing names of parameters to this function.

get_locals()
   Return a tuple containing names of locals in this function.

getGlobals()
   Return a tuple containing names of globals in this function.

get_frees()
   Return a tuple containing names of free variables in this function.

class symtable.Class
A namespace of a class. This class inherits `SymbolTable`.

```python
get_methods()
```

Return a tuple containing the names of methods declared in the class.

```python
class symtable.Symbol
```

An entry in a `SymbolTable` corresponding to an identifier in the source. The constructor is not public.

```python
get_name()
```

Return the symbol's name.

```python
is_referenced()
```

Return `True` if the symbol is used in its block.

```python
is_imported()
```

Return `True` if the symbol is created from an import statement.

```python
is_parameter()
```

Return `True` if the symbol is a parameter.

```python
is_global()
```

Return `True` if the symbol is global.

```python
is_declared_global()
```

Return `True` if the symbol is declared global with a global statement.

```python
is_local()
```

Return `True` if the symbol is local to its block.

```python
is_free()
```
Return `True` if the symbol is referenced in its block, but not assigned to.

**is_assigned()**

Return `True` if the symbol is assigned to in its block.

**is_namespace()**

Return `True` if name binding introduces new namespace.

If the name is used as the target of a function or class statement, this will be true.

For example:

```python
>>> table = symtable.symtable("def some_func():
">>> table.lookup("some_func").is_namespace()
True
```

Note that a single name can be bound to multiple objects. If the result is `True`, the name may also be bound to other objects, like an int or list, that does not introduce a new namespace.

**get_namespaces()**

Return a list of namespaces bound to this name.

**get_namespace()**

Return the namespace bound to this name. If more than one namespace is bound, `ValueError` is raised.

Created using Sphinx 1.6.3.
32.4. symbol — Constants used with Python parse trees

Source code: Lib/symbol.py

This module provides constants which represent the numeric values of internal nodes of the parse tree. Unlike most Python constants, these use lower-case names. Refer to the file Grammar/Grammar in the Python distribution for the definitions of the names in the context of the language grammar. The specific numeric values which the names map to may change between Python versions.

This module also provides one additional data object:

symbol.sym_name

Dictionary mapping the numeric values of the constants defined in this module back to name strings, allowing more human-readable representation of parse trees to be generated.
32.5. **token** — Constants used with Python parse trees

**Source code:** Lib/token.py

This module provides constants which represent the numeric values of leaf nodes of the parse tree (terminal tokens). Refer to the file `Grammar/Grammar` in the Python distribution for the definitions of the names in the context of the language grammar. The specific numeric values which the names map to may change between Python versions.

The module also provides a mapping from numeric codes to names and some functions. The functions mirror definitions in the Python C header files.

**token.** `tok_name`  
Dictionary mapping the numeric values of the constants defined in this module back to name strings, allowing more human-readable representation of parse trees to be generated.

**token.** `ISTERMINAL(x)`  
Return true for terminal token values.

**token.** `ISNONTERMINAL(x)`  
Return true for non-terminal token values.

**token.** `ISEOF(x)`  
Return true if `x` is the marker indicating the end of input.
The token constants are:

token. **ENDMARKER**
token. **NAME**
token. **NUMBER**
token. **STRING**
token. **NEWLINE**
token. **INDENT**
token. **DEDENT**
token. **LPAR**
token. **RPAR**
token. **LSQB**
token. **RSQB**
token. **COLON**
token. **COMMA**
token. **SEMI**
token. **PLUS**
token. **MINUS**
token. **STAR**
token. **SLASH**
token. **VBAR**
token. **AMPER**
token. **LESS**
token. **GREATER**
token. **EQUAL**
token. **DOT**
token. **PERCENT**
token. **LBRACE**
token. **RBRACE**
token. **EQEQUAL**
token. **NOTEQUAL**
token. **LESSEQUAL**
token. **GREATEREQUAL**
 token.TILDE
 token.CIRCUMFLEX
 token.LEFTSHIFT
 token.RIGHTSHIFT
 token.DOUBLESTAR
 token.PLUSEQUAL
 token.MINEQUAL
 token.STAREQUAL
 token.SLASHEQUAL
 token.PERCENTEQUAL
 token.AMPEREQUAL
 token.VBAREQUAL
 token.CIRCUMFLEXEQUAL
 token.LEFTSHIFTEQUAL
 token.RIGHTSHIFTEQUAL
 token.DOUBLESTAREQUAL
 token.DOUBLESASHASH
 token.DOUBLESHEQUAL
 token.AT
 token.ATEQUAL
 token.RARROW
 token.ELLIPSIS
 token.OP
 token.AWAIT
 tokeniens
 token.ERRORTOKEN
 token.N_TOKENS
 token.NT_OFFSET

Changed in version 3.5: Added Await and Async tokens. Starting with Python 3.7, “async” and “await” will be tokenized as NAME tokens, and Await and Async will be removed.
32.6. **keyword** — Testing for Python keywords

**Source code:** Lib/keyword.py

This module allows a Python program to determine if a string is a keyword.

```python
keyword.iskeyword(s)
```

Return true if `s` is a Python keyword.

```python
keyword.kwlist
```

Sequence containing all the keywords defined for the interpreter. If any keywords are defined to only be active when particular `__future__` statements are in effect, these will be included as well.
32.7. **tokenize** — Tokenizer for Python source

**Source code:** Lib/tokenize.py

The `tokenize` module provides a lexical scanner for Python source code, implemented in Python. The scanner in this module returns comments as tokens as well, making it useful for implementing “pretty-printers,” including colorizers for on-screen displays.

To simplify token stream handling, all `operator` and `delimiter` tokens and `Ellipsis` are returned using the generic `OP` token type. The exact type can be determined by checking the `exact_type` property on the `named tuple` returned from `tokenize.tokenize()`.
32.7.1. Tokenizing Input

The primary entry point is a generator:

tokenize. **tokenize**(readline)

The **tokenize()** generator requires one argument, **readline**, which must be a callable object which provides the same interface as the `io.IOBase.readline()` method of file objects. Each call to the function should return one line of input as bytes.

The generator produces 5-tuples with these members: the token type; the token string; a 2-tuple `(srow, scol)` of ints specifying the row and column where the token begins in the source; a 2-tuple `(erow, ecol)` of ints specifying the row and column where the token ends in the source; and the line on which the token was found. The line passed (the last tuple item) is the *logical* line; continuation lines are included. The 5 tuple is returned as a named tuple with the field names: `type` `string` `start` `end` `line`.

The returned named tuple has an additional property named `exact_type` that contains the exact operator type for `token.OP` tokens. For all other token types `exact_type` equals the named tuple `type` field.

*Changed in version 3.1:* Added support for named tuples.

*Changed in version 3.3:* Added support for `exact_type`.

**tokenize()** determines the source encoding of the file by looking for a UTF-8 BOM or encoding cookie, according to PEP 263.

All constants from the `token` module are also exported from
**tokenize**, as are three additional token type values:

**tokenize. COMMENT**
Token value used to indicate a comment.

**tokenize. NL**
Token value used to indicate a non-terminating newline. The NEWLINE token indicates the end of a logical line of Python code; NL tokens are generated when a logical line of code is continued over multiple physical lines.

**tokenize. ENCODING**
Token value that indicates the encoding used to decode the source bytes into text. The first token returned by `tokenize()` will always be an ENCODING token.

Another function is provided to reverse the tokenization process. This is useful for creating tools that tokenize a script, modify the token stream, and write back the modified script.

**tokenize. untokenize(iterable)**
Converts tokens back into Python source code. The `iterable` must return sequences with at least two elements, the token type and the token string. Any additional sequence elements are ignored.

The reconstructed script is returned as a single string. The result is guaranteed to tokenize back to match the input so that the conversion is lossless and round-trips are assured. The guarantee applies only to the token type and token string as the spacing between tokens (column positions) may change.

It returns bytes, encoded using the ENCODING token, which is the first token sequence output by `tokenize()`.
`tokenize()` needs to detect the encoding of source files it tokenizes. The function it uses to do this is available:

```python
tokenize.detect_encoding(readline)
```

The `detect_encoding()` function is used to detect the encoding that should be used to decode a Python source file. It requires one argument, `readline`, in the same way as the `tokenize()` generator.

It will call `readline` a maximum of twice, and return the encoding used (as a string) and a list of any lines (not decoded from bytes) it has read in.

It detects the encoding from the presence of a UTF-8 BOM or an encoding cookie as specified in PEP 263. If both a BOM and a cookie are present, but disagree, a SyntaxError will be raised. Note that if the BOM is found, 'utf-8-sig' will be returned as an encoding.

If no encoding is specified, then the default of 'utf-8' will be returned.

Use `open()` to open Python source files: it uses `detect_encoding()` to detect the file encoding.

```python
tokenize.open(filename)
```

Open a file in read only mode using the encoding detected by `detect_encoding()`.

*New in version 3.2.*

**exception** `tokenize.TokenError`

Raised when either a docstring or expression that may be split over
several lines is not completed anywhere in the file, for example:
"""Beginning of
docstring
or:
[1,
2,
3
Note that unclosed single-quoted strings do not cause an error to be
raised. They are tokenized as ERRORTOKEN, followed by the
tokenization of their contents.


32.7.2. Command-Line Usage

*New in version 3.3.*

The `tokenize` module can be executed as a script from the command line. It is as simple as:

```
python -m tokenize [-e] [filename.py]
```

The following options are accepted:

- `-h, --help`
  
  show this help message and exit

- `-e, --exact`
  
  display token names using the exact type

If `filename.py` is specified its contents are tokenized to stdout. Otherwise, tokenization is performed on stdin.
32.7.3. Examples

Example of a script rewriter that transforms float literals into Decimal objects:

```python
from tokenize import tokenize, untokenize, NUMBER, STRING
from io import BytesIO

def decistmt(s):
    """Substitute Decimals for floats in a string of statements."

    >>> from decimal import Decimal
    >>> s = 'print(+21.3e-5*-1.234/81.7)'
    >>> decistmt(s)
    "print (+Decimal ("21.3e-5")*-Decimal ("1.234")/Decimal ("81.7"))"

    The format of the exponent is inherited from the platform C library.
    Known cases are "e-007" (Windows) and "e-07" (not Windows).
    Since we're only showing 12 digits, and the 13th isn't close to 5,
    the rest of the output should be platform-independent.

    >>> exec(s)  # doctest: +ELLIPSIS
    -3.21716034272e-0...7

    Output from calculations with Decimal should be identical across all platforms.

    >>> exec(decistmt(s))
    -3.217160342717258261933904529E-7

    """

    result = []
g = tokenize(BytesIO(s.encode('utf-8')).readline)
    for toknum, tokval, _, _, _ in g:
        if toknum == NUMBER and '.' in tokval:  # replace NUMBER tokens
            result.extend([}
```
Example of tokenizing from the command line. The script:

```python
def say_hello():
    print("Hello, World!")
say_hello()
```

will be tokenized to the following output where the first column is the range of the line/column coordinates where the token is found, the second column is the name of the token, and the final column is the value of the token (if any)

```
$ python -m tokenize hello.py
0,0-0,0: ENCODING 'utf-8'
1,0-1,3: NAME 'def'
1,4-1,13: NAME 'say_hello'
1,13-1,14: OP '('
1,14-1,15: OP ')
1,15-1,16: OP ':'
1,16-1,17: NEWLINE '\n'
2,0-2,4: INDENT '  '
2,4-2,9: NAME 'print'
2,9-2,10: OP '('
2,10-2,25: STRING '"Hello, World!"'
2,25-2,26: OP ')
2,26-2,27: NEWLINE '\n'
```
The exact token type names can be displayed using the `-e` option:

```
$ python -m tokenize -e hello.py
0,0-0,0:    ENCODING       'utf-8'
1,0-1,3:    NAME           'def'
1,4-1,13:   NAME           'say_hello'
1,13-1,14:  LPAR           '('
1,14-1,15:  RPAR           ')'
1,15-1,16:  COLON          ':'
1,16-1,17:  NEWLINE        '

2,0-2,4:    INDENT         '
2,4-2,9:    NAME           'print'
2,9-2,10:   LPAR           '('
2,10-2,25:  STRING         '"Hello, World!"
2,25-2,26:  RPAR           ')
2,26-2,27:  NEWLINE        '

3,0-3,1:    NL              '
4,0-4,0:    DEDENT         '
4,0-4,9:    NAME           'say_hello'
4,9-4,10:   LPAR           '('
4,10-4,11:  RPAR           ')'
4,11-4,12:  NEWLINE        '

5,0-5,0:    ENDmarker       '
```
32.8. tabnanny — Detection of ambiguous indentation

Source code: Lib/tabnanny.py

For the time being this module is intended to be called as a script. However it is possible to import it into an IDE and use the function `check()` described below.

**Note:** The API provided by this module is likely to change in future releases; such changes may not be backward compatible.

```python
tabnanny.check(file_or_dir)
```

If `file_or_dir` is a directory and not a symbolic link, then recursively descend the directory tree named by `file_or_dir`, checking all `.py` files along the way. If `file_or_dir` is an ordinary Python source file, it is checked for whitespace related problems. The diagnostic messages are written to standard output using the `print()` function.

```python
tabnanny.verbose
```

Flag indicating whether to print verbose messages. This is incremented by the `-v` option if called as a script.

```python
tabnanny.filename_only
```

Flag indicating whether to print only the filenames of files containing whitespace related problems. This is set to true by the `-q` option if called as a script.
exception tabnanny. NannyNag

Raised by process_tokens() if detecting an ambiguous indent. Captured and handled in check().

tabnanny. process_tokens(tokens)

This function is used by check() to process tokens generated by the tokenize module.

See also:

Module tokenize
Lexical scanner for Python source code.
32.9. `pyclbr` — Python class browser support

Source code: Lib/pyclbr.py

The `pyclbr` module can be used to determine some limited information about the classes, methods and top-level functions defined in a module. The information provided is sufficient to implement a traditional three-pane class browser. The information is extracted from the source code rather than by importing the module, so this module is safe to use with untrusted code. This restriction makes it impossible to use this module with modules not implemented in Python, including all standard and optional extension modules.

`pyclbr.readmodule(module, path=None)`

Read a module and return a dictionary mapping class names to class descriptor objects. The parameter `module` should be the name of a module as a string; it may be the name of a module within a package. The `path` parameter should be a sequence, and is used to augment the value of `sys.path`, which is used to locate module source code.

`pyclbr.readmodule_ex(module, path=None)`

Like `readmodule()`, but the returned dictionary, in addition to mapping class names to class descriptor objects, also maps top-level function names to function descriptor objects. Moreover, if the module being read is a package, the key '__path__' in the returned dictionary has as its value a list which contains the package search path.
32.9.1. Class Objects

The Class objects used as values in the dictionary returned by `readmodule()` and `readmodule_ex()` provide the following data attributes:

Class. **module**
- The name of the module defining the class described by the class descriptor.

Class. **name**
- The name of the class.

Class. **super**
- A list of Class objects which describe the immediate base classes of the class being described. Classes which are named as superclasses but which are not discoverable by `readmodule()` are listed as a string with the class name instead of as Class objects.

Class. **methods**
- A dictionary mapping method names to line numbers.

Class. **file**
- Name of the file containing the class statement defining the class.

Class. **lineno**
- The line number of the class statement within the file named by file.
32.9.2. Function Objects

The Function objects used as values in the dictionary returned by readmodule_ex() provide the following attributes:

Function. **module**

The name of the module defining the function described by the function descriptor.

Function. **name**

The name of the function.

Function. **file**

Name of the file containing the def statement defining the function.

Function. **lineno**

The line number of the def statement within the file named by file.
32.10. `py_compile` — Compile Python source files

**Source code:** Lib/py_compile.py

The `py_compile` module provides a function to generate a byte-code file from a source file, and another function used when the module source file is invoked as a script.

Though not often needed, this function can be useful when installing modules for shared use, especially if some of the users may not have permission to write the byte-code cache files in the directory containing the source code.

*exception* `py_compile.PyCompileError`

Exception raised when an error occurs while attempting to compile the file.

`py_compile.compile(file, cfile=None, dfile=None, dorigaise=False, optimize=-1)`

Compile a source file to byte-code and write out the byte-code cache file. The source code is loaded from the file named `file`. The byte-code is written to `cfile`, which defaults to the PEP 3147/PEP 488 path, ending in `.pyc`. For example, if `file` is `/foo/bar/baz.py` `cfile` will default to `/foo/bar/__pycache__/baz.cpython-32.pyc` for Python 3.2. If `dfile` is specified, it is used as the name of the source file in error messages when instead of `file`. If `doraise` is true, a `PyCompileError` is raised when an error is encountered while
compiling file. If `doraise` is false (the default), an error string is written to `sys.stderr`, but no exception is raised. This function returns the path to byte-compiled file, i.e. whatever `cfile` value was used.

If the path that `cfile` becomes (either explicitly specified or computed) is a symlink or non-regular file, `FileExistsError` will be raised. This is to act as a warning that import will turn those paths into regular files if it is allowed to write byte-compiled files to those paths. This is a side-effect of import using file renaming to place the final byte-compiled file into place to prevent concurrent file writing issues.

`optimize` controls the optimization level and is passed to the built-in `compile()` function. The default of `-1` selects the optimization level of the current interpreter.

*Changed in version 3.2:* Changed default value of `cfile` to be PEP 3147-compliant. Previous default was `file + 'c'` (`'o'` if optimization was enabled). Also added the `optimize` parameter.

*Changed in version 3.4:* Changed code to use `importlib` for the byte-code cache file writing. This means file creation/writing semantics now match what `importlib` does, e.g. permissions, write-and-move semantics, etc. Also added the caveat that `FileExistsError` is raised if `cfile` is a symlink or non-regular file.

`py_compile.main(args=None)`

Compile several source files. The files named in `args` (or on the command line, if `args` is `None`) are compiled and the resulting byte-code is cached in the normal manner. This function does not search a directory structure to locate source files; it only compiles
files named explicitly. If `-` is the only parameter in args, the list of files is taken from standard input.

*Changed in version 3.2:* Added support for `-`.

When this module is run as a script, the `main()` is used to compile all the files named on the command line. The exit status is nonzero if one of the files could not be compiled.

**See also:**

**Module `compileall`**

Utilities to compile all Python source files in a directory tree.
32.11. **compileall** — Byte-compile Python libraries

**Source code:** Lib/compileall.py

This module provides some utility functions to support installing Python libraries. These functions compile Python source files in a directory tree. This module can be used to create the cached bytecode files at library installation time, which makes them available for use even by users who don't have write permission to the library directories.
32.11.1. Command-line use

This module can work as a script (using `python -m compileall`) to compile Python sources.

**directory ...**

**file ...**

Positional arguments are files to compile or directories that contain source files, traversed recursively. If no argument is given, behave as if the command line was `-l <directories from sys.path>`.

**-l**

Do not recurse into subdirectories, only compile source code files directly contained in the named or implied directories.

**-f**

Force rebuild even if timestamps are up-to-date.

**-q**

Do not print the list of files compiled. If passed once, error messages will still be printed. If passed twice (`-qq`), all output is suppressed.

**-d destdir**

Directory prepended to the path to each file being compiled. This will appear in compilation time tracebacks, and is also compiled in to the byte-code file, where it will be used in tracebacks and other messages in cases where the source file does not exist at the time the byte-code file is executed.

**-x regex**
regex is used to search the full path to each file considered for compilation, and if the regex produces a match, the file is skipped.

- **i** list
  Read the file list and add each line that it contains to the list of files and directories to compile. If list is -, read lines from stdin.

- **b**
  Write the byte-code files to their legacy locations and names, which may overwrite byte-code files created by another version of Python. The default is to write files to their PEP 3147 locations and names, which allows byte-code files from multiple versions of Python to coexist.

- **r**
  Control the maximum recursion level for subdirectories. If this is given, then -1 option will not be taken into account. `python -m compileall <directory> -r 0` is equivalent to `python -m compileall <directory> -1`.

- **j** N
  Use N workers to compile the files within the given directory. If 0 is used, then the result of `os.cpu_count()` will be used.

*Changed in version 3.2:* Added the -i, -b and -h options.

*Changed in version 3.5:* Added the -j, -r, and -qq options. -q option was changed to a multilevel value. -b will always produce a byte-code file ending in .pyc, never .pyo.

There is no command-line option to control the optimization level used by the `compile()` function, because the Python interpreter itself
already provides the option: `python -O -m compileall`. 
32.11.2. Public functions

compileall.compile_dir(dir, maxlevels=10, ddir=None, force=False, rx=None, quiet=0, legacy=False, optimize=-1, workers=1)

Recursively descend the directory tree named by dir, compiling all .py files along the way. Return a true value if all the files compiled successfully, and a false value otherwise.

The maxlevels parameter is used to limit the depth of the recursion; it defaults to 10.

If ddir is given, it is prepended to the path to each file being compiled for use in compilation time tracebacks, and is also compiled in to the byte-code file, where it will be used in tracebacks and other messages in cases where the source file does not exist at the time the byte-code file is executed.

If force is true, modules are re-compiled even if the timestamps are up to date.

If rx is given, its search method is called on the complete path to each file considered for compilation, and if it returns a true value, the file is skipped.

If quiet is False or 0 (the default), the filenames and other information are printed to standard out. Set to 1, only errors are printed. Set to 2, all output is suppressed.

If legacy is true, byte-code files are written to their legacy locations and names, which may overwrite byte-code files created by another version of Python. The default is to write files to their PEP 3147 locations and names, which allows byte-code files from
multiple versions of Python to coexist.

`optimize` specifies the optimization level for the compiler. It is passed to the built-in `compile()` function.

The argument `workers` specifies how many workers are used to compile files in parallel. The default is to not use multiple workers. If the platform can’t use multiple workers and `workers` argument is given, then sequential compilation will be used as a fallback. If `workers` is lower than 0, a `ValueError` will be raised.

*Changed in version 3.2:* Added the `legacy` and `optimize` parameter.

*Changed in version 3.5:* Added the `workers` parameter.

*Changed in version 3.5:* `quiet` parameter was changed to a multilevel value.

*Changed in version 3.5:* The `legacy` parameter only writes out `.pyc` files, not `.pyo` files no matter what the value of `optimize` is.

*Changed in version 3.6:* Accepts a path-like object.

```python
import compileall

calculate.compile_file(fullname, ddir=None, force=False, rx=None, quiet=0, legacy=False, optimize=-1)
```

Compile the file with path `fullname`. Return a true value if the file compiled successfully, and a false value otherwise.

If `ddir` is given, it is prepended to the path to the file being compiled for use in compilation time tracebacks, and is also compiled in to the byte-code file, where it will be used in tracebacks and other messages in cases where the source file does not exist at the time the byte-code file is executed.
If $rx$ is given, its search method is passed the full path name to the file being compiled, and if it returns a true value, the file is not compiled and `True` is returned.

If `quiet` is `False` or 0 (the default), the filenames and other information are printed to standard out. Set to 1, only errors are printed. Set to 2, all output is suppressed.

If `legacy` is true, byte-code files are written to their legacy locations and names, which may overwrite byte-code files created by another version of Python. The default is to write files to their PEP 3147 locations and names, which allows byte-code files from multiple versions of Python to coexist.

`optimize` specifies the optimization level for the compiler. It is passed to the built-in `compile()` function.

`New in version 3.2.`

`Changed in version 3.5: quiet parameter was changed to a multilevel value.`

`Changed in version 3.5: The legacy parameter only writes out .pyc files, not .pyo files no matter what the value of optimize is.`

```
compileall.compile_path(skip_curdir=True, maxlevels=0, force=False, quiet=0, legacy=False, optimize=-1)
```

Byte-compile all the `.py` files found along `sys.path`. Return a true value if all the files compiled successfully, and a false value otherwise.

If `skip_curdir` is true (the default), the current directory is not included in the search. All other parameters are passed to the
**compile_dir()** function. Note that unlike the other compile functions, **maxlevels** defaults to 0.

*Changed in version 3.2:* Added the **legacy** and **optimize** parameter.

*Changed in version 3.5:* **quiet** parameter was changed to a multilevel value.

*Changed in version 3.5:* The **legacy** parameter only writes out .pyc files, not .pyo files no matter what the value of **optimize** is.

To force a recompile of all the .py files in the Lib/ subdirectory and all its subdirectories:

```python
import compileall
compileall.compile_dir('Lib/', force=True)
```

# Perform same compilation, excluding files in .svn
import re
compileall.compile_dir('Lib/', rx=re.compile(r'/\[./\]'))

# pathlib.Path objects can also be used.
import pathlib
compileall.compile_dir(pathlib.Path('Lib/'), force=True)

**See also:**

**Module py_compile**

Byte-compile a single source file.
32.12. `dis` — Disassembler for Python bytecode

Source code: Lib/dis.py

The `dis` module supports the analysis of CPython `bytecode` by disassembling it. The CPython bytecode which this module takes as an input is defined in the file `Include/opcode.h` and used by the compiler and the interpreter.

**CPython implementation detail:** Bytecode is an implementation detail of the CPython interpreter. No guarantees are made that bytecode will not be added, removed, or changed between versions of Python. Use of this module should not be considered to work across Python VMs or Python releases.

*Changed in version 3.6:* Use 2 bytes for each instruction. Previously the number of bytes varied by instruction.

Example: Given the function `myfunc()`:

```python
def myfunc(alist):
    return len(alist)
```

the following command can be used to display the disassembly of `myfunc()`:

```python
>>> dis.dis(myfunc)
   2           0 LOAD_GLOBAL           0 (len)
   2           2 LOAD_FAST            0 (alist)
   4           4 CALL_FUNCTION        1
```
(The “2” is a line number).
32.12.1. Bytecode analysis

New in version 3.4.

The bytecode analysis API allows pieces of Python code to be wrapped in a Bytecode object that provides easy access to details of the compiled code.

```python
class dis.Bytecode(x, *, first_line=None, current_offset=None)
```

Analyse the bytecode corresponding to a function, generator, method, string of source code, or a code object (as returned by compile()).

This is a convenience wrapper around many of the functions listed below, most notably get_instructions(), as iterating over a Bytecode instance yields the bytecode operations as Instruction instances.

If `first_line` is not None, it indicates the line number that should be reported for the first source line in the disassembled code. Otherwise, the source line information (if any) is taken directly from the disassembled code object.

If `current_offset` is not None, it refers to an instruction offset in the disassembled code. Setting this means `dis()` will display a “current instruction” marker against the specified opcode.

```python
classmethod from_traceback(tb)
```

Construct a Bytecode instance from the given traceback, setting `current_offset` to the instruction responsible for the exception.
**codeobj**
The compiled code object.

**first_line**
The first source line of the code object (if available)

**dis()**
Return a formatted view of the bytecode operations (the same as printed by `dis.dis()`, but returned as a multi-line string).

**info()**
Return a formatted multi-line string with detailed information about the code object, like `code_info()`.

Example:

```python
>>> bytecode = dis.Bytecode(myfunc)
>>> for instr in bytecode:
...    print(instr.opname)
...
LOAD_GLOBAL
LOAD_FAST
CALL_FUNCTION
RETURN_VALUE
```
32.12.2. Analysis functions

The dis module also defines the following analysis functions that convert the input directly to the desired output. They can be useful if only a single operation is being performed, so the intermediate analysis object isn’t useful:

```
    dis.code_info(x)
```

Return a formatted multi-line string with detailed code object information for the supplied function, generator, method, source code string or code object.

Note that the exact contents of code info strings are highly implementation dependent and they may change arbitrarily across Python VMs or Python releases.

*New in version 3.2.*

```
    dis.show_code(x, *, file=None)
```

Print detailed code object information for the supplied function, method, source code string or code object to file (or sys.stdout if file is not specified).

This is a convenient shorthand for `print(code_info(x), file=file)`, intended for interactive exploration at the interpreter prompt.

*New in version 3.2. *

*Changed in version 3.4:* Added file parameter.

```
    dis.dis(x=None, *, file=None)
```
Disassemble the x object. x can denote either a module, a class, a method, a function, a generator, a code object, a string of source code or a byte sequence of raw bytecode. For a module, it disassembles all functions. For a class, it disassembles all methods (including class and static methods). For a code object or sequence of raw bytecode, it prints one line per bytecode instruction. Strings are first compiled to code objects with the compile() built-in function before being disassembled. If no object is provided, this function disassembles the last traceback.

The disassembly is written as text to the supplied file argument if provided and to sys.stdout otherwise.

*Changed in version 3.4: Added file parameter.*

```python
dis.distb(tb=None, *, file=None)
```

Disassemble the top-of-stack function of a traceback, using the last traceback if none was passed. The instruction causing the exception is indicated.

The disassembly is written as text to the supplied file argument if provided and to sys.stdout otherwise.

*Changed in version 3.4: Added file parameter.*

```python
dis.disassemble(code, lasti=-1, *, file=None)
n
dis.disco(code, lasti=-1, *, file=None)
```

Disassemble a code object, indicating the last instruction if lasti was provided. The output is divided in the following columns:

1. the line number, for the first instruction of each line
2. the current instruction, indicated as -->
3. a labelled instruction, indicated with >>,
4. the address of the instruction,
5. the operation code name,
6. operation parameters, and
7. interpretation of the parameters in parentheses.
The parameter interpretation recognizes local and global variable
names, constant values, branch targets, and compare operators.

The disassembly is written as text to the supplied file argument if
provided and to sys.stdout otherwise.

*Changed in version 3.4: Added file parameter.*

**dis.get_instructions(x, *, first_line=None)**

Return an iterator over the instructions in the supplied function,
method, source code string or code object.

The iterator generates a series of Instruction named tuples
giving the details of each operation in the supplied code.

If first_line is not None, it indicates the line number that should be
reported for the first source line in the disassembled code. Otherwise,
the source line information (if any) is taken directly from
the disassembled code object.

*New in version 3.4.*

**dis.findlinestarts(code)**

This generator function uses the co_firstlineno and
co_lnotab attributes of the code object code to find the offsets
which are starts of lines in the source code. They are generated as
(offset, lineno) pairs. See Objects/Lnotab_notes.txt for the
colnotab format and how to decode it.
Changed in version 3.6: Line numbers can be decreasing. Before, they were always increasing.

`dis.findlabels(code)`
Detect all offsets in the code object `code` which are jump targets, and return a list of these offsets.

`dis.stack_effect(opcode[, oparg])`
Compute the stack effect of `opcode` with argument `oparg`.

*New in version 3.4.*
32.12.3. Python Bytecode Instructions

The `get_instructions()` function and `Bytecode` class provide details of bytecode instructions as `Instruction` instances:

```python
class dis.Instruction
    Details for a bytecode operation
    
    opcode
        numeric code for operation, corresponding to the opcode values
        listed below and the bytecode values in the Opcode collections.
    
    opname
        human readable name for operation
    
    arg
        numeric argument to operation (if any), otherwise None
    
    argval
        resolved arg value (if known), otherwise same as arg
    
    argrepr
        human readable description of operation argument
    
    offset
        start index of operation within bytecode sequence
    
    starts_line
        line started by this opcode (if any), otherwise None
    
    is_jump_target
        True if other code jumps to here, otherwise False
```
New in version 3.4.

The Python compiler currently generates the following bytecode instructions.

General instructions

**NOP**
Do nothing code. Used as a placeholder by the bytecode optimizer.

**POP_TOP**
Removes the top-of-stack (TOS) item.

**ROT_TWO**
Swaps the two top-most stack items.

**ROT_THREE**
Lifts second and third stack item one position up, moves top down to position three.

**DUP_TOP**
Duplicates the reference on top of the stack.

**DUP_TOP_TWO**
Duplicates the two references on top of the stack, leaving them in the same order.

Unary operations

Unary operations take the top of the stack, apply the operation, and push the result back on the stack.

**UNARY_POSITIVE**
Implements TOS = +TOS.
**UNARY_NEGATIVE**

Implements $\text{TOS} = -\text{TOS}$.

**UNARY_NOT**

Implements $\text{TOS} = \text{not} \ \text{TOS}$.

**UNARY_INVERT**

Implements $\text{TOS} = \sim\text{TOS}$.

**GET_ITER**

Implements $\text{TOS} = \text{iter(}\text{TOS}\text{)}$.

**GET_YIELD_FROM_ITER**

If $\text{TOS}$ is a generator iterator or coroutine object it is left as is. Otherwise, implements $\text{TOS} = \text{iter(}\text{TOS}\text{)}$.

*New in version 3.5.*

**Binary operations**

Binary operations remove the top of the stack (TOS) and the second top-most stack item (TOS1) from the stack. They perform the operation, and put the result back on the stack.

**BINARY_POWER**

Implements $\text{TOS} = \text{TOS1} \ ** \ \text{TOS}$.

**BINARY_MULTIPLY**

Implements $\text{TOS} = \text{TOS1} \ * \ \text{TOS}$.

**BINARY_MATRIX_MULTIPLY**

Implements $\text{TOS} = \text{TOS1} \ @ \ \text{TOS}$.

*New in version 3.5.*
**BINARY_FLOOR_DIVIDE**

Implements \( \text{TOS} = \text{TOS1} \div \text{TOS} \).

**BINARY_TRUE_DIVIDE**

Implements \( \text{TOS} = \text{TOS1} \div \text{TOS} \).

**BINARY_MODULO**

Implements \( \text{TOS} = \text{TOS1} \mod \text{TOS} \).

**BINARY_ADD**

Implements \( \text{TOS} = \text{TOS1} + \text{TOS} \).

**BINARY_SUBTRACT**

Implements \( \text{TOS} = \text{TOS1} - \text{TOS} \).

**BINARY_SUBSCR**

Implements \( \text{TOS} = \text{TOS1}[\text{TOS}] \).

**BINARY_LSHIFT**

Implements \( \text{TOS} = \text{TOS1} \ll \text{TOS} \).

**BINARY_RSHIFT**

Implements \( \text{TOS} = \text{TOS1} \gg \text{TOS} \).

**BINARY_AND**

Implements \( \text{TOS} = \text{TOS1} \& \text{TOS} \).

**BINARY_XOR**

Implements \( \text{TOS} = \text{TOS1} \oplus \text{TOS} \).

**BINARY_OR**

Implements \( \text{TOS} = \text{TOS1} \lor \text{TOS} \).
In-place operations

In-place operations are like binary operations, in that they remove TOS and TOS1, and push the result back on the stack, but the operation is done in-place when TOS1 supports it, and the resulting TOS may be (but does not have to be) the original TOS1.

**INPLACE_POWER**
Implements in-place \( TOS = TOS1 \times TOS \).

**INPLACE_MULTIPLY**
Implements in-place \( TOS = TOS1 \times TOS \).

**INPLACE_MATRIX_MULTIPLY**
Implements in-place \( TOS = TOS1 @ TOS \).

*New in version 3.5.*

**INPLACE_FLOOR_DIVIDE**
Implements in-place \( TOS = TOS1 // TOS \).

**INPLACE_TRUE_DIVIDE**
Implements in-place \( TOS = TOS1 / TOS \).

**INPLACE_MODULO**
Implements in-place \( TOS = TOS1 \% TOS \).

**INPLACE_ADD**
Implements in-place \( TOS = TOS1 + TOS \).

**INPLACE_SUBTRACT**
Implements in-place \( TOS = TOS1 - TOS \).

**INPLACE_LSHIFT**
Implements in-place $TOS = TOS1 \ll TOS$.

**INPLACE_RSHIFT**
Implements in-place $TOS = TOS1 \gg TOS$.

**INPLACE_AND**
Implements in-place $TOS = TOS1 & TOS$.

**INPLACE_XOR**
Implements in-place $TOS = TOS1 \^ TOS$.

**INPLACE_OR**
Implements in-place $TOS = TOS1 | TOS$.

**STORE_SUBSCR**
Implements $TOS1[TOS] = TOS2$.

**DELETE_SUBSCR**
Implements `del TOS1[TOS]`.

**Coroutine opcodes**

**GET_AWAITABLE**
Implements $TOS = \text{get\_awaitable}(TOS)$, where $\text{get\_awaitable}(o)$ returns $o$ if $o$ is a coroutine object or a generator object with the CO_ITERABLE_COROUTINE flag, or resolves $o.__await__$.

**GET_AITER**
Implements $TOS = \text{get\_awaitable}(TOS.__aiter__())$. See **GET_AWAITABLE** for details about get\_awaitable

**GET_ANEXT**
Implements `PUSH(get_awaitable(TOS.__anext__()))`. See `GET_AWAITABLE` for details about `get_awaitable`.

**BEFORE_ASYNC_WITH**

Resolves `__aenter__` and `__aexit__` from the object on top of the stack. Pushes `__aexit__` and result of `__aenter__()` to the stack.

**SETUP_ASYNC_WITH**

Creates a new frame object.

**Miscellaneous opcodes**

**PRINT_EXPR**

Implements the expression statement for the interactive mode. TOS is removed from the stack and printed. In non-interactive mode, an expression statement is terminated with `POP_TOP`.

**BREAK_LOOP**

Terminates a loop due to a `break` statement.

**CONTINUE_LOOP** *(target)*

Continues a loop due to a `continue` statement. `target` is the address to jump to (which should be a `FOR_ITER` instruction).

**SET_ADD** *(i)*

Calls `set.add(TOS1[-i], TOS)`. Used to implement set comprehensions.

**LIST_APPEND** *(i)*

Calls `list.append(TOS[-i], TOS)`. Used to implement list comprehensions.
MAP_ADD(i)
Calls \texttt{dict.setitem(TOS1[-i], TOS, TOS1)}. Used to implement dict comprehensions.

For all of the \texttt{SET_ADD}, \texttt{LIST_APPEND} and \texttt{MAP_ADD} instructions, while the added value or key/value pair is popped off, the container object remains on the stack so that it is available for further iterations of the loop.

RETURN_VALUE
Returns with TOS to the caller of the function.

YIELD_VALUE
Pops TOS and yields it from a generator.

YIELD_FROM
Pops TOS and delegates to it as a subiterator from a generator.

\textit{New in version 3.3.}

SETUP_ANNOTATIONS
Checks whether \texttt{__annotations__} is defined in \texttt{locals()}, if not it is set up to an empty \texttt{dict}. This opcode is only emitted if a class or module body contains variable annotations statically.

\textit{New in version 3.6.}

IMPORT_STAR
Loads all symbols not starting with '_', directly from the module TOS to the local namespace. The module is popped after loading all names. This opcode implements \texttt{from module import *}.

POP_BLOCK
Removes one block from the block stack. Per frame, there is a stack of blocks, denoting nested loops, try statements, and such.

**POP_EXCEPT**
Removes one block from the block stack. The popped block must be an exception handler block, as implicitly created when entering an except handler. In addition to popping extraneous values from the frame stack, the last three popped values are used to restore the exception state.

**END_FINALLY**
Terminates a `finally` clause. The interpreter recalls whether the exception has to be re-raised, or whether the function returns, and continues with the outer-next block.

**LOAD_BUILD_CLASS**
Pushes `builtins.__build_class__()` onto the stack. It is later called by `CALL_FUNCTION` to construct a class.

**SETUP_WITH**(delta)
This opcode performs several operations before a with block starts. First, it loads `__exit__()` from the context manager and pushes it onto the stack for later use by `WITH_CLEANUP`. Then, `__enter__()` is called, and a finally block pointing to `delta` is pushed. Finally, the result of calling the enter method is pushed onto the stack. The next opcode will either ignore it (`POP_TOP`), or store it in (a) variable(s) (`STORE_FAST`, `STORE_NAME`, or `UNPACK_SEQUENCE`).

**WITH_CLEANUP_START**
Cleans up the stack when a `with` statement block exits. TOS is the context manager’s `__exit__()` bound method. Below TOS
are 1–3 values indicating how/why the finally clause was entered:

- SECOND = None
- (SECOND, THIRD) = (WHY_{RETURN, CONTINUE}), retval
- SECOND = WHY_*; no retval below it
- (SECOND, THIRD, FOURTH) = exc_info()

In the last case, TOS(SECOND, THIRD, FOURTH) is called, otherwise TOS(None, None, None). Pushes SECOND and result of the call to the stack.

**WITH_CLEANUP_FINISH**

Pops exception type and result of ‘exit’ function call from the stack.

If the stack represents an exception, and the function call returns a ‘true’ value, this information is “zapped” and replaced with a single WHY_SILENCED to prevent END_FINALLY from re-raising the exception. (But non-local gotos will still be resumed.)

All of the following opcodes use their arguments.

**STORE_NAME(namei)**

Implements name = TOS. namei is the index of name in the attribute co_names of the code object. The compiler tries to use STORE_FAST or STORE_GLOBAL if possible.

**DELETE_NAME(namei)**

Implements del name, where namei is the index into co_names attribute of the code object.

**UNPACK_SEQUENCE(count)**

Unpacks TOS into count individual values, which are put onto the stack right-to-left.
**UNPACK_EX**(counts)

Implements assignment with a starred target: Unpacks an iterable in TOS into individual values, where the total number of values can be smaller than the number of items in the iterable: one of the new values will be a list of all leftover items.

The low byte of counts is the number of values before the list value, the high byte of counts the number of values after it. The resulting values are put onto the stack right-to-left.

**STORE_ATTR**(namei)

Implements TOS.name = TOS1, where namei is the index of name in co_names.

**DELETE_ATTR**(namei)

Implements del TOS.name, using namei as index into co_names.

**STORE_GLOBAL**(namei)

Works as STORE_NAME, but stores the name as a global.

**DELETE_GLOBAL**(namei)

Works as DELETE_NAME, but deletes a global name.

**LOAD_CONST**(consti)

Pushes co_consts[consti] onto the stack.

**LOAD_NAME**(namei)

Pushes the value associated with co_names[namei] onto the stack.

**BUILD_TUPLE**(count)
Creates a tuple consuming *count* items from the stack, and pushes 
the resulting tuple onto the stack.

**BUILD_LIST**(count)
Works as **BUILD_TUPLE**, but creates a list.

**BUILD_SET**(count)
Works as **BUILD_TUPLE**, but creates a set.

**BUILD_MAP**(count)
Pushes a new dictionary object onto the stack. Pops 2 * count 
items so that the dictionary holds *count* entries: 
\{\ldots, T0S3: T0S2, T0S1: T0S\}.

*Changed in version 3.5:* The dictionary is created from stack items 
instead of creating an empty dictionary pre-sized to hold *count* 
items.

**BUILD_CONST_KEY_MAP**(count)
The version of **BUILD_MAP** specialized for constant keys. *count* 
values are consumed from the stack. The top element on the stack 
contains a tuple of keys.

*New in version 3.6.*

**BUILD_STRING**(count)
Concatenates *count* strings from the stack and pushes the 
resulting string onto the stack.

*New in version 3.6.*

**BUILD_TUPLE_UNPACK**(count)
Pops *count* iterables from the stack, joins them in a single tuple,
and pushes the result. Implements iterable unpacking in tuple displays \((*x, *y, *z)\).

*New in version 3.5.*

**BUILD_TUPLE_UNPACK** (count)
This is similar to **BUILD_TUPLE_UNPACK**, but is used for \(f(*x, *y, *z)\) call syntax. The stack item at position \(\text{count} + 1\) should be the corresponding callable \(f\).

*New in version 3.6.*

**BUILD_LIST_UNPACK** (count)
This is similar to **BUILD_TUPLE_UNPACK**, but pushes a list instead of tuple. Implements iterable unpacking in list displays \([*x, *y, *z]\).

*New in version 3.5.*

**BUILD_SET_UNPACK** (count)
This is similar to **BUILD_TUPLE_UNPACK**, but pushes a set instead of tuple. Implements iterable unpacking in set displays \(\{*x, *y, *z\}\).

*New in version 3.5.*

**BUILD_MAP_UNPACK** (count)
Pops \(\text{count}\) mappings from the stack, merges them into a single dictionary, and pushes the result. Implements dictionary unpacking in dictionary displays \(\{**x, **y, **z\}\).

*New in version 3.5.*
**BUILD_MAP_UNPACK_WITH_CALL**(count)

This is similar to **BUILD_MAP_UNPACK**, but is used for \( f(**x, **y, **z) \) call syntax. The stack item at position \( \text{count} + 2 \) should be the corresponding callable \( f \).

*New in version 3.5.*

*Changed in version 3.6:* The position of the callable is determined by adding 2 to the opcode argument instead of encoding it in the second byte of the argument.

**LOAD_ATTR**(namei)

Replaces TOS with `getattr(TOS, co_names[namei])`.

**COMPARE_OP**(opname)

Performs a Boolean operation. The operation name can be found in `cmp_op[opname]`.

**IMPORT_NAME**(namei)

Imports the module `co_names[namei]`. TOS and TOS1 are popped and provide the `fromlist` and `level` arguments of `__import__()`. The module object is pushed onto the stack. The current namespace is not affected: for a proper import statement, a subsequent `STORE_FAST` instruction modifies the namespace.

**IMPORT_FROM**(namei)

Loads the attribute `co_names[namei]` from the module found in TOS. The resulting object is pushed onto the stack, to be subsequently stored by a `STORE_FAST` instruction.

**JUMP_FORWARD**(delta)

Increments bytecode counter by `delta`. 
POP_JUMP_IF_TRUE(target)
If TOS is true, sets the bytecode counter to target. TOS is popped.

POP_JUMP_IF_FALSE(target)
If TOS is false, sets the bytecode counter to target. TOS is popped.

JUMP_IF_TRUE_OR_POP(target)
If TOS is true, sets the bytecode counter to target and leaves TOS on the stack. Otherwise (TOS is false), TOS is popped.

JUMP_IF_FALSE_OR_POP(target)
If TOS is false, sets the bytecode counter to target and leaves TOS on the stack. Otherwise (TOS is true), TOS is popped.

JUMP_ABSOLUTE(target)
Set bytecode counter to target.

FOR_ITER(delta)
TOS is an iterator. Call its __next__() method. If this yields a new value, push it on the stack (leaving the iterator below it). If the iterator indicates it is exhausted TOS is popped, and the byte code counter is incremented by delta.

LOAD_GLOBAL(namei)
_loads the global named co_names[namei] onto the stack.

SETUP_LOOP(delta)
Pushes a block for a loop onto the block stack. The block spans from the current instruction with a size of delta bytes.

SETUP_EXCEPT(delta)
Pushes a try block from a try-except clause onto the block stack. delta points to the first except block.
**SETUPFINALLY**(delta)

Pushes a try block from a try-except clause onto the block stack. 
*delta* points to the finally block.

**LOAD_FAST**(var_num)

Pushes a reference to the local co_varnames[var_num] onto the stack.

**STORE_FAST**(var_num)

Stores TOS into the local co_varnames[var_num].

**DELETE_FAST**(var_num)

Deletes local co_varnames[var_num].

**STORE_ANNOTATION**(namei)

Stores TOS as locals()[`__annotations__`][co_names[namei]] = TOS.

*New in version 3.6.*

**LOAD_CLOSURE**(i)

Pushes a reference to the cell contained in slot *i* of the cell and free variable storage. The name of the variable is co_cellvars[*i*] if *i* is less than the length of co_cellvars. Otherwise it is co_freevars[*i* - len(co_cellvars)].

**LOAD_DEREF**(i)

Loads the cell contained in slot *i* of the cell and free variable storage. Pushes a reference to the object the cell contains on the stack.

**LOAD_CLASSDEREF**(i)
Much like `LOAD_DEREF` but first checks the locals dictionary before consulting the cell. This is used for loading free variables in class bodies.

**STORE_DEREF(i)**
Stores TOS into the cell contained in slot $i$ of the cell and free variable storage.

**DELETE_DEREF(i)**
Empties the cell contained in slot $i$ of the cell and free variable storage. Used by the `del` statement.

**RAISE_VARARGS(argc)**
Raises an exception. $argc$ indicates the number of parameters to the raise statement, ranging from 0 to 3. The handler will find the traceback as TOS2, the parameter as TOS1, and the exception as TOS.

**CALL_FUNCTION(argc)**
Calls a function. $argc$ indicates the number of positional arguments. The positional arguments are on the stack, with the right-most argument on top. Below the arguments, the function object to call is on the stack. Pops all function arguments, and the function itself off the stack, and pushes the return value.

*Changed in version 3.6:* This opcode is used only for calls with positional arguments.

**CALL_FUNCTION_KW(argc)**
Calls a function. $argc$ indicates the number of arguments (positional and keyword). The top element on the stack contains a tuple of keyword argument names. Below the tuple, keyword arguments are on the stack, in the order corresponding to the
tuple. Below the keyword arguments, the positional arguments are on the stack, with the right-most parameter on top. Below the arguments, the function object to call is on the stack. Pops all function arguments, and the function itself off the stack, and pushes the return value.

*Changed in version 3.6:* Keyword arguments are packed in a tuple instead of a dictionary, \texttt{argc} indicates the total number of arguments

\textbf{CALL\_FUNCTION\_EX}(\textit{flags})

Calls a function. The lowest bit of \textit{flags} indicates whether the var-keyword argument is placed at the top of the stack. Below the var-keyword argument, the var-positional argument is on the stack. Below the arguments, the function object to call is placed. Pops all function arguments, and the function itself off the stack, and pushes the return value. Note that this opcode pops at most three items from the stack. Var-positional and var-keyword arguments are packed by \texttt{BUILD\_MAP\_UNPACK\_WITH\_CALL} and \texttt{BUILD\_MAP\_UNPACK\_WITH\_CALL}.

*New in version 3.6.*

\textbf{MAKE\_FUNCTION}(\textit{argc})

Pushes a new function object on the stack. From bottom to top, the consumed stack must consist of values if the argument carries a specified flag value

- 0x01 a tuple of default argument objects in positional order
- 0x02 a dictionary of keyword-only parameters’ default values
- 0x04 an annotation dictionary
- 0x08 a tuple containing cells for free variables, making a closure
- the code associated with the function (at TOS1)
- the qualified name of the function (at TOS)

**BUILD_SLICE**(argc)

Pushes a slice object on the stack. argc must be 2 or 3. If it is 2, slice(TOS1, TOS) is pushed; if it is 3, slice(TOS2, TOS1, TOS) is pushed. See the slice() built-in function for more information.

**EXTENDED_ARG**(ext)

Prefixes any opcode which has an argument too big to fit into the default two bytes. ext holds two additional bytes which, taken together with the subsequent opcode’s argument, comprise a four-byte argument, ext being the two most-significant bytes.

**FORMAT_VALUE**(flags)

Used for implementing formatted literal strings (f-strings). Pops an optional fmt_spec from the stack, then a required value. flags is interpreted as follows:

- `(flags & 0x03) == 0x00: value is formatted as-is.
- `(flags & 0x03) == 0x01: call str() on value before formatting it.
- `(flags & 0x03) == 0x02: call repr() on value before formatting it.
- `(flags & 0x03) == 0x03: call ascii() on value before formatting it.
- `(flags & 0x04) == 0x04: pop fmt_spec from the stack and use it, else use an empty fmt_spec.

Formatting is performed using PyObject_Format(). The result is pushed on the stack.

*New in version 3.6.*
HAVE_ARGUMENT

This is not really an opcode. It identifies the dividing line between opcodes which don’t use their argument and those that do (\textless{}\ HAVE\_ARGUMENT and \textgreater{}=\ HAVE\_ARGUMENT, respectively).

\textit{Changed in version 3.6}: Now every instruction has an argument, but opcodes \textless{}\ HAVE\_ARGUMENT ignore it. Before, only opcodes \textgreater{}=\ HAVE\_ARGUMENT had an argument.
32.12.4. Opcode collections

These collections are provided for automatic introspection of bytecode instructions:

- **dis. opname**
  Sequence of operation names, indexable using the bytecode.

- **dis. opmap**
  Dictionary mapping operation names to bytecodes.

- **dis. cmp_op**
  Sequence of all compare operation names.

- **dis. hasconst**
  Sequence of bytecodes that have a constant parameter.

- **dis. hasfree**
  Sequence of bytecodes that access a free variable (note that ‘free’ in this context refers to names in the current scope that are referenced by inner scopes or names in outer scopes that are referenced from this scope. It does not include references to global or builtin scopes).

- **dis. hasname**
  Sequence of bytecodes that access an attribute by name.

- **dis. hasjrel**
  Sequence of bytecodes that have a relative jump target.

- **dis. hasjabs**
  Sequence of bytecodes that have an absolute jump target.
**dis.haslocal**
Sequence of bytecodes that access a local variable.

**dis.hascompare**
Sequence of bytecodes of Boolean operations.
32.13. **pickletools** — Tools for pickle developers

**Source code:** Lib/pickletools.py

This module contains various constants relating to the intimate details of the `pickle` module, some lengthy comments about the implementation, and a few useful functions for analyzing pickled data. The contents of this module are useful for Python core developers who are working on the `pickle`; ordinary users of the `pickle` module probably won't find the `pickletools` module relevant.
32.13.1. Command line usage

New in version 3.2.

When invoked from the command line, `python -m pickletools` will disassemble the contents of one or more pickle files. Note that if you want to see the Python object stored in the pickle rather than the details of pickle format, you may want to use `-m pickle` instead. However, when the pickle file that you want to examine comes from an untrusted source, `-m pickletools` is a safer option because it does not execute pickle bytecode.

For example, with a tuple `(1, 2)` pickled in file `x.pickle`:

```
$ python -m pickle x.pickle
(1, 2)

$ python -m pickletools x.pickle
   0: \x80 PROTO 3
   2: K BININT1 1
   4: K BININT1 2
   6: \x86 TUPLE2
   7: q BININPUT 0
   9: . STOP
highest protocol among opcodes = 2
```

32.13.1.1. Command line options

- `-a`, `--annotate`
  Annotate each line with a short opcode description.

- `-o`, `--output=<file>`
Name of a file where the output should be written.

-1, --indentlevel=<num>
The number of blanks by which to indent a new MARK level.

-m, --memo
When multiple objects are disassembled, preserve memo between disassemblies.

-p, --preamble=<preamble>
When more than one pickle file are specified, print given preamble before each disassembly.
32.13.2. Programmatic Interface

pickletools.\texttt{\textbf{dis}(pickle, out=None, memo=None, indentlevel=4, annotate=0)}

Outputs a symbolic disassembly of the pickle to the file-like object \texttt{out}, defaulting to \texttt{sys.stdout}. \texttt{pickle} can be a string or a file-like object. \texttt{memo} can be a Python dictionary that will be used as the pickle's memo; it can be used to perform disassemblies across multiple pickles created by the same pickler. Successive levels, indicated by \texttt{MARK} opcodes in the stream, are indented by \texttt{indentlevel} spaces. If a nonzero value is given to \texttt{annotate}, each opcode in the output is annotated with a short description. The value of \texttt{annotate} is used as a hint for the column where annotation should start.

\textit{New in version 3.2}: The \texttt{annotate} argument.

pickletools.\texttt{\textbf{genops}(pickle)}

Provides an \texttt{iterator} over all of the opcodes in a pickle, returning a sequence of \texttt{(opcode, arg, pos)} triples. \texttt{opcode} is an instance of an \texttt{OpcodeInfo} class; \texttt{arg} is the decoded value, as a Python object, of the opcode's argument; \texttt{pos} is the position at which this opcode is located. \texttt{pickle} can be a string or a file-like object.

pickletools.\texttt{\textbf{optimize}(picklestring)}

Returns a new equivalent pickle string after eliminating unused \texttt{PUT} opcodes. The optimized pickle is shorter, takes less transmission time, requires less storage space, and unpickles more efficiently.
33. Miscellaneous Services

The modules described in this chapter provide miscellaneous services that are available in all Python versions. Here's an overview:

- **33.1. formatter — Generic output formatting**
  - 33.1.1. The Formatter Interface
  - 33.1.2. Formatter Implementations
  - 33.1.3. The Writer Interface
  - 33.1.4. Writer Implementations
33.1. `formatter` — Generic output formatting

*Deprecated since version 3.4:* Due to lack of usage, the `formatter` module has been deprecated.

This module supports two interface definitions, each with multiple implementations: The `formatter` interface, and the `writer` interface which is required by the `formatter` interface.

Formatter objects transform an abstract flow of formatting events into specific output events on writer objects. Formatters manage several stack structures to allow various properties of a writer object to be changed and restored; writers need not be able to handle relative changes nor any sort of “change back” operation. Specific writer properties which may be controlled via formatter objects are horizontal alignment, font, and left margin indentations. A mechanism is provided which supports providing arbitrary, non-exclusive style settings to a writer as well. Additional interfaces facilitate formatting events which are not reversible, such as paragraph separation.

Writer objects encapsulate device interfaces. Abstract devices, such as file formats, are supported as well as physical devices. The provided implementations all work with abstract devices. The interface makes available mechanisms for setting the properties which formatter objects manage and inserting data into the output.
33.1.1. The Formatter Interface

Interfaces to create formatters are dependent on the specific formatter class being instantiated. The interfaces described below are the required interfaces which all formatters must support once initialized.

One data element is defined at the module level:

formatter.\texttt{AS\_IS}

Value which can be used in the font specification passed to the \texttt{push\_font()} method described below, or as the new value to any other \texttt{push\_property()} method. Pushing the \texttt{AS\_IS} value allows the corresponding \texttt{pop\_property()} method to be called without having to track whether the property was changed.

The following attributes are defined for formatter instance objects:

formatter.\texttt{writer}

The writer instance with which the formatter interacts.

formatter.\texttt{end\_paragraph(\textit{blanklines})}

Close any open paragraphs and insert at least \textit{blanklines} before the next paragraph.

formatter.\texttt{add\_line\_break()}

Add a hard line break if one does not already exist. This does not break the logical paragraph.

formatter.\texttt{add\_hor\_rule(*args, **kw)}

Insert a horizontal rule in the output. A hard break is inserted if there is data in the current paragraph, but the logical paragraph is not broken. The arguments and keywords are passed on to the
writer's send_line_break() method.

**formatter.add_flowing_data(data)**

Provide data which should be formatted with collapsed whitespace. Whitespace from preceding and successive calls to add_flowing_data() is considered as well when the whitespace collapse is performed. The data which is passed to this method is expected to be word-wrapped by the output device. Note that any word-wrapping still must be performed by the writer object due to the need to rely on device and font information.

**formatter.add_literal_data(data)**

Provide data which should be passed to the writer unchanged. Whitespace, including newline and tab characters, are considered legal in the value of data.

**formatter.add_label_data(format, counter)**

Insert a label which should be placed to the left of the current left margin. This should be used for constructing bulleted or numbered lists. If the format value is a string, it is interpreted as a format specification for counter, which should be an integer. The result of this formatting becomes the value of the label; if format is not a string it is used as the label value directly. The label value is passed as the only argument to the writer's send_label_data() method. Interpretation of non-string label values is dependent on the associated writer.

Format specifications are strings which, in combination with a counter value, are used to compute label values. Each character in the format string is copied to the label value, with some characters recognized to indicate a transform on the counter value. Specifically, the character '1' represents the counter value.
formatter as an Arabic number, the characters 'A' and 'a' represent alphabetic representations of the counter value in upper and lower case, respectively, and 'I' and 'i' represent the counter value in Roman numerals, in upper and lower case. Note that the alphabetic and roman transforms require that the counter value be greater than zero.

formatter. **flush_softspace()**

Send any pending whitespace buffered from a previous call to `add_flowing_data()` to the associated writer object. This should be called before any direct manipulation of the writer object.

formatter. **push_alignment(**align**)**

Push a new alignment setting onto the alignment stack. This may be **AS_IS** if no change is desired. If the alignment value is changed from the previous setting, the writer’s `new_alignment()` method is called with the `align` value.

formatter. **pop_alignment()**

Restore the previous alignment.

formatter. **push_font**( **(size, italic, bold, teletype))**

Change some or all font properties of the writer object. Properties which are not set to **AS_IS** are set to the values passed in while others are maintained at their current settings. The writer’s `new_font()` method is called with the fully resolved font specification.

formatter. **pop_font()**

Restore the previous font.

formatter. **push_margin**( **margin**)}
Increase the number of left margin indentations by one, associating the logical tag margin with the new indentation. The initial margin level is 0. Changed values of the logical tag must be true values; false values other than AS_IS are not sufficient to change the margin.

formatter.pop_margin()

Restore the previous margin.

formatter.push_style(*styles)

Push any number of arbitrary style specifications. All styles are pushed onto the styles stack in order. A tuple representing the entire stack, including AS_IS values, is passed to the writer's new_styles() method.

formatter.pop_style(n=1)

Pop the last n style specifications passed to push_style(). A tuple representing the revised stack, including AS_IS values, is passed to the writer's new_styles() method.

formatter.set_spacing(spacing)

Set the spacing style for the writer.

formatter.assert_line_data(flag=1)

Inform the formatter that data has been added to the current paragraph out-of-band. This should be used when the writer has been manipulated directly. The optional flag argument can be set to false if the writer manipulations produced a hard line break at the end of the output.
33.1.2. Formatter Implementations

Two implementations of formatter objects are provided by this module. Most applications may use one of these classes without modification or subclassing.

```python
class formatter.NullFormatter(writer=None)
   A formatter which does nothing. If writer is omitted, a NullWriter instance is created. No methods of the writer are called by NullFormatter instances. Implementations should inherit from this class if implementing a writer interface but don’t need to inherit any implementation.

class formatter.AbstractFormatter(writer)
   The standard formatter. This implementation has demonstrated wide applicability to many writers, and may be used directly in most circumstances. It has been used to implement a full-featured World Wide Web browser.
```
33.1.3. The Writer Interface

Interfaces to create writers are dependent on the specific writer class being instantiated. The interfaces described below are the required interfaces which all writers must support once initialized. Note that while most applications can use the AbstractFormatter class as a formatter, the writer must typically be provided by the application.

**writer.flush()**
Flush any buffered output or device control events.

**writer.new_alignment(align)**
Set the alignment style. The `align` value can be any object, but by convention is a string or `None`, where `None` indicates that the writer’s “preferred” alignment should be used. Conventional `align` values are 'left', 'center', 'right', and 'justify'.

**writer.new_font(font)**
Set the font style. The value of `font` will be `None`, indicating that the device’s default font should be used, or a tuple of the form `(size, italic, bold, teletype)`. Size will be a string indicating the size of font that should be used; specific strings and their interpretation must be defined by the application. The `italic`, `bold`, and `teletype` values are Boolean values specifying which of those font attributes should be used.

**writer.new_margin(margin, level)**
Set the margin level to the integer `level` and the logical tag to `margin`. Interpretation of the logical tag is at the writer’s discretion; the only restriction on the value of the logical tag is that it not be a false value for non-zero values of `level`. 
writer.new_spacing(spacing)
Set the spacing style to spacing.

writer.new_styles(styles)
Set additional styles. The styles value is a tuple of arbitrary values; the value AS_IS should be ignored. The styles tuple may be interpreted either as a set or as a stack depending on the requirements of the application and writer implementation.

writer.send_line_break()
Break the current line.

writer.send_paragraph(blankline)
Produce a paragraph separation of at least blankline blank lines, or the equivalent. The blankline value will be an integer. Note that the implementation will receive a call to send_line_break() before this call if a line break is needed; this method should not include ending the last line of the paragraph. It is only responsible for vertical spacing between paragraphs.

writer.send_hor_rule(*args, **kw)
Display a horizontal rule on the output device. The arguments to this method are entirely application- and writer-specific, and should be interpreted with care. The method implementation may assume that a line break has already been issued via send_line_break().

writer.send_flowing_data(data)
Output character data which may be word-wrapped and re-flowed as needed. Within any sequence of calls to this method, the writer may assume that spans of multiple whitespace characters have been collapsed to single space characters.
**writer.send_literal_data(data)**

Output character data which has already been formatted for display. Generally, this should be interpreted to mean that line breaks indicated by newline characters should be preserved and no new line breaks should be introduced. The data may contain embedded newline and tab characters, unlike data provided to the send_formatted_data() interface.

**writer.send_label_data(data)**

Set data to the left of the current left margin, if possible. The value of data is not restricted; treatment of non-string values is entirely application- and writer-dependent. This method will only be called at the beginning of a line.
33.1.4. Writer Implementations

Three implementations of the writer object interface are provided as examples by this module. Most applications will need to derive new writer classes from the `NullWriter` class.

```python
class formatter.NullWriter
    A writer which only provides the interface definition; no actions are taken on any methods. This should be the base class for all writers which do not need to inherit any implementation methods.
```

```python
class formatter(AbstractWriter
    A writer which can be used in debugging formatters, but not much else. Each method simply announces itself by printing its name and arguments on standard output.
```

```python
class formatter.DumbWriter(file=None, maxcol=72)
    Simple writer class which writes output on the file object passed in as file or, if file is omitted, on standard output. The output is simply word-wrapped to the number of columns specified by maxcol. This class is suitable for reflowing a sequence of paragraphs.
```
34. MS Windows Specific Services

This chapter describes modules that are only available on MS Windows platforms.

- **34.1. msilib** — Read and write Microsoft Installer files
  - 34.1.1. Database Objects
  - 34.1.2. View Objects
  - 34.1.3. Summary Information Objects
  - 34.1.4. Record Objects
  - 34.1.5. Errors
  - 34.1.6. CAB Objects
  - 34.1.7. Directory Objects
  - 34.1.8. Features
  - 34.1.9. GUI classes
  - 34.1.10. Precomputed tables
- **34.2. msvcrt** — Useful routines from the MS VC++ runtime
  - 34.2.1. File Operations
  - 34.2.2. Console I/O
  - 34.2.3. Other Functions
- **34.3. winreg** — Windows registry access
  - 34.3.1. Functions
  - 34.3.2. Constants
    - 34.3.2.1. HKEY_* Constants
    - 34.3.2.2. Access Rights
      - 34.3.2.2.1. 64-bit Specific
    - 34.3.2.3. Value Types
  - 34.3.3. Registry Handle Objects
- **34.4. winsound** — Sound-playing interface for Windows
34.1. msilib — Read and write Microsoft Installer files

Source code: Lib/msilib/__init__.py

The msilib supports the creation of Microsoft Installer (.msi) files. Because these files often contain an embedded “cabinet” file (.cab), it also exposes an API to create CAB files. Support for reading .cab files is currently not implemented; read support for the .msi database is possible.

This package aims to provide complete access to all tables in an .msi file, therefore, it is a fairly low-level API. Two primary applications of this package are the distutils command bdist_msi, and the creation of Python installer package itself (although that currently uses a different version of msilib).

The package contents can be roughly split into four parts: low-level CAB routines, low-level MSI routines, higher-level MSI routines, and standard table structures.

msilib.FCICreate(cabname, files)

Create a new CAB file named cabname. files must be a list of tuples, each containing the name of the file on disk, and the name of the file inside the CAB file.

The files are added to the CAB file in the order they appear in the list. All files are added into a single CAB file, using the MSZIP compression algorithm.
Callbacks to Python for the various steps of MSI creation are currently not exposed.

`msilib.UuidCreate()`
Return the string representation of a new unique identifier. This wraps the Windows API functions `UuidCreate()` and `UuidToString()`.

`msilib.OpenDatabase(path, persist)`
Return a new database object by calling `MsiOpenDatabase`. `path` is the file name of the MSI file; `persist` can be one of the constants `MSIDBOPEN_CREATEDIRECT`, `MSIDBOPEN_CREATE`, `MSIDBOPEN_DIRECT`, `MSIDBOPEN_READONLY`, or `MSIDBOPEN_TRANSACT`, and may include the flag `MSIDBOPEN_PATCHFILE`. See the Microsoft documentation for the meaning of these flags; depending on the flags, an existing database is opened, or a new one created.

`msilib.CreateRecord(count)`
Return a new record object by calling `MSICreateRecord()`. `count` is the number of fields of the record.

`msilib.init_database(name, schema, ProductName, ProductCode, ProductVersion, Manufacturer)`
Create and return a new database `name`, initialize it with `schema`, and set the properties `ProductName`, `ProductCode`, `ProductVersion`, and `Manufacturer`.

`schema` must be a module object containing `tables` and `Validation_records` attributes; typically, `msilib.schema` should be used.
The database will contain just the schema and the validation records when this function returns.

```
msilib.add_data(database, table, records)
```

Add all records to the table named table in database.

The table argument must be one of the predefined tables in the MSI schema, e.g. 'Feature', 'File', 'Component', 'Dialog', 'Control', etc.

records should be a list of tuples, each one containing all fields of a record according to the schema of the table. For optional fields, None can be passed.

Field values can be ints, strings, or instances of the Binary class.

```
class msilib.Binary(filename)
```

Represents entries in the Binary table; inserting such an object using add_data() reads the file named filename into the table.

```
msilib.add_tables(database, module)
```

Add all table content from module to database. module must contain an attribute tables listing all tables for which content should be added, and one attribute per table that has the actual content.

This is typically used to install the sequence tables.

```
msilib.add_stream(database, name, path)
```

Add the file path into the _Stream table of database, with the stream name name.

```
msilib.gen_uuid()
```

Return a new UUID, in the format that MSI typically requires (i.e. in
curly braces, and with all hexdigits in upper-case).

See also: FCICreateFile UuidCreate UuidToString
34.1.1. Database Objects

Database. **OpenView**(sql)

Return a view object, by calling MSIDatabaseOpenView(). sql is the SQL statement to execute.

Database. **Commit**()

Commit the changes pending in the current transaction, by calling MSIDatabaseCommit().

Database. **GetSummaryInformation**(count)

Return a new summary information object, by calling MsiGetSummaryInformation(). count is the maximum number of updated values.

**See also:** MSIDatabaseOpenView MSIDatabaseCommit MsiGetSummaryInformation
34.1.2. View Objects

View. **Execute**(params)

Execute the SQL query of the view, through **MSIViewExecute()**. If **params** is not **None**, it is a record describing actual values of the parameter tokens in the query.

View. **GetColumnInfo**(kind)

Return a record describing the columns of the view, through calling **MsiViewGetColumnInfo()**. **kind** can be either **MSICOLINFO_NAMES** or **MSICOLINFO_TYPES**.

View. **Fetch**()

Return a result record of the query, through calling **MsiViewFetch()**.

View. **Modify**(kind, data)

Modify the view, by calling **MsiViewModify()**. **kind** can be one of **MSIMODIFY_SEEK**, **MSIMODIFY_REFRESH**, **MSIMODIFY_INSERT**, **MSIMODIFY_UPDATE**, **MSIMODIFY_ASSIGN**, **MSIMODIFY_REPLACE**, **MSIMODIFY_MERGE**, **MSIMODIFY_DELETE**, **MSIMODIFY_INSERT_TEMPORARY**, **MSIMODIFY_VALIDATE**, **MSIMODIFY_VALIDATE_NEW**, **MSIMODIFY_VALIDATE_FIELD**, or **MSIMODIFY_VALIDATE_DELETE**.

**data** must be a record describing the new data.

View. **Close**()

Close the view, through **MsiViewClose()**.
See also:  MsiViewExecute MSIViewGetColumnInfo MsiViewFetch MsiViewModify MsiViewClose
34.1.3. Summary Information Objects

SummaryInformation. **GetProperty**(field)

Return a property of the summary, through MsiSummaryInfoGetProperty(). *field* is the name of the property, and can be one of the constants PID_CODEPAGE, PID_TITLE, PID_SUBJECT, PID_AUTHOR, PID_KEYWORDS, PID_COMMENTS, PID_TEMPLATE, PID_LASTAUTHOR, PID_REVISION, PID_LASTPRINTED, PID_CREATE_DTM, PID_LASTSAVE_DTM, PID_PAGECOUNT, PID_WORDCOUNT, PID_CHARCOUNT, PID_APPNAME, or PID_SECURITY.

SummaryInformation. **GetPropertyCount**()

Return the number of summary properties, through MsiSummaryInfoGetPropertyCount().

SummaryInformation. **SetProperty**(field, value)

Set a property through MsiSummaryInfoSetProperty(). *field* can have the same values as in `GetProperty()`, *value* is the new value of the property. Possible value types are integer and string.

SummaryInformation. **Persist**()

Write the modified properties to the summary information stream, using MsiSummaryInfoPersist().

See also: MsiSummaryInfoGetProperty
MsiSummaryInfoGetPropertyCount MsiSummaryInfoSetProperty
MsiSummaryInfoPersist
34.1.4. Record Objects

Record. `GetFieldCount()`
Return the number of fields of the record, through MsiRecordGetFieldCount().

Record. `GetInteger(field)`
Return the value of `field` as an integer where possible. `field` must be an integer.

Record. `GetString(field)`
Return the value of `field` as a string where possible. `field` must be an integer.

Record. `SetString(field, value)`
Set `field` to `value` through MsiRecordSetString(). `field` must be an integer; `value` a string.

Record. `SetStream(field, value)`
Set `field` to the contents of the file named `value`, through MsiRecordSetStream(). `field` must be an integer; `value` a string.

Record. `SetInteger(field, value)`
Set `field` to `value` through MsiRecordSetInteger(). Both `field` and `value` must be an integer.

Record. `ClearData()`
Set all fields of the record to 0, through MsiRecordClearData().
See also:  MsiRecordGetFieldCount MsiRecordSetString
        MsiRecordSetStream MsiRecordSetInteger MsiRecordClear
34.1.5. Errors

All wrappers around MSI functions raise MsiError; the string inside the exception will contain more detail.
34.1.6. CAB Objects

class msilib.CAB(name)

The class CAB represents a CAB file. During MSI construction, files will be added simultaneously to the Files table, and to a CAB file. Then, when all files have been added, the CAB file can be written, then added to the MSI file.

name is the name of the CAB file in the MSI file.

append(full, file, logical)

Add the file with the pathname full to the CAB file, under the name logical. If there is already a file named logical, a new file name is created.

Return the index of the file in the CAB file, and the new name of the file inside the CAB file.

commit(database)

Generate a CAB file, add it as a stream to the MSI file, put it into the Media table, and remove the generated file from the disk.
34.1.7. Directory Objects

class msilib.Directory(database, cab, basedir, physical, logical, default[, componentflags])

Create a new directory in the Directory table. There is a current component at each point in time for the directory, which is either explicitly created through start_component(), or implicitly when files are added for the first time. Files are added into the current component, and into the cab file. To create a directory, a base directory object needs to be specified (can be None), the path to the physical directory, and a logical directory name. default specifies the DefaultDir slot in the directory table. componentflags specifies the default flags that new components get.

start_component(component=None, feature=None, flags=None, keyfile=None, uuid=None)

Add an entry to the Component table, and make this component the current component for this directory. If no component name is given, the directory name is used. If no feature is given, the current feature is used. If no flags are given, the directory's default flags are used. If no keyfile is given, the KeyPath is left null in the Component table.

add_file(file, src=None, version=None, language=None)

Add a file to the current component of the directory, starting a new one if there is no current component. By default, the file name in the source and the file table will be identical. If the src file is specified, it is interpreted relative to the current directory. Optionally, a version and a language can be specified for the entry in the File table.
**glob**(*pattern*, *exclude=None*)

Add a list of files to the current component as specified in the glob pattern. Individual files can be excluded in the *exclude* list.

**remove_pyc()**

Remove `.pyc`/`.pyo` files on uninstall.

See also: Directory Table File Table Component Table
FeatureComponents Table
34.1.8. Features

class msilib.Feature(db, id, title, desc, display, level=1, parent=None, directory=None, attributes=0)

Add a new record to the Feature table, using the values id, parent.id, title, desc, display, level, directory, and attributes. The resulting feature object can be passed to the start_component() method of Directory.

set_current()

Make this feature the current feature of msilib. New components are automatically added to the default feature, unless a feature is explicitly specified.

See also: Feature Table
34.1.9. GUI classes

`msilib` provides several classes that wrap the GUI tables in an MSI database. However, no standard user interface is provided; use `bdist_msi` to create MSI files with a user-interface for installing Python packages.

```python
class msilib.Control(dlg, name)
    Base class of the dialog controls. `dlg` is the dialog object the control belongs to, and `name` is the control's name.

    event(event, argument, condition=1, ordering=None)
        Make an entry into the ControlEvent table for this control.

    mapping(event, attribute)
        Make an entry into the EventMapping table for this control.

    condition(action, condition)
        Make an entry into the ControlCondition table for this control.
```

```python
class msilib.RadioButtonGroup(dlg, name, property)
    Create a radio button control named `name`. `property` is the installer property that gets set when a radio button is selected.

    add(name, x, y, width, height, text, value=None)
        Add a radio button named `name` to the group, at the coordinates `x`, `y`, `width`, `height`, and with the label `text`. If `value` is None, it defaults to `name`.
```

```python
class msilib.Dialog(db, name, x, y, w, h, attr, title, first, default, cancel)
```
Return a new Dialog object. An entry in the Dialog table is made, with the specified coordinates, dialog attributes, title, name of the first, default, and cancel controls.

control(name, type, x, y, width, height, attributes, property, text, control_next, help)
   Return a new Control object. An entry in the Control table is made with the specified parameters.

   This is a generic method; for specific types, specialized methods are provided.

text(name, x, y, width, height, attributes, text)
   Add and return a Text control.

bitmap(name, x, y, width, height, text)
   Add and return a Bitmap control.

line(name, x, y, width, height)
   Add and return a Line control.

pushbutton(name, x, y, width, height, attributes, text, next_control)
   Add and return a PushButton control.

radiogroup(name, x, y, width, height, attributes, property, text, next_control)
   Add and return a RadioButtonGroup control.

checkbox(name, x, y, width, height, attributes, property, text, next_control)
   Add and return a CheckBox control.
See also: Dialog Table Control Table Control Types
ControlCondition Table ControlEvent Table EventMapping Table
RadioButton Table
34.1.10. Precomputed tables

`msilib` provides a few subpackages that contain only schema and table definitions. Currently, these definitions are based on MSI version 2.0.

`msilib.schema`  
This is the standard MSI schema for MSI 2.0, with the `tables` variable providing a list of table definitions, and `_Validation_records` providing the data for MSI validation.

`msilib.sequence`  
This module contains table contents for the standard sequence tables: `AdminExecuteSequence`, `AdminUISequence`, `AdvtExecuteSequence`, `InstallExecuteSequence`, and `InstallUISequence`.

`msilib.text`  
This module contains definitions for the UIText and ActionText tables, for the standard installer actions.
34.2. msvcrtn — Useful routines from the MS VC++ runtime

These functions provide access to some useful capabilities on Windows platforms. Some higher-level modules use these functions to build the Windows implementations of their services. For example, the getpass module uses this in the implementation of the getpass() function.

Further documentation on these functions can be found in the Platform API documentation.

The module implements both the normal and wide char variants of the console I/O api. The normal API deals only with ASCII characters and is of limited use for internationalized applications. The wide char API should be used where ever possible.

*Changed in version 3.3:* Operations in this module now raise OSError where IOError was raised.
34.2.1. File Operations

```python
msvcrt.locking(fd, mode, nbytes)
```
Lock part of a file based on file descriptor `fd` from the C runtime. Raises `OSError` on failure. The locked region of the file extends from the current file position for `nbytes` bytes, and may continue beyond the end of the file. `mode` must be one of the LK_* constants listed below. Multiple regions in a file may be locked at the same time, but may not overlap. Adjacent regions are not merged; they must be unlocked individually.

```python
msvcrt.LK_LOCK
msvcrt.LK_RLCK
```
Locks the specified bytes. If the bytes cannot be locked, the program immediately tries again after 1 second. If, after 10 attempts, the bytes cannot be locked, `OSError` is raised.

```python
msvcrt.LK_NBLCK
msvcrt.LK_NBRLCK
```
Locks the specified bytes. If the bytes cannot be locked, `OSError` is raised.

```python
msvcrt.LK_UNLCK
```
Unlocks the specified bytes, which must have been previously locked.

```python
msvcrt.setmode(fd, flags)
```
Set the line-end translation mode for the file descriptor `fd`. To set it to text mode, `flags` should be `os.O_TEXT`; for binary, it should be `os.O_BINARY`. 
msvcrt.**open_osfhandle**(handle, flags)

Create a C runtime file descriptor from the file handle `handle`. The `flags` parameter should be a bitwise OR of `os.O_APPEND`, `os.O_RDONLY`, and `os.O_TEXT`. The returned file descriptor may be used as a parameter to `os.fdopen()` to create a file object.

msvcrt.**get_osfhandle**(fd)

Return the file handle for the file descriptor `fd`. Raises `OSError` if `fd` is not recognized.
34.2.2. Console I/O

**msvcrt.**\texttt{kbhit()**}

Return true if a keypress is waiting to be read.

**msvcrt.**\texttt{getch()**}

Read a keypress and return the resulting character as a byte string. Nothing is echoed to the console. This call will block if a keypress is not already available, but will not wait for \texttt{Enter} to be pressed. If the pressed key was a special function key, this will return \texttt{'\000'} or \texttt{'\xe0'}; the next call will return the keycode. The \texttt{Control-C} keypress cannot be read with this function.

**msvcrt.**\texttt{getwch()**}

Wide char variant of \texttt{getch()}, returning a Unicode value.

**msvcrt.**\texttt{getche()**}

Similar to \texttt{getch()}, but the keypress will be echoed if it represents a printable character.

**msvcrt.**\texttt{getwche()**}

Wide char variant of \texttt{getche()}, returning a Unicode value.

**msvcrt.**\texttt{putch(char)**}

Print the byte string \texttt{char} to the console without buffering.

**msvcrt.**\texttt{putwch(unicode_char)**}

Wide char variant of \texttt{putch()}, accepting a Unicode value.

**msvcrt.**\texttt{ungetch(char)**}

Cause the byte string \texttt{char} to be “pushed back” into the console
buffer; it will be the next character read by `getch()` or `getche()`.

`msvcrt.ungetwch(unicode_char)`

Wide char variant of `ungetch()`, accepting a Unicode value.
34.2.3. Other Functions

```
msvcrt.heapmin()
```

Force the malloc() heap to clean itself up and return unused blocks to the operating system. On failure, this raises `OSError`.
34.3. *winreg* — Windows registry access

These functions expose the Windows registry API to Python. Instead of using an integer as the registry handle, a handle object is used to ensure that the handles are closed correctly, even if the programmer neglects to explicitly close them.

*Changed in version 3.3:* Several functions in this module used to raise a `WindowsError`, which is now an alias of `OSError`. 
34.3.1. Functions

This module offers the following functions:

\texttt{winreg.\texttt{CloseKey}\(hkey\)}

Closes a previously opened registry key. The \texttt{hkey} argument specifies a previously opened key.

\begin{itemize}
  \item \textbf{Note:} If \texttt{hkey} is not closed using this method (or via \texttt{hkey.Close()}), it is closed when the \texttt{hkey} object is destroyed by Python.
\end{itemize}

\texttt{winreg.\texttt{ConnectRegistry}(computer\_name, key)}

Establishes a connection to a predefined registry handle on another computer, and returns a handle object.

\begin{itemize}
  \item \textit{computer\_name} is the name of the remote computer, of the form \texttt{r"\computername"}. If \texttt{None}, the local computer is used.
  \item \textit{key} is the predefined handle to connect to.
\end{itemize}

The return value is the handle of the opened key. If the function fails, an \texttt{OSError} exception is raised.

\textit{Changed in version 3.3}: See \texttt{above}.

\texttt{winreg.\texttt{CreateKey}(key, sub\_key)}

Creates or opens the specified key, returning a handle object.

\begin{itemize}
  \item \textit{key} is an already open key, or one of the predefined \texttt{HKEY\_* constants}.
\end{itemize}
sub_key is a string that names the key this method opens or creates.

If key is one of the predefined keys, sub_key may be None. In that case, the handle returned is the same key handle passed in to the function.

If the key already exists, this function opens the existing key.

The return value is the handle of the opened key. If the function fails, an OSError exception is raised.

Changed in version 3.3: See above.

winreg.CreateKeyEx(key, sub_key, reserved=0, access=KEY_WRITE)

Creates or opens the specified key, returning a handle object.

key is an already open key, or one of the predefined HKEY_* constants.

sub_key is a string that names the key this method opens or creates.

reserved is a reserved integer, and must be zero. The default is zero.

access is an integer that specifies an access mask that describes the desired security access for the key. Default is KEY_WRITE. See Access Rights for other allowed values.

If key is one of the predefined keys, sub_key may be None. In that case, the handle returned is the same key handle passed in to the function.
If the key already exists, this function opens the existing key.

The return value is the handle of the opened key. If the function fails, an OSError exception is raised.

*New in version 3.2.*

*Changed in version 3.3:* See [above](#).

`winreg.DeleteKey(key, sub_key)`

Deletes the specified key.

`key` is an already open key, or one of the predefined HKEY_* constants.

`sub_key` is a string that must be a subkey of the key identified by the `key` parameter. This value must not be `None`, and the key may not have subkeys.

*This method can not delete keys with subkeys.*

If the method succeeds, the entire key, including all of its values, is removed. If the method fails, an OSError exception is raised.

*Changed in version 3.3:* See [above](#).

`winreg.DeleteKeyEx(key, sub_key, access=KEY_WOW64_64KEY, reserved=0)`

Deletes the specified key.

**Note:** The `DeleteKeyEx()` function is implemented with the RegDeleteKeyEx Windows API function, which is specific to 64-bit versions of Windows. See the RegDeleteKeyEx documentation.
key is an already open key, or one of the predefined HKEY_* constants.

sub_key is a string that must be a subkey of the key identified by the key parameter. This value must not be None, and the key may not have subkeys.

reserved is a reserved integer, and must be zero. The default is zero.

access is an integer that specifies an access mask that describes the desired security access for the key. Default is KEY_WOW64_64KEY. See Access Rights for other allowed values.

This method can not delete keys with subkeys.

If the method succeeds, the entire key, including all of its values, is removed. If the method fails, an OSError exception is raised.

On unsupported Windows versions, NotImplementedError is raised.

New in version 3.2.

Changed in version 3.3: See above.

winreg. DeleteValue(key, value)
    Removes a named value from a registry key.

key is an already open key, or one of the predefined HKEY_* constants.

value is a string that identifies the value to remove.

winreg. EnumKey(key, index)
Enumerates subkeys of an open registry key, returning a string.

`key` is an already open key, or one of the predefined `HKEY_*` constants.

`index` is an integer that identifies the index of the key to retrieve.

The function retrieves the name of one subkey each time it is called. It is typically called repeatedly until an `OSError` exception is raised, indicating, no more values are available.

*Changed in version 3.3:* See above.

```python
winreg.EnumValue(key, index)
```

Enumerates values of an open registry key, returning a tuple.

`key` is an already open key, or one of the predefined `HKEY_*` constants.

`index` is an integer that identifies the index of the value to retrieve.

The function retrieves the name of one subkey each time it is called. It is typically called repeatedly, until an `OSError` exception is raised, indicating no more values.

The result is a tuple of 3 items:

<table>
<thead>
<tr>
<th>Index</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>A string that identifies the value name</td>
</tr>
<tr>
<td>1</td>
<td>An object that holds the value data, and whose type depends on the underlying registry type</td>
</tr>
<tr>
<td>2</td>
<td>An integer that identifies the type of the value data (see table in docs for <code>SetValueEx()</code>)</td>
</tr>
</tbody>
</table>
**Changed in version 3.3:** See above.

**winreg.**`ExpandEnvironmentStrings(str)`

Expands environment variable placeholders `%NAME%` in strings like `REG_EXPAND_SZ`:

```python
>>> ExpandEnvironmentStrings('%windir%')
'C:\Windows'
```

**winreg.**`FlushKey(key)`

Writes all the attributes of a key to the registry.

`key` is an already open key, or one of the predefined `HKEY_*` constants.

It is not necessary to call `FlushKey()` to change a key. Registry changes are flushed to disk by the registry using its lazy flusher. Registry changes are also flushed to disk at system shutdown. Unlike `CloseKey()`, the `FlushKey()` method returns only when all the data has been written to the registry. An application should only call `FlushKey()` if it requires absolute certainty that registry changes are on disk.

**Note:** If you don't know whether a `FlushKey()` call is required, it probably isn't.

**winreg.**`LoadKey(key, sub_key, file_name)`

Creates a subkey under the specified key and stores registration information from a specified file into that subkey.

`key` is a handle returned by `ConnectRegistry()` or one of the constants `HKEY_USERS` or `HKEY_LOCAL_MACHINE`. 
**sub_key** is a string that identifies the subkey to load.

**file_name** is the name of the file to load registry data from. This file must have been created with the **SaveKey()** function. Under the file allocation table (FAT) file system, the filename may not have an extension.

A call to **LoadKey()** fails if the calling process does not have the **SE_RESTORE_PRIVILEGE** privilege. Note that privileges are different from permissions – see the **RegLoadKey** documentation for more details.

If **key** is a handle returned by **ConnectRegistry()**, then the path specified in **file_name** is relative to the remote computer.

```plaintext
winreg.OpenKey(key, sub_key, reserved=0, access=KEY_READ)
winreg.OpenKeyEx(key, sub_key, reserved=0, access=KEY_READ)
```

Opens the specified key, returning a handle object.

**key** is an already open key, or one of the predefined **HKEY_* constants**.

**sub_key** is a string that identifies the sub_key to open.

**reserved** is a reserved integer, and must be zero. The default is zero.

**access** is an integer that specifies an access mask that describes the desired security access for the key. Default is **KEY_READ**. See **Access Rights** for other allowed values.

The result is a new handle to the specified key.
If the function fails, `OSError` is raised.

*Changed in version 3.2:* Allow the use of named arguments.

*Changed in version 3.3:* See above.

`winreg.QueryInfoKey(key)`

Returns information about a key, as a tuple.

`key` is an already open key, or one of the predefined `HKEY_*` constants.

The result is a tuple of 3 items:

<table>
<thead>
<tr>
<th>Index</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>An integer giving the number of sub keys this key has.</td>
</tr>
<tr>
<td>1</td>
<td>An integer giving the number of values this key has.</td>
</tr>
<tr>
<td>2</td>
<td>An integer giving when the key was last modified (if available) as 100’s of nanoseconds since Jan 1, 1601.</td>
</tr>
</tbody>
</table>

`winreg.QueryValue(key, sub_key)`

Retrieves the unnamed value for a key, as a string.

`key` is an already open key, or one of the predefined `HKEY_*` constants.

`sub_key` is a string that holds the name of the subkey with which the value is associated. If this parameter is `None` or empty, the function retrieves the value set by the `SetValue()` method for the key identified by `key`.

Values in the registry have name, type, and data components. This method retrieves the data for a key's first value that has a NULL
name. But the underlying API call doesn’t return the type, so always use `QueryValueEx()` if possible.

**winreg. QueryValueEx(key, value_name)**

Retrieves the type and data for a specified value name associated with an open registry key.

`key` is an already open key, or one of the predefined `HKEY_* constants`.

`value_name` is a string indicating the value to query.

The result is a tuple of 2 items:

<table>
<thead>
<tr>
<th>Index</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>The value of the registry item.</td>
</tr>
<tr>
<td>1</td>
<td>An integer giving the registry type for this value (see table in docs for <code>SetValueEx()</code></td>
</tr>
</tbody>
</table>

**winreg. SaveKey(key, file_name)**

Saves the specified key, and all its subkeys to the specified file.

`key` is an already open key, or one of the predefined `HKEY_* constants`.

`file_name` is the name of the file to save registry data to. This file cannot already exist. If this filename includes an extension, it cannot be used on file allocation table (FAT) file systems by the `LoadKey()` method.

If `key` represents a key on a remote computer, the path described by `file_name` is relative to the remote computer. The caller of this method must possess the `SeBackupPrivilege` security
privilege. Note that privileges are different than permissions – see the Conflicts Between User Rights and Permissions documentation for more details.

This function passes NULL for security_attributes to the API.

`winreg.SetValue(key, sub_key, type, value)`

Associates a value with a specified key.

*key* is an already open key, or one of the predefined `HKEY_*` constants.

*sub_key* is a string that names the subkey with which the value is associated.

*type* is an integer that specifies the type of the data. Currently this must be `REG_SZ`, meaning only strings are supported. Use the `SetValueEx()` function for support for other data types.

*value* is a string that specifies the new value.

If the key specified by the *sub_key* parameter does not exist, the SetValue function creates it.

Value lengths are limited by available memory. Long values (more than 2048 bytes) should be stored as files with the filenames stored in the configuration registry. This helps the registry perform efficiently.

The key identified by the *key* parameter must have been opened with `KEY_SET_VALUE` access.

`winreg.SetValueEx(key, value_name, reserved, type, value)`

Stores data in the value field of an open registry key.
key is an already open key, or one of the predefined HKEY_* constants.

value_name is a string that names the subkey with which the value is associated.

reserved can be anything – zero is always passed to the API.

type is an integer that specifies the type of the data. See Value Types for the available types.

value is a string that specifies the new value.

This method can also set additional value and type information for the specified key. The key identified by the key parameter must have been opened with KEY_SET_VALUE access.

To open the key, use the CreateKey() or OpenKey() methods.

Value lengths are limited by available memory. Long values (more than 2048 bytes) should be stored as files with the filenames stored in the configuration registry. This helps the registry perform efficiently.

winreg.DisableReflectionKey(key)

Disables registry reflection for 32-bit processes running on a 64-bit operating system.

key is an already open key, or one of the predefined HKEY_* constants.

Will generally raise NotImplemented if executed on a 32-bit operating system.
If the key is not on the reflection list, the function succeeds but has no effect. Disabling reflection for a key does not affect reflection of any subkeys.

\[ \text{winreg.} \text{EnableReflectionKey}(key) \]

Restores registry reflection for the specified disabled key.

\textit{key} is an already open key, or one of the predefined \texttt{HKEY_*} constants.

Will generally raise \texttt{NotImplemented} if executed on a 32-bit operating system.

Restoring reflection for a key does not affect reflection of any subkeys.

\[ \text{winreg.} \text{QueryReflectionKey}(key) \]

Determines the reflection state for the specified key.

\textit{key} is an already open key, or one of the predefined \texttt{HKEY_*} constants.

Returns \texttt{True} if reflection is disabled.

Will generally raise \texttt{NotImplemented} if executed on a 32-bit operating system.
34.3.2. Constants

The following constants are defined for use in many _winreg functions.

34.3.2.1. HKEY_* Constants

winreg.\**HKEY_CLASSES_ROOT**
Registry entries subordinate to this key define types (or classes) of documents and the properties associated with those types. Shell and COM applications use the information stored under this key.

winreg.\**HKEY_CURRENT_USER**
Registry entries subordinate to this key define the preferences of the current user. These preferences include the settings of environment variables, data about program groups, colors, printers, network connections, and application preferences.

winreg.\**HKEY_LOCAL_MACHINE**
Registry entries subordinate to this key define the physical state of the computer, including data about the bus type, system memory, and installed hardware and software.

winreg.\**HKEY_USERS**
Registry entries subordinate to this key define the default user configuration for new users on the local computer and the user configuration for the current user.

winreg.\**HKEY_PERFORMANCE_DATA**
Registry entries subordinate to this key allow you to access performance data. The data is not actually stored in the registry;
the registry functions cause the system to collect the data from its source.

winreg. **HKEY_CURRENT_CONFIG**
Contains information about the current hardware profile of the local computer system.

winreg. **HKEY_DYN_DATA**
This key is not used in versions of Windows after 98.

### 34.3.2.2. Access Rights

For more information, see *Registry Key Security and Access*.

winreg. **KEY_ALL_ACCESS**
Combines the **STANDARD_RIGHTS_REQUIRED, KEY_QUERY_VALUE, KEY_SET_VALUE, KEY_CREATE_SUB_KEY, KEY_ENUMERATE_SUB_KEYS, KEY_NOTIFY, and KEY_CREATE_LINK** access rights.

winreg. **KEY_WRITE**
Combines the **STANDARD_RIGHTS_WRITE, KEY_SET_VALUE, and KEY_CREATE_SUB_KEY** access rights.

winreg. **KEY_READ**
Combines the **STANDARD_RIGHTS_READ, KEY_QUERY_VALUE, KEY_ENUMERATE_SUB_KEYS, and KEY_NOTIFY** values.

winreg. **KEY_EXECUTE**
Equivalent to **KEY_READ**.

winreg. **KEY_QUERY_VALUE**
Required to query the values of a registry key.

\[\text{winreg.} \text{KEY\_SET\_VALUE}\]
Required to create, delete, or set a registry value.

\[\text{winreg.} \text{KEY\_CREATE\_SUB\_KEY}\]
Required to create a subkey of a registry key.

\[\text{winreg.} \text{KEY\_ENUMERATE\_SUB\_KEYS}\]
Required to enumerate the subkeys of a registry key.

\[\text{winreg.} \text{KEY\_NOTIFY}\]
Required to request change notifications for a registry key or for subkeys of a registry key.

\[\text{winreg.} \text{KEY\_CREATE\_LINK}\]
Reserved for system use.

34.3.2.2.1. 64-bit Specific

For more information, see Accessing an Alternate Registry View.

\[\text{winreg.} \text{KEY\_WOW64\_64KEY}\]
Indicates that an application on 64-bit Windows should operate on the 64-bit registry view.

\[\text{winreg.} \text{KEY\_WOW64\_32KEY}\]
Indicates that an application on 64-bit Windows should operate on the 32-bit registry view.

34.3.2.3. Value Types

For more information, see Registry Value Types.
winreg.**REG_BINARY**

Binary data in any form.

winreg.**REG_DWORD**

32-bit number.

winreg.**REG_DWORD_LITTLE_ENDIAN**

A 32-bit number in little-endian format. Equivalent to **REG_DWORD**.

winreg.**REG_DWORD_BIG_ENDIAN**

A 32-bit number in big-endian format.

winreg.**REG_EXPAND_SZ**

Null-terminated string containing references to environment variables (%PATH%).

winreg.**REG_LINK**

A Unicode symbolic link.

winreg.**REG_MULTI_SZ**

A sequence of null-terminated strings, terminated by two null characters. (Python handles this termination automatically.)

winreg.**REG_NONE**

No defined value type.

winreg.**REG_QWORD**

A 64-bit number.

*New in version 3.6.*

winreg.**REG_QWORD_LITTLE_ENDIAN**

A 64-bit number in little-endian format. Equivalent to **REG_QWORD**.
New in version 3.6.

winreg. **REGRESOURCELIST**
  A device-driver resource list.

winreg. **REGFULLRESOURCEDESCRIPTOR**
  A hardware setting.

winreg. **REGRESOURCEREQUIREDLIST**
  A hardware resource list.

winreg. **REGSZ**
  A null-terminated string.
34.3.3. Registry Handle Objects

This object wraps a Windows HKEY object, automatically closing it when the object is destroyed. To guarantee cleanup, you can call either the `Close()` method on the object, or the `CloseKey()` function.

All registry functions in this module return one of these objects.

All registry functions in this module which accept a handle object also accept an integer, however, use of the handle object is encouraged.

Handle objects provide semantics for `__bool__()` – thus

```python
if handle:
    print("Yes")
```

will print `Yes` if the handle is currently valid (has not been closed or detached).

The object also support comparison semantics, so handle objects will compare true if they both reference the same underlying Windows handle value.

Handle objects can be converted to an integer (e.g., using the built-in `int()` function), in which case the underlying Windows handle value is returned. You can also use the `Detach()` method to return the integer handle, and also disconnect the Windows handle from the handle object.

`PyHKEY.close()`

Closes the underlying Windows handle.
If the handle is already closed, no error is raised.

**PyHKEY.** **Detach()**

Detaches the Windows handle from the handle object.

The result is an integer that holds the value of the handle before it is detached. If the handle is already detached or closed, this will return zero.

After calling this function, the handle is effectively invalidated, but the handle is not closed. You would call this function when you need the underlying Win32 handle to exist beyond the lifetime of the handle object.

**PyHKEY.** **__enter__()**

**PyHKEY.** **__exit__(***exc_info**)

The HKEY object implements **__enter__()** and **__exit__()** and thus supports the context protocol for the **with** statement:

```
with OpenKey(HKEY_LOCAL_MACHINE, "foo") as key:
    ...
    # work with key
```

will automatically close **key** when control leaves the **with** block.
34.4. **winsound** — Sound-playing interface for Windows

The **winsound** module provides access to the basic sound-playing machinery provided by Windows platforms. It includes functions and several constants.

**winsound.** **Beep**(frequency, duration)

Beep the PC’s speaker. The *frequency* parameter specifies frequency, in hertz, of the sound, and must be in the range 37 through 32,767. The *duration* parameter specifies the number of milliseconds the sound should last. If the system is not able to beep the speaker, **RuntimeError** is raised.

**winsound.** **PlaySound**(sound, flags)

Call the underlying PlaySound() function from the Platform API. The *sound* parameter may be a filename, a system sound alias, audio data as a *bytes-like object*, or **None**. Its interpretation depends on the value of *flags*, which can be a bitwise ORed combination of the constants described below. If the *sound* parameter is **None**, any currently playing waveform sound is stopped. If the system indicates an error, **RuntimeError** is raised.

**winsound.** **MessageBeep**(type=MB_OK)

Call the underlying MessageBeep() function from the Platform API. This plays a sound as specified in the registry. The *type* argument specifies which sound to play; possible values are -1, **MB_ICONASTERISK**, **MB_ICONEXCLAMATION**, **MB_ICONHAND**, **MB_ICONERROR**, **MB_ICONQUESTION**, **MB_ICONWARNING**, **MB_ICONINFORMATION**.
MB_ICONQUESTION, and MB_OK, all described below. The value -1 produces a “simple beep”; this is the final fallback if a sound cannot be played otherwise. If the system indicates an error, RuntimeError is raised.

winsound. **SND_FILENAME**

The sound parameter is the name of a WAV file. Do not use with **SND_ALIAS**.

winsound. **SND_ALIAS**

The sound parameter is a sound association name from the registry. If the registry contains no such name, play the system default sound unless **SND_NODEFAULT** is also specified. If no default sound is registered, raise RuntimeError. Do not use with **SND_FILENAME**.

All Win32 systems support at least the following; most systems support many more:

<table>
<thead>
<tr>
<th>PlaySound() name</th>
<th>Corresponding Control Panel Sound name</th>
</tr>
</thead>
<tbody>
<tr>
<td>'SystemAsterisk'</td>
<td>Asterisk</td>
</tr>
<tr>
<td>'SystemExclamation'</td>
<td>Exclamation</td>
</tr>
<tr>
<td>'SystemExit'</td>
<td>Exit Windows</td>
</tr>
<tr>
<td>'SystemHand'</td>
<td>Critical Stop</td>
</tr>
<tr>
<td>'SystemQuestion'</td>
<td>Question</td>
</tr>
</tbody>
</table>

For example:

```
import winsound
#
# Play Windows exit sound.
winsound.PlaySound("SystemExit", winsound.SND_ALIAS)
```
# Probably play Windows default sound, if any is
# * probably isn't the registered name of any sound.
winsound.PlaySound("*", winsound.SND_ALIAS)

winsound.SND_LOOP
Play the sound repeatedly. The SND_ASYNC flag must also be used to avoid blocking. Cannot be used with SND_MEMORY.

winsound.SND_MEMORY
The sound parameter to PlaySound() is a memory image of a WAV file, as a bytes-like object.

Note: This module does not support playing from a memory image asynchronously, so a combination of this flag and SND_ASYNC will raise RuntimeError.

winsound.SND_PURGE
Stop playing all instances of the specified sound.

Note: This flag is not supported on modern Windows platforms.

winsound.SND_ASYNC
Return immediately, allowing sounds to play asynchronously.

winsound.SND_NODEFAULT
If the specified sound cannot be found, do not play the system default sound.

winsound.SND_NOSTOP
Do not interrupt sounds currently playing.
\texttt{winsound.\texttt{SND\_NOWAIT}}

Return immediately if the sound driver is busy.

\textbf{Note:} This flag is not supported on modern Windows platforms.

\texttt{winsound.\texttt{MB\_ICONASTERISK}}

Play the \texttt{SystemDefault} sound.

\texttt{winsound.\texttt{MB\_ICONEXCLAMATION}}

Play the \texttt{SystemExclamation} sound.

\texttt{winsound.\texttt{MB\_ICONHAND}}

Play the \texttt{SystemHand} sound.

\texttt{winsound.\texttt{MB\_ICONQUESTION}}

Play the \texttt{SystemQuestion} sound.

\texttt{winsound.\texttt{MB\_OK}}

Play the \texttt{SystemDefault} sound.
35. Unix Specific Services

The modules described in this chapter provide interfaces to features that are unique to the Unix operating system, or in some cases to some or many variants of it. Here's an overview:

- **35.1. posix — The most common POSIX system calls**
  - 35.1.1. Large File Support
  - 35.1.2. Notable Module Contents
- **35.2. pwd — The password database**
- **35.3. spwd — The shadow password database**
- **35.4. grp — The group database**
- **35.5. crypt — Function to check Unix passwords**
  - 35.5.1. Hashing Methods
  - 35.5.2. Module Attributes
  - 35.5.3. Module Functions
  - 35.5.4. Examples
- **35.6. termios — POSIX style tty control**
  - 35.6.1. Example
- **35.7. tty — Terminal control functions**
- **35.8. pty — Pseudo-terminal utilities**
  - 35.8.1. Example
- **35.9. fcntl — The fcntl and ioctl system calls**
- **35.10. pipes — Interface to shell pipelines**
  - 35.10.1. Template Objects
- **35.11. resource — Resource usage information**
  - 35.11.1. Resource Limits
  - 35.11.2. Resource Usage
- **35.12. nis — Interface to Sun's NIS (Yellow Pages)**
- **35.13. syslog — Unix syslog library routines**
  - 35.13.1. Examples
    - 35.13.1.1. Simple example
35.1. **posix** — The most common POSIX system calls

This module provides access to operating system functionality that is standardized by the C Standard and the POSIX standard (a thinly disguised Unix interface).

**Do not import this module directly.** Instead, import the module `os`, which provides a *portable* version of this interface. On Unix, the `os` module provides a superset of the `posix` interface. On non-Unix operating systems the `posix` module is not available, but a subset is always available through the `os` interface. Once `os` is imported, there is *no* performance penalty in using it instead of `posix`. In addition, `os` provides some additional functionality, such as automatically calling `putenv()` when an entry in `os.environ` is changed.

Errors are reported as exceptions; the usual exceptions are given for type errors, while errors reported by the system calls raise `OSError`.
35.1.1. Large File Support

Several operating systems (including AIX, HP-UX, Irix and Solaris) provide support for files that are larger than 2 GiB from a C programming model where int and long are 32-bit values. This is typically accomplished by defining the relevant size and offset types as 64-bit values. Such files are sometimes referred to as large files.

Large file support is enabled in Python when the size of an off_t is larger than a long and the long long type is available and is at least as large as an off_t. It may be necessary to configure and compile Python with certain compiler flags to enable this mode. For example, it is enabled by default with recent versions of Irix, but with Solaris 2.6 and 2.7 you need to do something like:

```
CFLAGS="`getconf LFS_CFLAGS`" OPT="-g -O2 $CFLAGS"
./configure
```

On large-file-capable Linux systems, this might work:

```
CFLAGS=''-D_LARGEFILE64_SOURCE -D_FILE_OFFSET_BITS=64'
./configure
```
35.1.2. Notable Module Contents

In addition to many functions described in the os module documentation, posix defines the following data item:

posix.environ

A dictionary representing the string environment at the time the interpreter was started. Keys and values are bytes on Unix and str on Windows. For example, environ[b'HOME'] (environ['HOME'] on Windows) is the pathname of your home directory, equivalent to getenv("HOME") in C.

Modifying this dictionary does not affect the string environment passed on by execv(), popen() or system(); if you need to change the environment, pass environ to execve() or add variable assignments and export statements to the command string for system() or popen().

*Changed in version 3.2:* On Unix, keys and values are bytes.

**Note:** The os module provides an alternate implementation of environ which updates the environment on modification. Note also that updating os.environ will render this dictionary obsolete. Use of the os module version of this is recommended over direct access to the posix module.
35.2. `pwd` — The password database

This module provides access to the Unix user account and password database. It is available on all Unix versions.

Password database entries are reported as a tuple-like object, whose attributes correspond to the members of the `passwd` structure (Attribute field below, see `<pwd.h>`):

<table>
<thead>
<tr>
<th>Index</th>
<th>Attribute</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td><code>pw_name</code></td>
<td>Login name</td>
</tr>
<tr>
<td>1</td>
<td><code>pw_passwd</code></td>
<td>Optional encrypted password</td>
</tr>
<tr>
<td>2</td>
<td><code>pw_uid</code></td>
<td>Numerical user ID</td>
</tr>
<tr>
<td>3</td>
<td><code>pw_gid</code></td>
<td>Numerical group ID</td>
</tr>
<tr>
<td>4</td>
<td><code>pw_gecos</code></td>
<td>User name or comment field</td>
</tr>
<tr>
<td>5</td>
<td><code>pw_dir</code></td>
<td>User home directory</td>
</tr>
<tr>
<td>6</td>
<td><code>pw_shell</code></td>
<td>User command interpreter</td>
</tr>
</tbody>
</table>

The uid and gid items are integers, all others are strings. `KeyError` is raised if the entry asked for cannot be found.

**Note:** In traditional Unix the field `pw_passwd` usually contains a password encrypted with a DES derived algorithm (see module `crypt`). However most modern unices use a so-called `shadow` password system. On those unices the `pw_passwd` field only contains an asterisk ("*"") or the letter 'x' where the encrypted
password is stored in a file /etc/shadow which is not world readable. Whether the \texttt{pw\_passwd} field contains anything useful is system-dependent. If available, the \texttt{spwd} module should be used where access to the encrypted password is required.

It defines the following items:

\begin{verbatim}
\texttt{pwd. getpwuid(uid)}
\end{verbatim}

Return the password database entry for the given numeric user ID.

\begin{verbatim}
\texttt{pwd. getpwnam(name)}
\end{verbatim}

Return the password database entry for the given user name.

\begin{verbatim}
\texttt{pwd. getpwall()}
\end{verbatim}

Return a list of all available password database entries, in arbitrary order.

\textbf{See also:}

\textbf{Module} \texttt{grp}

An interface to the group database, similar to this.

\textbf{Module} \texttt{spwd}

An interface to the shadow password database, similar to this.
35.3. **spwd** — The shadow password database

This module provides access to the Unix shadow password database. It is available on various Unix versions.

You must have enough privileges to access the shadow password database (this usually means you have to be root).

Shadow password database entries are reported as a tuple-like object, whose attributes correspond to the members of the `spwd` structure (Attribute field below, see `<shadow.h>`):

<table>
<thead>
<tr>
<th>Index</th>
<th>Attribute</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td><code>sp_namp</code></td>
<td>Login name</td>
</tr>
<tr>
<td>1</td>
<td><code>sp_pwdp</code></td>
<td>Encrypted password</td>
</tr>
<tr>
<td>2</td>
<td><code>sp_lstchg</code></td>
<td>Date of last change</td>
</tr>
<tr>
<td>3</td>
<td><code>sp_min</code></td>
<td>Minimal number of days between changes</td>
</tr>
<tr>
<td>4</td>
<td><code>sp_max</code></td>
<td>Maximum number of days between changes</td>
</tr>
<tr>
<td>5</td>
<td><code>sp_warn</code></td>
<td>Number of days before password expires to warn user about it</td>
</tr>
<tr>
<td>6</td>
<td><code>sp_inact</code></td>
<td>Number of days after password expires until account is disabled</td>
</tr>
<tr>
<td>7</td>
<td><code>sp_expire</code></td>
<td>Number of days since 1970-01-01 when account expires</td>
</tr>
<tr>
<td>8</td>
<td><code>sp_flag</code></td>
<td>Reserved</td>
</tr>
</tbody>
</table>
The `sp_namp` and `sp_pwdp` items are strings, all others are integers. 
`KeyError` is raised if the entry asked for cannot be found.

The following functions are defined:

```
spwd.getspnam(name)
```

Return the shadow password database entry for the given user name.

*Changed in version 3.6:* Raises a `PermissionError` instead of `KeyError` if the user doesn't have privileges.

```
spwd.getspall()
```

Return a list of all available shadow password database entries, in arbitrary order.

**See also:**

- **Module `grp`**
  - An interface to the group database, similar to this.

- **Module `pwd`**
  - An interface to the normal password database, similar to this.
35.4. `grp` — The group database

This module provides access to the Unix group database. It is available on all Unix versions.

Group database entries are reported as a tuple-like object, whose attributes correspond to the members of the `group` structure (Attribute field below, see `<pwd.h>`):

<table>
<thead>
<tr>
<th>Index</th>
<th>Attribute</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>gr_name</td>
<td>the name of the group</td>
</tr>
<tr>
<td>1</td>
<td>gr_passwd</td>
<td>the (encrypted) group password; often empty</td>
</tr>
<tr>
<td>2</td>
<td>gr_gid</td>
<td>the numerical group ID</td>
</tr>
<tr>
<td>3</td>
<td>gr_mem</td>
<td>all the group member’s user names</td>
</tr>
</tbody>
</table>

The gid is an integer, name and password are strings, and the member list is a list of strings. (Note that most users are not explicitly listed as members of the group they are in according to the password database. Check both databases to get complete membership information. Also note that a `gr_name` that starts with a `+` or `-` is likely to be a YP/NIS reference and may not be accessible via `getgrnam()` or `getgrgid()`.)

It defines the following items:

```
grp.getgrgid(gid)
```

Return the group database entry for the given numeric group ID. `KeyError` is raised if the entry asked for cannot be found.
Deprecated since version 3.6: Since Python 3.6 the support of non-integer arguments like floats or strings in `getgrgid()` is deprecated.

**grp.** `getgrnam(name)`

Return the group database entry for the given group name. `KeyError` is raised if the entry asked for cannot be found.

**grp.** `getgrall()`

Return a list of all available group entries, in arbitrary order.

**See also:**

- **Module** `pwd`
  
  An interface to the user database, similar to this.

- **Module** `spwd`
  
  An interface to the shadow password database, similar to this.
35.5. `crypt` — Function to check Unix passwords

**Source code:** `Lib/crypt.py`

This module implements an interface to the `crypt(3)` routine, which is a one-way hash function based upon a modified DES algorithm; see the Unix man page for further details. Possible uses include storing hashed passwords so you can check passwords without storing the actual password, or attempting to crack Unix passwords with a dictionary.

Notice that the behavior of this module depends on the actual implementation of the `crypt(3)` routine in the running system. Therefore, any extensions available on the current implementation will also be available on this module.
35.5.1. Hashing Methods

*New in version 3.3.*

The `crypt` module defines the list of hashing methods (not all methods are available on all platforms):

```plaintext
crypt.METHOD_SHA512
    A Modular Crypt Format method with 16 character salt and 86 character hash. This is the strongest method.

crypt.METHOD_SHA256
    Another Modular Crypt Format method with 16 character salt and 43 character hash.

crypt.METHOD_MD5
    Another Modular Crypt Format method with 8 character salt and 22 character hash.

crypt.METHOD_CRYPT
    The traditional method with a 2 character salt and 13 characters of hash. This is the weakest method.
```
35.5.2. Module Attributes

*New in version 3.3.*

crypt.\texttt{methods}

A list of available password hashing algorithms, as \texttt{crypt.METHOD_*} objects. This list is sorted from strongest to weakest.
35.5.3. Module Functions

The `crypt` module defines the following functions:

```python
crypt.crypt(word, salt=None)
```

`word` will usually be a user’s password as typed at a prompt or in a graphical interface. The optional `salt` is either a string as returned from `mksalt()`, one of the `crypt.METHOD_*` values (though not all may be available on all platforms), or a full encrypted password including salt, as returned by this function. If `salt` is not provided, the strongest method will be used (as returned by `methods()`).

Checking a password is usually done by passing the plain-text password as `word` and the full results of a previous `crypt()` call, which should be the same as the results of this call.

`salt` (either a random 2 or 16 character string, possibly prefixed with `$digit$` to indicate the method) which will be used to perturb the encryption algorithm. The characters in `salt` must be in the set `[/a-zA-Z0-9]`, with the exception of Modular Crypt Format which prefixes a `$digit$`.

Returns the hashed password as a string, which will be composed of characters from the same alphabet as the salt.

Since a few `crypt(3)` extensions allow different values, with different sizes in the `salt`, it is recommended to use the full crypted password as salt when checking for a password.

*Changed in version 3.3: Accept `crypt.METHOD_*` values in addition to strings for `salt`.***
crypt.mksalt(method=None)

Return a randomly generated salt of the specified method. If no method is given, the strongest method available as returned by methods() is used.

The return value is a string either of 2 characters in length for crypt.METHOD_CRYPT, or 19 characters starting with $digit$ and 16 random characters from the set [./a-zA-Z0-9], suitable for passing as the salt argument to crypt().

New in version 3.3.
35.5.4. Examples

A simple example illustrating typical use (a constant-time comparison operation is needed to limit exposure to timing attacks. \texttt{hmac.compare_digest()} is suitable for this purpose):

```python
import pwd
import crypt
import getpass
from hmac import compare_digest as compare_hash

def login():
    username = input('Python login: ')
    cryptedpasswd = pwd.getpwnam(username)[1]
    if cryptedpasswd:
        if cryptedpasswd == 'x' or cryptedpasswd ==
            raise ValueError('no support for shadow
    cleartext = getpass.getpass()
    return compare_hash(crypt.crypt(cleartext, c
else:
    return True
```

To generate a hash of a password using the strongest available method and check it against the original:

```python
import crypt
from hmac import compare_digest as compare_hash

hashed = crypt.crypt(plaintext)
if not compare_hash(hashed, crypt.crypt(plaintext, h
    raise ValueError("hashed version doesn't validat
```
35.6. termios — POSIX style tty control

This module provides an interface to the POSIX calls for tty I/O control. For a complete description of these calls, see termios(2) Unix manual page. It is only available for those Unix versions that support POSIX termios style tty I/O control configured during installation.

All functions in this module take a file descriptor \( fd \) as their first argument. This can be an integer file descriptor, such as returned by sys.stdin.fileno(), or a file object, such as sys.stdin itself.

This module also defines all the constants needed to work with the functions provided here; these have the same name as their counterparts in C. Please refer to your system documentation for more information on using these terminal control interfaces.

The module defines the following functions:

termios.tcgetattr(\( fd \))

Return a list containing the tty attributes for file descriptor \( fd \), as follows: [iflag, oflag, cflag, lflag, ispeed, ospeed, cc] where cc is a list of the tty special characters (each a string of length 1, except the items with indices VMIN and VTIME, which are integers when these fields are defined). The interpretation of the flags and the speeds as well as the indexing in the cc array must be done using the symbolic constants defined in the termios module.

termios.tcsetattr(\( fd, when, attributes \))
Set the tty attributes for file descriptor \textit{fd} from the \textit{attributes}, which is a list like the one returned by \texttt{tcgetattr()}. The \textit{when} argument determines when the attributes are changed: TCSANOW to change immediately, TCSADRAIN to change after transmitting all queued output, or TCSAFLUSH to change after transmitting all queued output and discarding all queued input.

\texttt{termios.tcsendbreak(fd, duration)}

Send a break on file descriptor \textit{fd}. A zero \textit{duration} sends a break for 0.25 – 0.5 seconds; a nonzero \textit{duration} has a system dependent meaning.

\texttt{termios.tcdrain(fd)}

Wait until all output written to file descriptor \textit{fd} has been transmitted.

\texttt{termios.tcflush(fd, queue)}

Discard queued data on file descriptor \textit{fd}. The \textit{queue} selector specifies which queue: TCIFLUSH for the input queue, TCOFLUSH for the output queue, or TCIOFLUSH for both queues.

\texttt{termios.tcflow(fd, action)}

Suspend or resume input or output on file descriptor \textit{fd}. The \textit{action} argument can be TC0OFF to suspend output, TC0ON to restart output, TC1OFF to suspend input, or TC1ON to restart input.

\textbf{See also:}

\textbf{Module \textit{tty}}

Convenience functions for common terminal control operations.
35.6.1. Example

Here's a function that prompts for a password with echoing turned off. Note the technique using a separate tcgetattr() call and a try ... finally statement to ensure that the old tty attributes are restored exactly no matter what happens:

```python
def getpass(prompt="Password: "):
    import termios, sys
    fd = sys.stdin.fileno()
    old = termios.tcgetattr(fd)
    new = termios.tcgetattr(fd)
    try:
        termios.tcsetattr(fd, termios.TCSADRAIN, new)
        passwd = input(prompt)
    finally:
        termios.tcsetattr(fd, termios.TCSADRAIN, old)
    return passwd
```
35. Unix Specific Services
35.7. **tty** — Terminal control functions

**Source code:** Lib/tty.py

The `tty` module defines functions for putting the tty into cbreak and raw modes.

Because it requires the `termios` module, it will work only on Unix.

The `tty` module defines the following functions:

```python
tty.setraw(fd, when=termios.TCSAFLUSH)
```

Change the mode of the file descriptor `fd` to raw. If `when` is omitted, it defaults to `termios.TCSAFLUSH`, and is passed to `termios.tcsetattr()`.

```python
tty.setcbreak(fd, when=termios.TCSAFLUSH)
```

Change the mode of file descriptor `fd` to cbreak. If `when` is omitted, it defaults to `termios.TCSAFLUSH`, and is passed to `termios.tcsetattr()`.

**See also:**

**Module** `termios`

Low-level terminal control interface.
35.8. pty — Pseudo-terminal utilities

Source code: Lib/pty.py

The pty module defines operations for handling the pseudo-terminal concept: starting another process and being able to write to and read from its controlling terminal programmatically.

Because pseudo-terminal handling is highly platform dependent, there is code to do it only for Linux. (The Linux code is supposed to work on other platforms, but hasn’t been tested yet.)

The pty module defines the following functions:

**pty.fork()**
Fork. Connect the child’s controlling terminal to a pseudo-terminal. Return value is (pid, fd). Note that the child gets pid 0, and the fd is invalid. The parent’s return value is the pid of the child, and fd is a file descriptor connected to the child’s controlling terminal (and also to the child’s standard input and output).

**pty.openpty()**
Open a new pseudo-terminal pair, using os.openpty() if possible, or emulation code for generic Unix systems. Return a pair of file descriptors (master, slave), for the master and the slave end, respectively.

**pty.spawn(argv[, master_read[, stdin_read]])**
Spawn a process, and connect its controlling terminal with the
current process’s standard io. This is often used to baffle programs which insist on reading from the controlling terminal.

The functions *master_read* and *stdin_read* should be functions which read from a file descriptor. The defaults try to read 1024 bytes each time they are called.

*Changed in version 3.4: spawn() now returns the status value from os.waitpid() on the child process.*
35.8.1. Example

The following program acts like the Unix command `script(1)`, using a pseudo-terminal to record all input and output of a terminal session in a “typescript”.

```python
import argparse
import os
import pty
import sys
import time

parser = argparse.ArgumentParser()
parser.add_argument('-a', dest='append', action='store_true',
parser.add_argument('-p', dest='use_python', action='store_true',
parser.add_argument('filename', nargs='?', default='typescript',
options = parser.parse_args()

shell = sys.executable if options.use_python else os
filename = options.filename
mode = 'ab' if options.append else 'wb'

with open(filename, mode) as script:
    def read(fd):
        data = os.read(fd, 1024)
        script.write(data)
        return data

    print('Script started, file is', filename)
    script.write(('Script started on %s\n' % time.asctime
pty.spawn(shell, read)

    script.write(('Script done on %s\n' % time.asctime
print('Script done, file is', filename)
```
35.9. `fcntl` — The `fcntl` and `ioctl` system calls

This module performs file control and I/O control on file descriptors. It is an interface to the `fcntl()` and `ioctl()` Unix routines. For a complete description of these calls, see `fcntl(2)` and `ioctl(2)` Unix manual pages.

All functions in this module take a file descriptor `fd` as their first argument. This can be an integer file descriptor, such as returned by `sys.stdin.fileno()`, or an `io.IOBase` object, such as `sys.stdin` itself, which provides a `fileno()` that returns a genuine file descriptor.

*Changed in version 3.3:* Operations in this module used to raise an `IOError` where they now raise an `OSError`.

The module defines the following functions:

**fcntl**. `fcntl(fd, cmd, arg=0)`

Perform the operation `cmd` on file descriptor `fd` (file objects providing a `fileno()` method are accepted as well). The values used for `cmd` are operating system dependent, and are available as constants in the `fcntl` module, using the same names as used in the relevant C header files. The argument `arg` can either be an integer value, or a `bytes` object. With an integer value, the return value of this function is the integer return value of the C `fcntl()` call. When the argument is bytes it represents a binary structure, e.g. created by `struct.pack()`. The binary data is copied to a
buffer whose address is passed to the C `fcntl()` call. The return value after a successful call is the contents of the buffer, converted to a bytes object. The length of the returned object will be the same as the length of the arg argument. This is limited to 1024 bytes. If the information returned in the buffer by the operating system is larger than 1024 bytes, this is most likely to result in a segmentation violation or a more subtle data corruption.

If the `fcntl()` fails, an OSError is raised.

```
fcntl.ioctl(fd, request, arg=0, mutate_flag=True)
```

This function is identical to the `fcntl()` function, except that the argument handling is even more complicated.

The request parameter is limited to values that can fit in 32-bits. Additional constants of interest for use as the request argument can be found in the `termios` module, under the same names as used in the relevant C header files.

The parameter arg can be one of an integer, an object supporting the read-only buffer interface (like bytes) or an object supporting the read-write buffer interface (like bytearray).

In all but the last case, behaviour is as for the `fcntl()` function.

If a mutable buffer is passed, then the behaviour is determined by the value of the mutate_flag parameter.

If it is false, the buffer’s mutability is ignored and behaviour is as for a read-only buffer, except that the 1024 byte limit mentioned above is avoided – so long as the buffer you pass is at least as long as what the operating system wants to put there, things should work.
If \textit{mutate\_flag} is true (the default), then the buffer is (in effect) passed to the underlying \texttt{ioctl()} system call, the latter’s return code is passed back to the calling Python, and the buffer’s new contents reflect the action of the \texttt{ioctl()}. This is a slight simplification, because if the supplied buffer is less than 1024 bytes long it is first copied into a static buffer 1024 bytes long which is then passed to \texttt{ioctl()} and copied back into the supplied buffer.

If the \texttt{ioctl()} fails, an \texttt{OSError} exception is raised.

An example:

```python
>>> import array, fcntl, struct, termios, os
>>> os.getpgrp()
13341
>>> struct.unpack('h', fcntl.ioctl(0, termios.TIOCGPGRP))
13341
>>> buf = array.array('h', [0])
>>> fcntl.ioctl(0, termios.TIOCGPGRP, buf, 1)
0
>>> buf
array('h', [13341])
```

\texttt{fcntl.flock(fd, operation)}

Perform the lock operation \textit{operation} on file descriptor \textit{fd} (file objects providing a \texttt{fileno()} method are accepted as well). See the Unix manual \texttt{flock(2)} for details. (On some systems, this function is emulated using \texttt{fcntl()}.)

If the \texttt{flock()} fails, an \texttt{OSError} exception is raised.

\texttt{fcntl.lockf(fd, cmd, len=0, start=0, whence=0)}

This is essentially a wrapper around the \texttt{fcntl()} locking calls. \textit{fd}
is the file descriptor of the file to lock or unlock, and `cmd` is one of the following values:

- LOCK_UN – unlock
- LOCK_SH – acquire a shared lock
- LOCK_EX – acquire an exclusive lock

When `cmd` is LOCK_SH or LOCK_EX, it can also be bitwise ORed with LOCK_NB to avoid blocking on lock acquisition. If LOCK_NB is used and the lock cannot be acquired, an `OSError` will be raised and the exception will have an `errno` attribute set to EACCES or EAGAIN (depending on the operating system; for portability, check for both values). On at least some systems, LOCK_EX can only be used if the file descriptor refers to a file opened for writing.

`len` is the number of bytes to lock, `start` is the byte offset at which the lock starts, relative to `whence`, and `whence` is as with `io.IOBase.seek()`, specifically:

- `0` – relative to the start of the file (`os.SEEK_SET`)
- `1` – relative to the current buffer position (`os.SEEK_CUR`)
- `2` – relative to the end of the file (`os.SEEK_END`)

The default for `start` is `0`, which means to start at the beginning of the file. The default for `len` is `0` which means to lock to the end of the file. The default for `whence` is also `0`.

Examples (all on a SVR4 compliant system):

```python
import struct, fcntl, os
f = open(...)  # open the file
rv = fcntl.fcntl(f, fcntl.F_SETFL, os.O_NDELAY)  # Set non-blocking
lockdata = struct.pack('hhllhh', fcntl.F_WRLCK, 0, 0, 0, 0, 0)
```
rv = fcntl.fcntl(f, fcntl.F_SETLKW, lockdata)

Note that in the first example the return value variable `rv` will hold an integer value; in the second example it will hold a `bytes` object. The structure lay-out for the `lockdata` variable is system dependent — therefore using the `flock()` call may be better.

**See also:**

**Module os**

If the locking flags `O_SHLOCK` and `O_EXLOCK` are present in the `os` module (on BSD only), the `os.open()` function provides an alternative to the `lockf()` and `flock()` functions.
35.10. **pipes** — Interface to shell pipelines

Source code: Lib/pipes.py

The **pipes** module defines a class to abstract the concept of a **pipeline** — a sequence of converters from one file to another.

Because the module uses **/bin/sh** command lines, a POSIX or compatible shell for **os.system()** and **os.popen()** is required.

The **pipes** module defines the following class:

```python
class pipes.Template
    An abstraction of a pipeline.
```

Example:

```python
>>> import pipes
>>> t = pipes.Template()
>>> t.append('tr a-z A-Z', '--')
>>> f = t.open('pipefile', 'w')
>>> f.write('hello world')
>>> f.close()
>>> open('pipefile').read()
'HELLO WORLD'
```
35.10.1. Template Objects

Template objects following methods:

**Template.** `reset()`

Restore a pipeline template to its initial state.

**Template.** `clone()`

Return a new, equivalent, pipeline template.

**Template.** `debug(flag)`

If `flag` is true, turn debugging on. Otherwise, turn debugging off. When debugging is on, commands to be executed are printed, and the shell is given `set -x` command to be more verbose.

**Template.** `append(cmd, kind)`

Append a new action at the end. The `cmd` variable must be a valid bourne shell command. The `kind` variable consists of two letters. The first letter can be either of ‘-’ (which means the command reads its standard input), ‘f’ (which means the commands reads a given file on the command line) or ‘.’ (which means the commands reads no input, and hence must be first.) Similarly, the second letter can be either of ‘-’ (which means the command writes to standard output), ‘f’ (which means the command writes a file on the command line) or ‘.’ (which means the command does not write anything, and hence must be last.)

**Template.** `prepend(cmd, kind)`

Add a new action at the beginning. See `append()` for explanations of the arguments.
Template. `open(file, mode)`

Return a file-like object, open to file, but read from or written to by the pipeline. Note that only one of 'r', 'w' may be given.

Template. `copy(infile, outfile)`

Copy infile to outfile through the pipe.
35.11. resource — Resource usage information

This module provides basic mechanisms for measuring and controlling system resources utilized by a program.

Symbolic constants are used to specify particular system resources and to request usage information about either the current process or its children.

An OSError is raised on syscall failure.

exception resource.error

A deprecated alias of OSError.

Changed in version 3.3: Following PEP 3151, this class was made an alias of OSError.
35.11.1. Resource Limits

Resources usage can be limited using the `setrlimit()` function described below. Each resource is controlled by a pair of limits: a soft limit and a hard limit. The soft limit is the current limit, and may be lowered or raised by a process over time. The soft limit can never exceed the hard limit. The hard limit can be lowered to any value greater than the soft limit, but not raised. (Only processes with the effective UID of the super-user can raise a hard limit.)

The specific resources that can be limited are system dependent. They are described in the `getrlimit(2)` man page. The resources listed below are supported when the underlying operating system supports them; resources which cannot be checked or controlled by the operating system are not defined in this module for those platforms.

**resource. RLIM_INFINITY**

Constant used to represent the limit for an unlimited resource.

**resource. getrlimit(resource)**

Returns a tuple `(soft, hard)` with the current soft and hard limits of `resource`. Raises `ValueError` if an invalid resource is specified, or `error` if the underlying system call fails unexpectedly.

**resource. setrlimit(resource, limits)**

Sets new limits of consumption of `resource`. The `limits` argument must be a tuple `(soft, hard)` of two integers describing the new limits. A value of `RLIM_INFINITY` can be used to request a limit that is unlimited.

Raises `ValueError` if an invalid resource is specified, if the new
soft limit exceeds the hard limit, or if a process tries to raise its hard limit. Specifying a limit of `RLIM_INFINITY` when the hard or system limit for that resource is not unlimited will result in a `ValueError`. A process with the effective UID of super-user can request any valid limit value, including unlimited, but `ValueError` will still be raised if the requested limit exceeds the system imposed limit.

`setrlimit` may also raise `error` if the underlying system call fails.

`resource.prlimit(pid, resource[, limits])`
Combines `setrlimit()` and `getrlimit()` in one function and supports to get and set the resources limits of an arbitrary process. If `pid` is 0, then the call applies to the current process. `resource` and `limits` have the same meaning as in `setrlimit()`, except that `limits` is optional.

When `limits` is not given the function returns the `resource` limit of the process `pid`. When `limits` is given the `resource` limit of the process is set and the former resource limit is returned.

Raises `ProcessLookupError` when `pid` can’t be found and `PermissionError` when the user doesn’t have `CAP_SYS_RESOURCE` for the process.

Availability: Linux 2.6.36 or later with glibc 2.13 or later

`New in version 3.4.`

These symbols define resources whose consumption can be controlled using the `setrlimit()` and `getrlimit()` functions described below. The values of these symbols are exactly the
constants used by C programs.

The Unix man page for `getrlimit(2)` lists the available resources. Note that not all systems use the same symbol or same value to denote the same resource. This module does not attempt to mask platform differences — symbols not defined for a platform will not be available from this module on that platform.

resource. **RLIMIT_CORE**

The maximum size (in bytes) of a core file that the current process can create. This may result in the creation of a partial core file if a larger core would be required to contain the entire process image.

resource. **RLIMIT_CPU**

The maximum amount of processor time (in seconds) that a process can use. If this limit is exceeded, a SIGXCPU signal is sent to the process. (See the `signal` module documentation for information about how to catch this signal and do something useful, e.g. flush open files to disk.)

resource. **RLIMIT_FSIZE**

The maximum size of a file which the process may create.

resource. **RLIMIT_DATA**

The maximum size (in bytes) of the process’s heap.

resource. **RLIMIT_STACK**

The maximum size (in bytes) of the call stack for the current process. This only affects the stack of the main thread in a multi-threaded process.

resource. **RLIMIT_RSS**

The maximum resident set size that should be made available to
the process.

resource. **RLIMIT_NPROC**

The maximum number of processes the current process may create.

resource. **RLIMIT_NOFILE**

The maximum number of open file descriptors for the current process.

resource. **RLIMITOfFile**

The BSD name for **RLIMIT_NFILE**.

resource. **RLIMIT_MEMLOCK**

The maximum address space which may be locked in memory.

resource. **RLIMIT_VMEM**

The largest area of mapped memory which the process may occupy.

resource. **RLIMIT_AS**

The maximum area (in bytes) of address space which may be taken by the process.

resource. **RLIMIT_MSGQUEUE**

The number of bytes that can be allocated for POSIX message queues.

Availability: Linux 2.6.8 or later.

*New in version 3.4.*

resource. **RLIMIT_NICE**

The ceiling for the process's nice level (calculated as 20 - rlim_cur).
Availability: Linux 2.6.12 or later.

*New in version 3.4.*

resource. **RLIMIT_RTPRIO**

The ceiling of the real-time priority.

Availability: Linux 2.6.12 or later.

*New in version 3.4.*

resource. **RLIMIT_RTTIME**

The time limit (in microseconds) on CPU time that a process can spend under real-time scheduling without making a blocking syscall.

Availability: Linux 2.6.25 or later.

*New in version 3.4.*

resource. **RLIMIT_SIGPENDING**

The number of signals which the process may queue.

Availability: Linux 2.6.8 or later.

*New in version 3.4.*

resource. **RLIMIT_SBSIZE**

The maximum size (in bytes) of socket buffer usage for this user. This limits the amount of network memory, and hence the amount of mbufs, that this user may hold at any time.

Availability: FreeBSD 9 or later.

*New in version 3.4.*
resource. **RLIMIT_SWAP**

The maximum size (in bytes) of the swap space that may be reserved or used by all of this user id's processes. This limit is enforced only if bit 1 of the vm.overcommit sysctl is set. Please see `tuning(7)` for a complete description of this sysctl.

Availability: FreeBSD 9 or later.

*New in version 3.4.*

resource. **RLIMIT_NPTS**

The maximum number of pseudo-terminals created by this user id.

Availability: FreeBSD 9 or later.

*New in version 3.4.*
35.11.2. Resource Usage

These functions are used to retrieve resource usage information:

resource. getrusage(who)

This function returns an object that describes the resources consumed by either the current process or its children, as specified by the who parameter. The who parameter should be specified using one of the RUSAGE_ constants described below.

The fields of the return value each describe how a particular system resource has been used, e.g. amount of time spent running is user mode or number of times the process was swapped out of main memory. Some values are dependent on the clock tick internal, e.g. the amount of memory the process is using.

For backward compatibility, the return value is also accessible as a tuple of 16 elements.

The fields ru_utime and ru_stime of the return value are floating point values representing the amount of time spent executing in user mode and the amount of time spent executing in system mode, respectively. The remaining values are integers. Consult the getrusage(2) man page for detailed information about these values. A brief summary is presented here:

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

This function will raise a `ValueError` if an invalid `who` parameter is specified. It may also raise `error` exception in unusual circumstances.

**resource. `getpagesize()`**

Returns the number of bytes in a system page. (This need not be the same as the hardware page size.)

The following `RUSAGE_*` symbols are passed to the `getrusage()` function to specify which processes information should be provided for.

**resource. `RUSAGE_SELF`**

Pass to `getrusage()` to request resources consumed by the calling process, which is the sum of resources used by all threads in the process.

**resource. `RUSAGE_CHILDREN`**
Pass to `getrusage()` to request resources consumed by child processes of the calling process which have been terminated and waited for.

resource. **RUSAGE_BOTH**

Pass to `getrusage()` to request resources consumed by both the current process and child processes. May not be available on all systems.

resource. **RUSAGE_THREAD**

Pass to `getrusage()` to request resources consumed by the current thread. May not be available on all systems.

*New in version 3.2.*
35.12. nis — Interface to Sun’s NIS (Yellow Pages)

The nis module gives a thin wrapper around the NIS library, useful for central administration of several hosts.

Because NIS exists only on Unix systems, this module is only available for Unix.

The nis module defines the following functions:

\[ \text{nis.match}(\text{key}, \text{mapname}, \text{domain}=\text{default\_domain}) \]

Return the match for key in map mapname, or raise an error (nis.error) if there is none. Both should be strings, key is 8-bit clean. Return value is an arbitrary array of bytes (may contain NULL and other joys).

Note that mapname is first checked if it is an alias to another name.

The domain argument allows overriding the NIS domain used for the lookup. If unspecified, lookup is in the default NIS domain.

\[ \text{nis.cat}(\text{mapname}, \text{domain}=\text{default\_domain}) \]

Return a dictionary mapping key to value such that \( \text{match(key, mapname)} == \text{value} \). Note that both keys and values of the dictionary are arbitrary arrays of bytes.

Note that mapname is first checked if it is an alias to another name.

The domain argument allows overriding the NIS domain used for the lookup. If unspecified, lookup is in the default NIS domain.
nis.maps\((domain=default\_domain)\)

Return a list of all valid maps.

The \textit{domain} argument allows overriding the NIS domain used for the lookup. If unspecified, lookup is in the default NIS domain.

nis.get_default_domain()

Return the system default NIS domain.

The \texttt{nis} module defines the following exception:

\texttt{exception nis.error}

An error raised when a NIS function returns an error code.
This module provides an interface to the Unix syslog library routines. Refer to the Unix manual pages for a detailed description of the syslog facility.

This module wraps the system syslog family of routines. A pure Python library that can speak to a syslog server is available in the logging.handlers module as SysLogHandler.

The module defines the following functions:

syslog.syslog(message)

syslog.syslog(priority, message)

Send the string message to the system logger. A trailing newline is added if necessary. Each message is tagged with a priority composed of a facility and a level. The optional priority argument, which defaults to LOG_INFO, determines the message priority. If the facility is not encoded in priority using logical-or (LOG_INFO | LOG_USER), the value given in the openlog() call is used.

If openlog() has not been called prior to the call to syslog(), openlog() will be called with no arguments.

syslog.openlog([ident, logoption[, facility]])

Logging options of subsequent syslog() calls can be set by calling openlog(). syslog() will call openlog() with no arguments if the log is not currently open.
The optional `ident` keyword argument is a string which is prepended to every message, and defaults to `sys.argv[0]` with leading path components stripped. The optional `logoption` keyword argument (default is 0) is a bit field – see below for possible values to combine. The optional `facility` keyword argument (default is `LOG_USER`) sets the default facility for messages which do not have a facility explicitly encoded.

*Changed in version 3.2:* In previous versions, keyword arguments were not allowed, and `ident` was required. The default for `ident` was dependent on the system libraries, and often was `python` instead of the name of the name of the python program file.

**syslog.**`closelog()`

Reset the syslog module values and call the system library `closelog()`.

This causes the module to behave as it does when initially imported. For example, `openlog()` will be called on the first `syslog()` call (if `openlog()` hasn't already been called), and `ident` and other `openlog()` parameters are reset to defaults.

**syslog.**`setlogmask(maskpri)`

Set the priority mask to `maskpri` and return the previous mask value. Calls to `syslog()` with a priority level not set in `maskpri` are ignored. The default is to log all priorities. The function `LOG_MASK(pri)` calculates the mask for the individual priority `pri`. The function `LOG_UPTO(pri)` calculates the mask for all priorities up to and including `pri`.

The module defines the following constants:

Priority levels (high to low):
LOG_EMERG, LOG_ALERT, LOG_CRIT, LOG_ERR, LOG_WARNING, LOG_NOTICE, LOG_INFO, LOG_DEBUG.

Facilities:
LOG_KERN, LOG_USER, LOG_MAIL, LOG_DAEMON, LOG_AUTH, LOG_LPR, LOG_NEWS, LOG_UUCP, LOG_CRON, LOG_SYSLOG, LOG_LOCAL0 to LOG_LOCAL7, and, if defined in <syslog.h>, LOG_AUTHPRIV.

Log options:
LOG_PID, LOG_CONS, LOG_NDELAY, and, if defined in <syslog.h>, LOG_ODELAY, LOG_NOWAIT, and LOG_PERROR.
35.13.1. Examples

35.13.1.1. Simple example

A simple set of examples:

```python
import syslog

syslog.syslog('Processing started')
if error:
    syslog.syslog(syslog.LOG_ERR, 'Processing started')
```

An example of setting some log options, these would include the process ID in logged messages, and write the messages to the destination facility used for mail logging:

```python
syslog.openlog(logoption=syslog.LOG_PID, facility=syslog.syslog)
syslog.syslog('E-mail processing initiated...')
```
36. Superseded Modules

The modules described in this chapter are deprecated and only kept for backwards compatibility. They have been superseded by other modules.

36.1. **optparse** — Parser for command line options

**Source code:** Lib/optparse.py

*Deprecated since version 3.2:* The **optparse** module is deprecated and will not be developed further; development will continue with the **argparse** module.

**optparse** is a more convenient, flexible, and powerful library for parsing command-line options than the old **getopt** module. **optparse** uses a more declarative style of command-line parsing: you create an instance of **OptionParser**, populate it with options, and parse the command line. **optparse** allows users to specify options in the conventional GNU/POSIX syntax, and additionally generates usage and help messages for you.

Here’s an example of using **optparse** in a simple script:

```python
from optparse import OptionParser

parser = OptionParser()
parser.add_option("-f", "--file", dest="filename",
                 help="write report to FILE", metavar="FILE")
parser.add_option("-q", "--quiet",
                 action="store_false", dest="verbose",
                 help="don't print status messages")

(options, args) = parser.parse_args()
```
With these few lines of code, users of your script can now do the “usual thing” on the command-line, for example:

```bash
<yourscript> --file=outfile -q
```

As it parses the command line, `optparse` sets attributes of the `options` object returned by `parse_args()` based on user-supplied command-line values. When `parse_args()` returns from parsing this command line, `options.filename` will be "outfile" and `options.verbose` will be False. `optparse` supports both long and short options, allows short options to be merged together, and allows options to be associated with their arguments in a variety of ways. Thus, the following command lines are all equivalent to the above example:

```bash
<yourscript> -f outfile --quiet
<yourscript> --quiet --file outfile
<yourscript> -q -foutfile
<yourscript> -qf outfile
```

Additionally, users can run one of

```bash
<yourscript> -h
<yourscript> --help
```

and `optparse` will print out a brief summary of your script's options:

```
Usage: <yourscript> [options]

Options:
 -h, --help          show this help message and exit
 -f FILE, --file=FILE write report to FILE
 -q, --quiet         don't print status messages
```
where the value of *yourscript* is determined at runtime (normally from `sys.argv[0]`).
36.1.1. Background

`optparse` was explicitly designed to encourage the creation of programs with straightforward, conventional command-line interfaces. To that end, it supports only the most common command-line syntax and semantics conventionally used under Unix. If you are unfamiliar with these conventions, read this section to acquaint yourself with them.

36.1.1.1. Terminology

**argument**

a string entered on the command-line, and passed by the shell to `exec1()` or `execv()`. In Python, arguments are elements of `sys.argv[1:]` (`sys.argv[0]` is the name of the program being executed). Unix shells also use the term “word”.

It is occasionally desirable to substitute an argument list other than `sys.argv[1:]`, so you should read “argument” as “an element of `sys.argv[1:]`, or of some other list provided as a substitute for `sys.argv[1:]`”.

**option**

an argument used to supply extra information to guide or customize the execution of a program. There are many different syntaxes for options; the traditional Unix syntax is a hyphen (“-“) followed by a single letter, e.g. `-x` or `-F`. Also, traditional Unix syntax allows multiple options to be merged into a single argument, e.g. `-x -F` is equivalent to `-xF`. The GNU project introduced `--` followed by a series of hyphen-separated words, e.g. `--file` or `--dry-run`. These are the only two option syntaxes provided by
Some other option syntaxes that the world has seen include:

- a hyphen followed by a few letters, e.g. `-pf` (this is *not* the same as multiple options merged into a single argument)
- a hyphen followed by a whole word, e.g. `-file` (this is technically equivalent to the previous syntax, but they aren’t usually seen in the same program)
- a plus sign followed by a single letter, or a few letters, or a word, e.g. `+f`, `+rgb`
- a slash followed by a letter, or a few letters, or a word, e.g. `/f`, `/file`

These option syntaxes are not supported by `optparse`, and they never will be. This is deliberate: the first three are non-standard on any environment, and the last only makes sense if you’re exclusively targeting VMS, MS-DOS, and/or Windows.

**option argument**

An argument that follows an option, is closely associated with that option, and is consumed from the argument list when that option is. With `optparse`, option arguments may either be in a separate argument from their option:

```
-f foo
--file foo
```

or included in the same argument:

```
-ffoo
--file=foo
```

Typically, a given option either takes an argument or it doesn’t. Lots
of people want an “optional option arguments” feature, meaning that some options will take an argument if they see it, and won't if they don't. This is somewhat controversial, because it makes parsing ambiguous: if `-a` takes an optional argument and `-b` is another option entirely, how do we interpret `-ab`? Because of this ambiguity, `optparse` does not support this feature.

**positional argument**

something leftover in the argument list after options have been parsed, i.e. after options and their arguments have been parsed and removed from the argument list.

**required option**

an option that must be supplied on the command-line; note that the phrase “required option” is self-contradictory in English. `optparse` doesn’t prevent you from implementing required options, but doesn’t give you much help at it either.

For example, consider this hypothetical command-line:

```
prog -v --report report.txt foo bar
```

`-v` and `--report` are both options. Assuming that `--report` takes one argument, `report.txt` is an option argument. `foo` and `bar` are positional arguments.

### 36.1.1.2. What are options for?

Options are used to provide extra information to tune or customize the execution of a program. In case it wasn’t clear, options are usually *optional*. A program should be able to run just fine with no options whatsoever. (Pick a random program from the Unix or GNU toolsets. Can it run without any options at all and still make sense? The main
exceptions are `find`, `tar`, and `dd`—all of which are mutant oddballs that have been rightly criticized for their non-standard syntax and confusing interfaces.)

Lots of people want their programs to have “required options”. Think about it. If it's required, then it's not optional! If there is a piece of information that your program absolutely requires in order to run successfully, that's what positional arguments are for.

As an example of good command-line interface design, consider the humble `cp` utility, for copying files. It doesn’t make much sense to try to copy files without supplying a destination and at least one source. Hence, `cp` fails if you run it with no arguments. However, it has a flexible, useful syntax that does not require any options at all:

```
cp SOURCE DEST
```
```
cp SOURCE ... DEST-DIR
```

You can get pretty far with just that. Most `cp` implementations provide a bunch of options to tweak exactly how the files are copied: you can preserve mode and modification time, avoid following symlinks, ask before clobbering existing files, etc. But none of this distracts from the core mission of `cp`, which is to copy either one file to another, or several files to another directory.

36.1.1.3. What are positional arguments for?

Positional arguments are for those pieces of information that your program absolutely, positively requires to run.

A good user interface should have as few absolute requirements as possible. If your program requires 17 distinct pieces of information in
order to run successfully, it doesn't much matter how you get that information from the user—most people will give up and walk away before they successfully run the program. This applies whether the user interface is a command-line, a configuration file, or a GUI: if you make that many demands on your users, most of them will simply give up.

In short, try to minimize the amount of information that users are absolutely required to supply—use sensible defaults whenever possible. Of course, you also want to make your programs reasonably flexible. That's what options are for. Again, it doesn't matter if they are entries in a config file, widgets in the “Preferences” dialog of a GUI, or command-line options—the more options you implement, the more flexible your program is, and the more complicated its implementation becomes. Too much flexibility has drawbacks as well, of course; too many options can overwhelm users and make your code much harder to maintain.
36.1.2. Tutorial

While `optparse` is quite flexible and powerful, it's also straightforward to use in most cases. This section covers the code patterns that are common to any `optparse`-based program.

First, you need to import the OptionParser class; then, early in the main program, create an OptionParser instance:

```python
from optparse import OptionParser
...
parser = OptionParser()
```

Then you can start defining options. The basic syntax is:

```python
parser.add_option(opt_str, ..., attr=value, ...)
```

Each option has one or more option strings, such as `-f` or `--file`, and several option attributes that tell `optparse` what to expect and what to do when it encounters that option on the command line.

Typically, each option will have one short option string and one long option string, e.g.:

```python
parser.add_option("-f", "--file", ...)
```

You're free to define as many short option strings and as many long option strings as you like (including zero), as long as there is at least one option string overall.

The option strings passed to `OptionParser.add_option()` are effectively labels for the option defined by that call. For brevity, we will
frequently refer to *encountering an option* on the command line; in reality, *optparse* encounters *option strings* and looks up options from them.

Once all of your options are defined, instruct *optparse* to parse your program's command line:

```python
(options, args) = parser.parse_args()
```

(If you like, you can pass a custom argument list to `parse_args()`, but that's rarely necessary: by default it uses `sys.argv[1:]`.)

`parse_args()` returns two values:

- **options**, an object containing values for all of your options—e.g. if `--file` takes a single string argument, then `options.file` will be the filename supplied by the user, or `None` if the user did not supply that option
- **args**, the list of positional arguments leftover after parsing options

This tutorial section only covers the four most important option attributes: `action`, `type`, `dest` (destination), and `help`. Of these, `action` is the most fundamental.

### 36.1.2.1. Understanding option actions

Actions tell *optparse* what to do when it encounters an option on the command line. There is a fixed set of actions hard-coded into *optparse*; adding new actions is an advanced topic covered in section *Extending optparse*. Most actions tell *optparse* to store a value in some variable—for example, take a string from the command
line and store it in an attribute of `options`.

If you don’t specify an option action, `optparse` defaults to `store`.

### 36.1.2.2. The store action

The most common option action is `store`, which tells `optparse` to take the next argument (or the remainder of the current argument), ensure that it is of the correct type, and store it to your chosen destination.

For example:

```python
parser.add_option("-f", "--file",
                 action="store", type="string",
                 dest="filename")
```

Now let’s make up a fake command line and ask `optparse` to parse it:

```python
args = ["-f", "foo.txt"]
(options, args) = parser.parse_args(args)
```

When `optparse` sees the option string `-f`, it consumes the next argument, `foo.txt`, and stores it in `options.filename`. So, after this call to `parse_args()`, `options.filename` is "foo.txt".

Some other option types supported by `optparse` are `int` and `float`. Here’s an option that expects an integer argument:

```python
parser.add_option("-n", type="int", dest="num")
```

Note that this option has no long option string, which is perfectly
acceptable. Also, there's no explicit action, since the default is `store`.

Let's parse another fake command-line. This time, we'll jam the option argument right up against the option: since `-n42` (one argument) is equivalent to `-n 42` (two arguments), the code

```python
(options, args) = parser.parse_args(["-n42")
print(options.num)
```

will print 42.

If you don't specify a type, `optparse` assumes `string`. Combined with the fact that the default action is `store`, that means our first example can be a lot shorter:

```python
parser.add_option("-f", "--file", dest="filename")
```

If you don't supply a destination, `optparse` figures out a sensible default from the option strings: if the first long option string is `--foo-bar`, then the default destination is `foo_bar`. If there are no long option strings, `optparse` looks at the first short option string: the default destination for `-f` is `f`.

`optparse` also includes the built-in `complex` type. Adding types is covered in section `Extending optparse`.

### 36.1.2.3. Handling boolean (flag) options

Flag options—set a variable to true or false when a particular option is seen—are quite common. `optparse` supports them with two separate actions, `store_true` and `store_false`. For example, you might have a `verbose` flag that is turned on with `-v` and off with `-q:`
Here we have two different options with the same destination, which is perfectly OK. (It just means you have to be a bit careful when setting default values—see below.)

When `optparse` encounters `-v` on the command line, it sets `options.verbose` to `True`; when it encounters `-q`, `options.verbose` is set to `False`.

### 36.1.2.4. Other actions

Some other actions supported by `optparse` are:

- **"store_const"**
  
  store a constant value

- **"append"**
  
  append this option's argument to a list

- **"count"**
  
  increment a counter by one

- **"callback"**
  
  call a specified function

These are covered in section Reference Guide, Reference Guide and section Option Callbacks.

### 36.1.2.5. Default values

All of the above examples involve setting some variable (the “destination”) when certain command-line options are seen. What
happens if those options are never seen? Since we didn’t supply any defaults, they are all set to None. This is usually fine, but sometimes you want more control. optparse lets you supply a default value for each destination, which is assigned before the command line is parsed.

First, consider the verbose/quiet example. If we want optparse to set verbose to True unless -q is seen, then we can do this:

```python
parser.add_option("-v", action="store_true", dest="verbose")
parser.add_option("-q", action="store_false", dest="verbose")
```

Since default values apply to the destination rather than to any particular option, and these two options happen to have the same destination, this is exactly equivalent:

```python
parser.add_option("-v", action="store_true", dest="verbose")
parser.add_option("-q", action="store_false", dest="verbose")
```

Consider this:

```python
parser.add_option("-v", action="store_true", dest="verbose")
parser.add_option("-q", action="store_false", dest="verbose")
```

Again, the default value for verbose will be True: the last default value supplied for any particular destination is the one that counts.

A clearer way to specify default values is the set_defaults() method of OptionParser, which you can call at any time before calling parse_args():

```python
parser.set_defaults(verbos=True)
```
As before, the last value specified for a given option destination is the one that counts. For clarity, try to use one method or the other of setting default values, not both.

### 36.1.2.6. Generating help

`optparse`'s ability to generate help and usage text automatically is useful for creating user-friendly command-line interfaces. All you have to do is supply a `help` value for each option, and optionally a short usage message for your whole program. Here’s an OptionParser populated with user-friendly (documented) options:

```python
usage = "usage: %prog [options] arg1 arg2"
parser = OptionParser(usage=usage)
parser.add_option("-v", "--verbose",
                  action="store_true", dest="verbose",
                  help="make lots of noise [default]"
)
parser.add_option("-q", "--quiet",
                  action="store_false", dest="verbose",
                  help="be vewwy quiet (I'm hunting"
)
parser.add_option("-f", "--filename",
                  metavar="FILE", help="write output"
)
parser.add_option("-m", "--mode",
                  default="intermediate",
                  help="interaction mode: novice, in"
                  "or expert [default: %default"
)
```

If `optparse` encounters either `-h` or `--help` on the command-line, or if you just call `parser.print_help()`, it prints the following to standard output:
Usage: `<yourscript> [options] arg1 arg2`

Options:
- `-h, --help` show this help message and exit
- `-v, --verbose` make lots of noise [default]
- `-q, --quiet` be vewwy quiet (I'm hunting)
- `-f FILE, --filename=FILE` write output to FILE
- `-m MODE, --mode=MODE` interaction mode: novice, intermediate, expert [default: intermediate]

(If the help output is triggered by a help option, `optparse` exits after printing the help text.)

There’s a lot going on here to help `optparse` generate the best possible help message:

- the script defines its own usage message:

  ```
  usage = "usage: %prog [options] arg1 arg2"
  ```

  `optparse` expands `%prog` in the usage string to the name of the current program, i.e. `os.path.basename(sys.argv[0])`. The expanded string is then printed before the detailed option help.

  If you don’t supply a usage string, `optparse` uses a bland but sensible default: "Usage: %prog [options]", which is fine if your script doesn’t take any positional arguments.

- every option defines a help string, and doesn’t worry about line-wrapping— `optparse` takes care of wrapping lines and making the help output look good.

- options that take a value indicate this fact in their automatically-
generated help message, e.g. for the “mode” option:

-\texttt{m \texttt{MODE}, \texttt{--mode}=\texttt{MODE}}

Here, “MODE” is called the meta-variable: it stands for the argument that the user is expected to supply to \texttt{-m/-\texttt{mode}}. By default, \texttt{optparse} converts the destination variable name to uppercase and uses that for the meta-variable. Sometimes, that's not what you want—for example, the \texttt{--filename} option explicitly sets \texttt{metavar=\texttt{FILE}}, resulting in this automatically-generated option description:

\texttt{-f \texttt{FILE}, \texttt{--filename}=\texttt{FILE}}

This is important for more than just saving space, though: the manually written help text uses the meta-variable \texttt{FILE} to clue the user in that there's a connection between the semi-formal syntax \texttt{-f \texttt{FILE}} and the informal semantic description “write output to \texttt{FILE}”. This is a simple but effective way to make your help text a lot clearer and more useful for end users.

- options that have a default value can include \texttt{\%default} in the help string—\texttt{optparse} will replace it with \texttt{\textit{str}} of the option's default value. If an option has no default value (or the default value is \texttt{None}), \texttt{\%default} expands to \texttt{none}.

36.1.2.6.1. Grouping Options

When dealing with many options, it is convenient to group these options for better help output. An \texttt{OptionParser} can contain several option groups, each of which can contain several options.
An option group is obtained using the class `OptionGroup`:

```python
class optparse.OptionGroup(parser, title, description=None)
```

where

- parser is the `OptionParser` instance the group will be inserted in to
- title is the group title
- description, optional, is a long description of the group

`OptionGroup` inherits from `OptionContainer` (like `OptionParser`) and so the `add_option()` method can be used to add an option to the group.

Once all the options are declared, using the `OptionParser` method `add_option_group()` the group is added to the previously defined parser.

Continuing with the parser defined in the previous section, adding an `OptionGroup` to a parser is easy:

```python
group = OptionGroup(parser, "Dangerous Options", "Caution: use these options at your own risk. It is believed that some of them bite.

parser.add_option("-g", action="store_true", help="Group option.
group.add_option_group(group)
```

This would result in the following help output:

```
Usage: <yourscript> [options] arg1 arg2

Options:
- -h, --help      show this help message and exit
- -v, --verbose   make lots of noise [default]
```
-q, --quiet be vewwy quiet (I'm hunting
-f FILE, --filename=FILE write output to FILE
-m MODE, --mode=MODE interaction mode: novice, intermediate, or expert [default: intermediate]

Dangerous Options:
 Caution: use these options at your own risk. It is believed that some of them bite.

-g Group option.

A bit more complete example might involve using more than one group: still extending the previous example:

group = OptionGroup(parser, "Dangerous Options",
                   "Caution: use these options at your own risk. It is believed that some of them bite.

Group = OptionGroup(parser, "Debug Options")
group.add_option("-d", "--debug", action="store_true",
                 help="Print debug information")
group.add_option("-s", "--sql", action="store_true",
                 help="Print all SQL statements executed")
group.add_option("-e", action="store_true", help="Print every action done")

parser.add_option_group(group)

that results in the following output:

Usage: <yourscript> [options] arg1 arg2

Options:
  -h, --help show this help message and exit
-v, --verbose               make lots of noise [default]
-q, --quiet                 be vewwy quiet (I'm hunting
-f FILE, --filename=FILE    write output to FILE
-m MODE, --mode=MODE        interaction mode: novice, in
[default: intermediate]

Dangerous Options:
Caution: use these options at your own risk. It of them bite.
-g                          Group option.

Debug Options:
-d, --debug                 Print debug information
-s, --sql                   Print all SQL statements exec
-e                          Print every action done

Another interesting method, in particular when working programmatically with option groups is:

OptionParser. get_option_group( opt_str )

    Return the OptionGroup to which the short or long option string
    opt_str (e.g. '-o' or '--option') belongs. If there's no such
    OptionGroup, return None.

36.1.2.7. Printing a version string

Similar to the brief usage string, optparse can also print a version string for your program. You have to supply the string as the version argument to OptionParser:

parser = OptionParser(usage=%prog [-f] [-q], version=)
%prog is expanded just like it is in usage. Apart from that, version can contain anything you like. When you supply it, optparse automatically adds a --version option to your parser. If it encounters this option on the command line, it expands your version string (by replacing %prog), prints it to stdout, and exits.

For example, if your script is called /usr/bin/foo:

```
$ /usr/bin/foo --version
foo 1.0
```

The following two methods can be used to print and get the version string:

OptionParser.print_version(file=None)

Print the version message for the current program (self.version) to file (default stdout). As with print_usage(), any occurrence of %prog in self.version is replaced with the name of the current program. Does nothing if self.version is empty or undefined.

OptionParser.get_version()

Same as print_version() but returns the version string instead of printing it.

### 36.1.2.8. How optparse handles errors

There are two broad classes of errors that optparse has to worry about: programmer errors and user errors. Programmer errors are usually erroneous calls to OptionParser.add_option(), e.g. invalid option strings, unknown option attributes, missing option
attributes, etc. These are dealt with in the usual way: raise an exception (either optparse.OptionError or TypeError) and let the program crash.

Handling user errors is much more important, since they are guaranteed to happen no matter how stable your code is. optparse can automatically detect some user errors, such as bad option arguments (passing \texttt{-n 4x} where \texttt{-n} takes an integer argument), missing arguments (\texttt{-n} at the end of the command line, where \texttt{-n} takes an argument of any type). Also, you can call OptionParser.error() to signal an application-defined error condition:

\begin{verbatim}
(options, args) = parser.parse_args()
...
if options.a and options.b:
    parser.error("options -a and -b are mutually exclusive")
\end{verbatim}

In either case, optparse handles the error the same way: it prints the program’s usage message and an error message to standard error and exits with error status 2.

Consider the first example above, where the user passes \texttt{4x} to an option that takes an integer:

\begin{verbatim}
$ /usr/bin/foo -n 4x
Usage: foo [options]
foo: error: option -n: invalid integer value: '4x'
\end{verbatim}

Or, where the user fails to pass a value at all:

\begin{verbatim}
$ /usr/bin/foo -n
\end{verbatim}
**Usage:** foo [options]

foo: error: -n option requires an argument

`optparse`-generated error messages take care always to mention the option involved in the error; be sure to do the same when calling `OptionParser.error()` from your application code.

If `optparse`'s default error-handling behaviour does not suit your needs, you'll need to subclass `OptionParser` and override its `exit()` and/or `error()` methods.

### 36.1.2.9. Putting it all together

Here's what `optparse`-based scripts usually look like:

```python
from optparse import OptionParser
...

def main():
    usage = "usage: %prog [options] arg"
    parser = OptionParser(usage)
    parser.add_option("-f", "--file", dest="filename",
                     help="read data from FILENAME"
                     parser.add_option("-v", "--verbose",
                        action="store_true", dest="verbose"
                    parser.add_option("-q", "--quiet",
                        action="store_false", dest="verbose"
                    ...
        (options, args) = parser.parse_args()
        if len(args) != 1:
            parser.error("incorrect number of arguments"
        if options.verbose:
            print("reading %s..." % options.filename)
```
if __name__ == "__main__":
    main()
36.1.3. Reference Guide

36.1.3.1. Creating the parser

The first step in using `optparse` is to create an OptionParser instance.

```python
class optparse.OptionParser(...)
```

The OptionParser constructor has no required arguments, but a number of optional keyword arguments. You should always pass them as keyword arguments, i.e. do not rely on the order in which the arguments are declared.

- **usage** (default: "%prog [options]")
  The usage summary to print when your program is run incorrectly or with a help option. When `optparse` prints the usage string, it expands `%prog` to `os.path.basename(sys.argv[0])` (or to `prog` if you passed that keyword argument). To suppress a usage message, pass the special value `optparse.SUPPRESS_USAGE`.

- **option_list** (default: `[]`)
  A list of Option objects to populate the parser with. The options in `option_list` are added after any options in `standard_option_list` (a class attribute that may be set by OptionParser subclasses), but before any version or help options. Deprecated; use `add_option()` after creating the parser instead.

- **option_class** (default: `optparse.Option`)
  Class to use when adding options to the parser in `add_option()`.
version (default: None)
A version string to print when the user supplies a version option. If you supply a true value for version, optparse automatically adds a version option with the single option string --version. The substring %prog is expanded the same as for usage.

conflict_handler (default: "error")
Specifies what to do when options with conflicting option strings are added to the parser; see section Conflicts between options.

description (default: None)
A paragraph of text giving a brief overview of your program. optparse reformats this paragraph to fit the current terminal width and prints it when the user requests help (after usage, but before the list of options).

formatter (default: a new IndentedHelpFormatter)
An instance of optparse.HelpFormatter that will be used for printing help text. optparse provides two concrete classes for this purpose: IndentedHelpFormatter and TitledHelpFormatter.

add_help_option (default: True)
If true, optparse will add a help option (with option strings -h and --help) to the parser.

prog
The string to use when expanding %prog in usage and version instead of os.path.basename(sys.argv[0]).

epilog (default: None)
A paragraph of help text to print after the option help.

36.1.3.2. Populating the parser
There are several ways to populate the parser with options. The preferred way is by using `OptionParser.add_option()`, as shown in section Tutorial. `add_option()` can be called in one of two ways:

- pass it an Option instance (as returned by `make_option()`)
- pass it any combination of positional and keyword arguments that are acceptable to `make_option()` (i.e., to the Option constructor), and it will create the Option instance for you

The other alternative is to pass a list of pre-constructed Option instances to the OptionParser constructor, as in:

```python
option_list = [
    make_option("-f", "--filename",
               action="store", type="string", dest=
    make_option("-q", "--quiet",
               action="store_false", dest="verbose"

parser = OptionParser(option_list=option_list)
```

`make_option()` is a factory function for creating Option instances; currently it is an alias for the Option constructor. A future version of `optparse` may split Option into several classes, and `make_option()` will pick the right class to instantiate. Do not instantiate Option directly.)

### 36.1.3.3. Defining options

Each Option instance represents a set of synonymous command-line option strings, e.g. `-f` and `--file`. You can specify any number of short or long option strings, but you must specify at least one overall option string.
The canonical way to create an Option instance is with the `add_option()` method of `OptionParser`.

```
OptionParser.add_option(option)
```
```
OptionParser.add_option(*opt_str, attr=value, ...)
```

To define an option with only a short option string:

```
parser.add_option("-f", attr=value, ...)
```

And to define an option with only a long option string:

```
parser.add_option("--foo", attr=value, ...)
```

The keyword arguments define attributes of the new Option object. The most important option attribute is `action`, and it largely determines which other attributes are relevant or required. If you pass irrelevant option attributes, or fail to pass required ones, `optparse` raises an `OptionError` exception explaining your mistake.

An option's `action` determines what `optparse` does when it encounters this option on the command-line. The standard option actions hard-coded into `optparse` are:

```
"store"
    store this option's argument (default)
"store_const"
    store a constant value
"store_true"
    store a true value
"store_false"
    store a false value
```
"append"
append this option's argument to a list

"append_const"
append a constant value to a list

"count"
increment a counter by one

"callback"
call a specified function

"help"
print a usage message including all options and the documentation for them

(If you don't supply an action, the default is "store". For this action, you may also supply type and dest option attributes; see Standard option actions.)

As you can see, most actions involve storing or updating a value somewhere. optparse always creates a special object for this, conventionally called options (it happens to be an instance of optparse.Values). Option arguments (and various other values) are stored as attributes of this object, according to the dest (destination) option attribute.

For example, when you call

    parser.parse_args()

one of the first things optparse does is create the options object:

    options = Values()

If one of the options in this parser is defined with
and the command-line being parsed includes any of the following:

```
-ffoo
-f foo
--file=foo
--file foo
```

then `optparse`, on seeing this option, will do the equivalent of

```
options.filename = "foo"
```

The `type` and `dest` option attributes are almost as important as `action`, but `action` is the only one that makes sense for all options.

### 36.1.3.4. Option attributes

The following option attributes may be passed as keyword arguments to `OptionParser.add_option()`. If you pass an option attribute that is not relevant to a particular option, or fail to pass a required option attribute, `optparse` raises `OptionError`.

**Option. `action`**

(default: "store")

Determines `optparse`’s behaviour when this option is seen on the command line; the available options are documented [here](#).

**Option. `type`**

(default: "string")
The argument type expected by this option (e.g., "string" or "int"); the available option types are documented here.

Option **dest**
(default: derived from option strings)

If the option's action implies writing or modifying a value somewhere, this tells optparse where to write it: dest names an attribute of the options object that optparse builds as it parses the command line.

Option **default**
The value to use for this option's destination if the option is not seen on the command line. See also OptionParser.set_defaults().

Option **nargs**
(default: 1)

How many arguments of type type should be consumed when this option is seen. If > 1, optparse will store a tuple of values to dest.

Option **const**
For actions that store a constant value, the constant value to store.

Option **choices**
For options of type "choice", the list of strings the user may choose from.

Option **callback**
For options with action "callback", the callable to call when this option is seen. See section Option Callbacks for detail on the
arguments passed to the callable.

Option `callback_args`

Option `callback_kwargs`

Additional positional and keyword arguments to pass to `callback` after the four standard callback arguments.

Option `help`

Help text to print for this option when listing all available options after the user supplies a `help` option (such as `--help`). If no help text is supplied, the option will be listed without help text. To hide this option, use the special value `optparse.SUPPRESS_HELP`.

Option `metavar`

(default: derived from option strings)

Stand-in for the option argument(s) to use when printing help text. See section Tutorial for an example.

36.1.3.5. Standard option actions

The various option actions all have slightly different requirements and effects. Most actions have several relevant option attributes which you may specify to guide `optparse`’s behaviour; a few have required attributes, which you must specify for any option using that action.

- "store" [relevant: type, dest, nargs, choices]

    The option must be followed by an argument, which is converted to a value according to type and stored in dest. If nargs > 1, multiple arguments will be consumed from the command line; all will be converted according to type and stored to dest as a
tuple. See the **Standard option types** section.

If `choices` is supplied (a list or tuple of strings), the type defaults to "choice".

If `type` is not supplied, it defaults to "string".

If `dest` is not supplied, `optparse` derives a destination from the first long option string (e.g., `--foo-bar` implies `foo_bar`). If there are no long option strings, `optparse` derives a destination from the first short option string (e.g., `-f` implies `f`).

Example:

```python
class parser:
    def add_option(self, *args, **kw):
        pass
```

As it parses the command line

```
-f foo.txt -p 1 -3.5 4 -fbar.txt
```

`optparse` will set

```
options.f = "foo.txt"
options.point = (1.0, -3.5, 4.0)
options.f = "bar.txt"
```

- **"store_const"** [required: `const`; relevant: `dest`]

  The value `const` is stored in `dest`.

Example:

```python
parser.add_option("-q", "--quiet",
```
If **--noisy** is seen, **optparse** will set

```
options.verbose = 2
```

- **"store_true"** [relevant: **dest**]

  A special case of **"store_const"** that stores a true value to **dest**.

- **"store_false"** [relevant: **dest**]

  Like **"store_true"**, but stores a false value.

  Example:

  ```
  parser.add_option("--clobber", action="store_true")
  parser.add_option("--no-clobber", action="store_true")
  ```

- **"append"** [relevant: **type, dest, nargs, choices**]

  The option must be followed by an argument, which is appended to the list in **dest**. If no default value for **dest** is supplied, an empty list is automatically created when **optparse** first encounters this option on the command-line. If **nargs** > 1, multiple arguments are consumed, and a tuple of length **nargs** is appended to **dest**.
The defaults for type and dest are the same as for the "store" action.

Example:

```python
caller.add_option("-t", "--tracks", action="append")
```

If `-t3` is seen on the command-line, optparse does the equivalent of:

```python
options.tracks = []
options.tracks.append(int("3"))
```

If, a little later on, `--tracks=4` is seen, it does:

```python
options.tracks.append(int("4"))
```

The append action calls the append method on the current value of the option. This means that any default value specified must have an append method. It also means that if the default value is non-empty, the default elements will be present in the parsed value for the option, with any values from the command line appended after those default values:

```python
>>> parser.add_option("--files", action="append")
```

```python
>>> opts, args = parser.parse_args(["--files", 
'overrides.mypkg', 
'~/mypkg/defaults', 'overrides.mypkg'])
```

- "append_const" [required: const; relevant: dest]

  Like "store_const", but the value const is appended to
*dest*; as with "*append*", *dest* defaults to None, and an empty list is automatically created the first time the option is encountered.

- **"count" [relevant: *dest]***

Increment the integer stored at *dest*. If no default value is supplied, *dest* is set to zero before being incremented the first time.

Example:

```python
def parser.add_option("-v", action="count", dest="verbosity")
```

The first time `-v` is seen on the command line, `optparse` does the equivalent of:

```python
options.verbosity = 0
options.verbosity += 1
```

Every subsequent occurrence of `-v` results in

```python
options.verbosity += 1
```

- **"callback" [required: *callback*; relevant: *type*, *nargs*, *callback_args*, *callback_kwargs]***

Call the function specified by *callback*, which is called as

```python
func(option, opt_str, value, parser, *args, **kwargs)
```

See section **Option Callbacks** for more detail.
Prints a complete help message for all the options in the current option parser. The help message is constructed from the usage string passed to OptionParser's constructor and the help string passed to every option.

If no help string is supplied for an option, it will still be listed in the help message. To omit an option entirely, use the special value optparse.SUPPRESS_HELP.

optparse automatically adds a help option to all OptionParsers, so you do not normally need to create one.

Example:

```python
from optparse import OptionParser, SUPPRESS_HELP

# usually, a help option is added automatically, # be suppressed using the add_help_option argument
parser = OptionParser(add_help_option=False)

parser.add_option("-h", "--help", action="help")
parsed.add_option("-v", action="store_true", dest=help="Be moderately verbose")
parsed.add_option("--file", dest="filename", help="Input file to read data from")
parsed.add_option("--secret", help=SUPPRESS_HELP)
```

If optparse sees either -h or --help on the command line, it will print something like the following help message to stdout (assuming sys.argv[0] is "foo.py"):

```
Usage: foo.py [options]
```
Options:
- **-h, --help**
  Show this help message and exit
- **-v**
  Be moderately verbose
- **--file=FILENAME**
  Input file to read data from

After printing the help message, **optparse** terminates your process with `sys.exit(0)`.

- **"version"**

  Prints the version number supplied to the OptionParser to stdout and exits. The version number is actually formatted and printed by the `print_version()` method of OptionParser. Generally only relevant if the `version` argument is supplied to the OptionParser constructor. As with help options, you will rarely create version options, since **optparse** automatically adds them when needed.

### 36.1.3.6. Standard option types

**optparse** has five built-in option types: "string", "int", "choice", "float" and "complex". If you need to add new option types, see section Extending optparse.

Arguments to string options are not checked or converted in any way: the text on the command line is stored in the destination (or passed to the callback) as-is.

Integer arguments (type "int") are parsed as follows:

- if the number starts with '0x', it is parsed as a hexadecimal number
- if the number starts with '0', it is parsed as an octal number
• if the number starts with \texttt{0b}, it is parsed as a binary number
• otherwise, the number is parsed as a decimal number

The conversion is done by calling \texttt{int()} with the appropriate base (2, 8, 10, or 16). If this fails, so will \texttt{optparse}, although with a more useful error message.

"float" and "complex" option arguments are converted directly with \texttt{float()} and \texttt{complex()}, with similar error-handling.

"choice" options are a subtype of "string" options. The \texttt{choices} option attribute (a sequence of strings) defines the set of allowed option arguments. \texttt{optparse.check_choice()} compares user-supplied option arguments against this master list and raises \texttt{OptionValueError} if an invalid string is given.

36.1.3.7. Parsing arguments

The whole point of creating and populating an OptionParser is to call its \texttt{parse_args()} method:

```
(options, args) = parser.parse_args(args=None, values=None)
```

where the input parameters are

\texttt{args}

the list of arguments to process (default: \texttt{sys.argv[1:]})

\texttt{values}

an \texttt{optparse.Values} object to store option arguments in (default: a new instance of \texttt{Values}) – if you give an existing object, the option defaults will not be initialized on it
and the return values are

```python
options
    the same object that was passed in as values, or the optparse.Values instance created by optparse

args
    the leftover positional arguments after all options have been processed
```

The most common usage is to supply neither keyword argument. If you supply `values`, it will be modified with repeated `setattr()` calls (roughly one for every option argument stored to an option destination) and returned by `parse_args()`.

If `parse_args()` encounters any errors in the argument list, it calls the OptionParser's `error()` method with an appropriate end-user error message. This ultimately terminates your process with an exit status of 2 (the traditional Unix exit status for command-line errors).

### 36.1.3.8. Querying and manipulating your option parser

The default behavior of the option parser can be customized slightly, and you can also poke around your option parser and see what's there. OptionParser provides several methods to help you out:

```python
OptionParser.disable_interspersed_args()
```

Set parsing to stop on the first non-option. For example, if `-a` and `-b` are both simple options that take no arguments, `optparse` normally accepts this syntax:

```
prog -a arg1 -b arg2
```
and treats it as equivalent to

```
prog -a -b arg1 arg2
```

To disable this feature, call `disable_interspersed_args()`. This restores traditional Unix syntax, where option parsing stops with the first non-option argument.

Use this if you have a command processor which runs another command which has options of its own and you want to make sure these options don’t get confused. For example, each command might have a different set of options.

**OptionParser**. `enable_interspersed_args()`

Set parsing to not stop on the first non-option, allowing interspersing switches with command arguments. This is the default behavior.

**OptionParser**. `get_option(opt_str)`

Returns the Option instance with the option string `opt_str`, or `None` if no options have that option string.

**OptionParser**. `has_option(opt_str)`

Return true if the OptionParser has an option with option string `opt_str` (e.g., `-q` or `--verbose`).

**OptionParser**. `remove_option(opt_str)`

If the OptionParser has an option corresponding to `opt_str`, that option is removed. If that option provided any other option strings, all of those option strings become invalid. If `opt_str` does not occur in any option belonging to this OptionParser, raises `ValueError`. 
36.1.3.9. Conflicts between options

If you’re not careful, it’s easy to define options with conflicting option strings:

```python
parser.add_option("-n", "--dry-run", ...)
...
parser.add_option("-n", "--noisy", ...)
```

(This is particularly true if you’ve defined your own OptionParser subclass with some standard options.)

Every time you add an option, `optparse` checks for conflicts with existing options. If it finds any, it invokes the current conflict-handling mechanism. You can set the conflict-handling mechanism either in the constructor:

```python
parser = OptionParser(..., conflict_handler=handler)
```

or with a separate call:

```python
parser.set_conflict_handler(handler)
```

The available conflict handlers are:

- **"error"** (default)
  
  assume option conflicts are a programming error and raise `OptionConflictError`

- **"resolve"**
  
  resolve option conflicts intelligently (see below)

As an example, let’s define an `OptionParser` that resolves conflicts
intelligently and add conflicting options to it:

```python
parser = OptionParser(conflict_handler="resolve")
parser.add_option("-n", "--dry-run", ..., help="do no harm")
parser.add_option("-n", "--noisy", ..., help="be noisy")
```

At this point, `optparse` detects that a previously-added option is already using the `-n` option string. Since `conflict_handler` is "resolve", it resolves the situation by removing `-n` from the earlier option’s list of option strings. Now `--dry-run` is the only way for the user to activate that option. If the user asks for help, the help message will reflect that:

```
Options:
    --dry-run      do no harm
    ...
    -n, --noisy    be noisy
```

It’s possible to whittle away the option strings for a previously-added option until there are none left, and the user has no way of invoking that option from the command-line. In that case, `optparse` removes that option completely, so it doesn’t show up in help text or anywhere else. Carrying on with our existing OptionParser:

```python
parser.add_option("--dry-run", ..., help="new dry-run option")
```

At this point, the original `-n/--dry-run` option is no longer accessible, so `optparse` removes it, leaving this help text:

```
Options:
    ...
    -n, --noisy    be noisy
```
36.1.3.10. Cleanup

OptionParser instances have several cyclic references. This should not be a problem for Python’s garbage collector, but you may wish to break the cyclic references explicitly by calling destroy() on your OptionParser once you are done with it. This is particularly useful in long-running applications where large object graphs are reachable from your OptionParser.

36.1.3.11. Other methods

OptionParser supports several other public methods:

OptionParser.set_usage(usage)
   Set the usage string according to the rules described above for the usage constructor keyword argument. Passing None sets the default usage string; use optparse.SUPPRESS_USAGE to suppress a usage message.

OptionParser.print_usage(file=None)
   Print the usage message for the current program (self.usage) to file (default stdout). Any occurrence of the string %prog in self.usage is replaced with the name of the current program. Does nothing if self.usage is empty or not defined.

OptionParser.get_usage()
   Same as print_usage() but returns the usage string instead of printing it.
OptionParser.set_defaults(dest=value,...)

Set default values for several option destinations at once. Using set_defaults() is the preferred way to set default values for options, since multiple options can share the same destination. For example, if several “mode” options all set the same destination, any one of them can set the default, and the last one wins:

```python
parser.add_option("--advanced", action="store_const", dest="mode", const="advanced", default="novice")  # overridden
parser.add_option("--novice", action="store_const", dest="mode", const="novice", default="advanced")  # override
```

To avoid this confusion, use set_defaults():

```python
parser.set_defaults(mode="advanced")
parser.add_option("--advanced", action="store_const", dest="mode", const="advanced")
parsed.add_option("--novice", action="store_const", dest="mode", const="novice")
```
36.1.4. Option Callbacks

When `optparse`'s built-in actions and types aren't quite enough for your needs, you have two choices: extend `optparse` or define a callback option. Extending `optparse` is more general, but overkill for a lot of simple cases. Quite often a simple callback is all you need.

There are two steps to defining a callback option:

- define the option itself using the "callback" action
- write the callback; this is a function (or method) that takes at least four arguments, as described below

36.1.4.1. Defining a callback option

As always, the easiest way to define a callback option is by using the `OptionParser.add_option()` method. Apart from `action`, the only option attribute you must specify is `callback`, the function to call:

```python
parser.add_option("-c", action="callback", callback=callback)
```

callback is a function (or other callable object), so you must have already defined `my_callback()` when you create this callback option. In this simple case, `optparse` doesn't even know if `-c` takes any arguments, which usually means that the option takes no arguments—the mere presence of `-c` on the command-line is all it needs to know. In some circumstances, though, you might want your callback to consume an arbitrary number of command-line arguments. This is where writing callbacks gets tricky; it's covered later in this
section.

optparse always passes four particular arguments to your callback, and it will only pass additional arguments if you specify them via callback_args and callback_kwargs. Thus, the minimal callback function signature is:

```python
def my_callback(option, opt, value, parser):
```

The four arguments to a callback are described below.

There are several other option attributes that you can supply when you define a callback option:

type
has its usual meaning: as with the "store" or "append" actions, it instructs optparse to consume one argument and convert it to type. Rather than storing the converted value(s) anywhere, though, optparse passes it to your callback function.

nargs
also has its usual meaning: if it is supplied and > 1, optparse will consume nargs arguments, each of which must be convertible to type. It then passes a tuple of converted values to your callback.

callback_args
da tuple of extra positional arguments to pass to the callback

callback_kwargs
da dictionary of extra keyword arguments to pass to the callback

36.1.4.2. How callbacks are called

All callbacks are called as follows:
func(option, opt_str, value, parser, *args, **kwargs)

where

option
    is the Option instance that's calling the callback

opt_str
    is the option string seen on the command-line that's triggering the callback. (If an abbreviated long option was used, opt_str will be the full, canonical option string—e.g. if the user puts --foo on the command-line as an abbreviation for --foobar, then opt_str will be "--foobar".)

value
    is the argument to this option seen on the command-line. optparse will only expect an argument if type is set; the type of value will be the type implied by the option's type. If type for this option is None (no argument expected), then value will be None. If nargs > 1, value will be a tuple of values of the appropriate type.

parser
    is the OptionParser instance driving the whole thing, mainly useful because you can access some other interesting data through its instance attributes:

    parser.largs
        the current list of leftover arguments, i.e. arguments that have been consumed but are neither options nor option arguments. Feel free to modify parser.largs, e.g. by adding more arguments to it. (This list will become args, the second return value of parse_args().)

    parser.rargs
the current list of remaining arguments, i.e. with `opt_str` and
`value` (if applicable) removed, and only the arguments
following them still there. Feel free to modify `parser.rargs`,
e.g. by consuming more arguments.

`parser.values`

the object where option values are by default stored (an
instance of `optparse.OptionValues`). This lets callbacks use the
same mechanism as the rest of `optparse` for storing option
values; you don’t need to mess around with globals or closures.
You can also access or modify the value(s) of any options
already encountered on the command-line.

`args`

is a tuple of arbitrary positional arguments supplied via the
`callback_args` option attribute.

`kwargs`

is a dictionary of arbitrary keyword arguments supplied via
`callback_kwargs`.

36.1.4.3. Raising errors in a callback

The callback function should raise `OptionValueError` if there are
any problems with the option or its argument(s). `optparse` catches
this and terminates the program, printing the error message you
supply to stderr. Your message should be clear, concise, accurate, and
mention the option at fault. Otherwise, the user will have a hard time
figuring out what he did wrong.

36.1.4.4. Callback example 1: trivial callback

Here’s an example of a callback option that takes no arguments, and
simply records that the option was seen:
def record_foo_seen(option, opt_str, value, parser):
    parser.values.saw_foo = True

parser.add_option("--foo", action="callback", callback=

Of course, you could do that with the "store_true" action.

36.1.4.5. Callback example 2: check option order

Here's a slightly more interesting example: record the fact that -a is seen, but blow up if it comes after -b in the command-line.

def check_order(option, opt_str, value, parser):
    if parser.values.b:
        raise OptionValueError("can't use -a after -b")
    parser.values.a = 1

... parser.add_option("-a", action="callback", callback=

36.1.4.6. Callback example 3: check option order (generalized)

If you want to re-use this callback for several similar options (set a flag, but blow up if -b has already been seen), it needs a bit of work: the error message and the flag that it sets must be generalized.

def check_order(option, opt_str, value, parser):
    if parser.values.b:
        raise OptionValueError("can't use %s after -b")

...
36.1.4.7. Callback example 4: check arbitrary condition

Of course, you could put any condition in there—you're not limited to checking the values of already-defined options. For example, if you have options that should not be called when the moon is full, all you have to do is this:

```python
def check_moon(option, opt_str, value, parser):
    if is_moon_full():
        raise OptionValueError("%s option invalid when %s is moon full" % (opt_str,))
    setattr(parser.values, option.dest, 1)

parser.add_option("-a", action="callback", callback=check_moon)
parser.add_option("-b", action="store_true", dest="b")
parser.add_option("-c", action="callback", callback=check_moon)
```

(The definition of `is_moon_full()` is left as an exercise for the reader.)

36.1.4.8. Callback example 5: fixed arguments

Things get slightly more interesting when you define callback options that take a fixed number of arguments. Specifying that a callback option takes arguments is similar to defining a "store" or "append" option: if you define `type`, then the option takes one argument that must be convertible to that type; if you further define `nargs`, then the
option takes nargs arguments.

Here's an example that just emulates the standard "store" action:

```python
def store_value(option, opt_str, value, parser):
    setattr(parser.values, option.dest, value)
...
parser.add_option("--foo",
    action="callback", callback=store_value,
type="int", nargs=3, dest="foo")
```

Note that optparse takes care of consuming 3 arguments and converting them to integers for you; all you have to do is store them. (Or whatever; obviously you don't need a callback for this example.)

36.1.4.9. Callback example 6: variable arguments

Things get hairy when you want an option to take a variable number of arguments. For this case, you must write a callback, as optparse doesn't provide any built-in capabilities for it. And you have to deal with certain intricacies of conventional Unix command-line parsing that optparse normally handles for you. In particular, callbacks should implement the conventional rules for bare -- and - arguments:

- either -- or - can be option arguments
- bare -- (if not the argument to some option): halt command-line processing and discard the --
- bare - (if not the argument to some option): halt command-line processing but keep the - (append it to parser.largs)

If you want an option that takes a variable number of arguments, there are several subtle, tricky issues to worry about. The exact
implementation you choose will be based on which trade-offs you’re willing to make for your application (which is why `optparse` doesn't support this sort of thing directly).

Nevertheless, here’s a stab at a callback for an option with variable arguments:

```python
def vararg_callback(option, opt_str, value, parser):
    assert value is None
    value = []

    def floatable(str):
        try:
            float(str)
            return True
        except ValueError:
            return False

    for arg in parser.rargs:
        # stop on --foo like options
        if arg[:2] == "--" and len(arg) > 2:
            break
        # stop on -a, but not on -3 or -3.0
        if arg[:1] == "-" and len(arg) > 1 and not floatable(arg):
            break
        value.append(arg)
        del parser.rargs[:len(value)]
        setattr(parser.values, option.dest, value)

    ...
```

```python
parser.add_option("-c", "--callback", dest="vararg_attr",
    action="callback", callback=vararg_callback)
```
36.1.5. Extending **optparse**

Since the two major controlling factors in how **optparse** interprets command-line options are the action and type of each option, the most likely direction of extension is to add new actions and new types.

36.1.5.1. Adding new types

To add new types, you need to define your own subclass of **optparse**'s Option class. This class has a couple of attributes that define **optparse**'s types: **TYPES** and **TYPE_CHECKER**.

**Option. TYPES**

A tuple of type names; in your subclass, simply define a new tuple **TYPES** that builds on the standard one.

**Option. TYPE_CHECKER**

A dictionary mapping type names to type-checking functions. A type-checking function has the following signature:

```python
def check_mytype(option, opt, value)
```

where `option` is an Option instance, `opt` is an option string (e.g., `-f`), and `value` is the string from the command line that must be checked and converted to your desired type. `check_mytype()` should return an object of the hypothetical type `mytype`. The value returned by a type-checking function will wind up in the OptionValues instance returned by `OptionParser.parse_args()`, or be passed to a callback as the `value` parameter.
Your type-checking function should raise `OptionValueError` if it encounters any problems. `OptionValueError` takes a single string argument, which is passed as-is to `OptionParser`'s `error()` method, which in turn prepends the program name and the string "error:" and prints everything to stderr before terminating the process.

Here's a silly example that demonstrates adding a "complex" option type to parse Python-style complex numbers on the command line. (This is even sillier than it used to be, because `optparse` 1.3 added built-in support for complex numbers, but never mind.)

First, the necessary imports:

```python
from copy import copy
from optparse import Option, OptionValueError
```

You need to define your type-checker first, since it's referred to later (in the `TYPE_CHECKER` class attribute of your Option subclass):

```python
def check_complex(option, opt, value):
    try:
        return complex(value)
    except ValueError:
        raise OptionValueError("option %s: invalid complex value: %r" %
```

Finally, the Option subclass:

```python
class MyOption (Option):
    TYPES = Option.TYPES + ("complex",)
    TYPE_CHECKER = copy(Option.TYPE_CHECKER)
    TYPE_CHECKER["complex"] = check_complex
```
(If we didn’t make a copy() of Option.TYPE_CHECKER, we would end up modifying the TYPE_CHECKER attribute of optparse’s Option class. This being Python, nothing stops you from doing that except good manners and common sense.)

That’s it! Now you can write a script that uses the new option type just like any other optparse-based script, except you have to instruct your OptionParser to use MyOption instead of Option:

```python
parser = OptionParser(option_class=MyOption)
parser.add_option("-c", type="complex")
```

Alternately, you can build your own option list and pass it to OptionParser; if you don’t use add_option() in the above way, you don’t need to tell OptionParser which option class to use:

```python
option_list = [MyOption("-c", action="store", type="complex")]
parser = OptionParser(option_list=option_list)
```

36.1.5.2. Adding new actions

Adding new actions is a bit trickier, because you have to understand that optparse has a couple of classifications for actions:

“store” actions

actions that result in optparse storing a value to an attribute of the current OptionValues instance; these options require a dest attribute to be supplied to the Option constructor.

“typed” actions

actions that take a value from the command line and expect it to be of a certain type; or rather, a string that can be converted to a certain type. These options require a type attribute to the Option
constructor.

These are overlapping sets: some default "store" actions are "store", "store_const", "append", and "count", while the default “typed” actions are "store", "append", and "callback".

When you add an action, you need to categorize it by listing it in at least one of the following class attributes of Option (all are lists of strings):

Option. ACTIONS
All actions must be listed in ACTIONS.

Option. STORE_ACTIONS
"store" actions are additionally listed here.

Option. TYPED_ACTIONS
"typed" actions are additionally listed here.

Option. ALWAYS_TYPED_ACTIONS
Actions that always take a type (i.e. whose options always take a value) are additionally listed here. The only effect of this is that optparse assigns the default type, "string", to options with no explicit type whose action is listed in ALWAYS_TYPED_ACTIONS.

In order to actually implement your new action, you must override Option's take_action() method and add a case that recognizes your action.

For example, let's add an "extend" action. This is similar to the standard "append" action, but instead of taking a single value from the command-line and appending it to an existing list, "extend" will take multiple values in a single comma-delimited string, and extend an
existing list with them. That is, if `--names` is an "extend" option of type "string", the command line

```
--names=foo,bar --names blah --names ding,dong
```

would result in a list

```
["foo", "bar", "blah", "ding", "dong"]
```

Again we define a subclass of Option:

```python
class MyOption(Option):
    ACTIONS = Option.ACTIONS + ("extend",)
    STORE_ACTION = Option.STORE_ACTION + ("extend")
    TYPED_ACTION = Option.TYPED_ACTION + ("extend")
    ALWAYS_TYPED_ACTION = Option.ALSALWAYS_TYPED_ACTION
    def take_action(self, action, dest, opt, value, 
        if action == "extend":
            lvalue = value.split(",")
            values.ensure_value(dest, []).extend(lvalue)
        else:
            Option.take_action(self, action, dest, opt, value, 
```

Features of note:

- "extend" both expects a value on the command-line and stores that value somewhere, so it goes in both `STORE_ACTIONS` and `TYPED_ACTIONS`.

- to ensure that `optparse` assigns the default type of "string" to "extend" actions, we put the "extend" action in
**ALWAYS_TYPED_ACTIONS** as well.

- MyOption.take_action() implements just this one new action, and passes control back to Option.take_action() for the standard **optparse** actions.

- **values** is an instance of the optparse_parser.Values class, which provides the very useful **ensure_value()** method. **ensure_value()** is essentially **getattr()** with a safety valve; it is called as

  ```python
  values.ensure_value(attr, value)
  ```

  If the **attr** attribute of **values** doesn’t exist or is **None**, then **ensure_value()** first sets it to **value**, and then returns ‘value’. This is very handy for actions like "extend", "append", and "count", all of which accumulate data in a variable and expect that variable to be of a certain type (a list for the first two, an integer for the latter). Using **ensure_value()** means that scripts using your action don’t have to worry about setting a default value for the option destinations in question; they can just leave the default as **None** and **ensure_value()** will take care of getting it right when it’s needed.
36.2. **imp** — Access the **import** internals

**Source code:** Lib/imp.py

*Deprecated since version 3.4:* The **imp** package is pending deprecation in favor of **importlib**.

This module provides an interface to the mechanisms used to implement the **import** statement. It defines the following constants and functions:

**imp.get_magic()**
Return the magic string value used to recognize byte-compiled code files (.pyc files). (This value may be different for each Python version.)

*Deprecated since version 3.4:* Use **importlib.util.IMAGIC_NUMBER** instead.

**imp.get_suffixes()**
Return a list of 3-element tuples, each describing a particular type of module. Each triple has the form (suffix, mode, type), where suffix is a string to be appended to the module name to form the filename to search for, mode is the mode string to pass to the built-in **open()** function to open the file (this can be 'r' for text files or 'rb' for binary files), and type is the file type, which has one of the values **PY_SOURCE**, **PY_COMPILED**, or **C_EXTENSION**, described below.
Deprecated since version 3.3: Use the constants defined on `importlib.machinery` instead.

```python
imp.find_module(name[, path])
```

Try to find the module `name`. If `path` is omitted or `None`, the list of directory names given by `sys.path` is searched, but first a few special places are searched: the function tries to find a built-in module with the given name (`C_BUILTIN`), then a frozen module (`PY_FROZEN`), and on some systems some other places are looked in as well (on Windows, it looks in the registry which may point to a specific file).

Otherwise, `path` must be a list of directory names; each directory is searched for files with any of the suffixes returned by `get_suffixes()` above. Invalid names in the list are silently ignored (but all list items must be strings).

If search is successful, the return value is a 3-element tuple `(file, pathname, description):

- `file` is an open file object positioned at the beginning, `pathname` is the pathname of the file found, and `description` is a 3-element tuple as contained in the list returned by `get_suffixes()` describing the kind of module found.

If the module does not live in a file, the returned `file` is `None`, `pathname` is the empty string, and the `description` tuple contains empty strings for its suffix and mode; the module type is indicated as given in parentheses above. If the search is unsuccessful, `ImportError` is raised. Other exceptions indicate problems with the arguments or environment.
If the module is a package, file is None, pathname is the package path and the last item in the description tuple is PKG_DIRECTORY.

This function does not handle hierarchical module names (names containing dots). In order to find \textit{P.M}, that is, submodule \textit{M} of package \textit{P}, use \texttt{find_module()} and \texttt{load_module()} to find and load package \textit{P}, and then use \texttt{find_module()} with the \textit{path} argument set to \texttt{P.__path__}. When \textit{P} itself has a dotted name, apply this recipe recursively.

\textit{Deprecated since version 3.3:} Use \texttt{importlib.util.find_spec()} instead unless Python 3.3 compatibility is required, in which case use \texttt{importlib.find_loader()}. For example usage of the former case, see the \texttt{Examples} section of the \texttt{importlib} documentation.

\texttt{imp.load_module(name, file, pathname, description)}

Load a module that was previously found by \texttt{find_module()} (or by an otherwise conducted search yielding compatible results). This function does more than importing the module: if the module was already imported, it will reload the module! The \textit{name} argument indicates the full module name (including the package name, if this is a submodule of a package). The \textit{file} argument is an open file, and \textit{pathname} is the corresponding file name; these can be None and '', respectively, when the module is a package or not being loaded from a file. The \textit{description} argument is a tuple, as would be returned by \texttt{get_suffixes()}, describing what kind of module must be loaded.

If the load is successful, the return value is the module object; otherwise, an exception (usually \texttt{ImportError}) is raised.
**Important:** the caller is responsible for closing the `file` argument, if it was not `None`, even when an exception is raised. This is best done using a `try ... finally` statement.

*Deprecated since version 3.3:* If previously used in conjunction with `imp.find_module()` then consider using `importlib.import_module()`, otherwise use the loader returned by the replacement you chose for `imp.find_module()`. If you called `imp.load_module()` and related functions directly with file path arguments then use a combination of `importlib.util.spec_from_file_location()` and `importlib.util.module_from_spec()`. See the Examples section of the `importlib` documentation for details of the various approaches.

```python
imp.new_module(name)
```

Return a new empty module object called `name`. This object is *not* inserted in `sys.modules`.

*Deprecated since version 3.4:* Use `importlib.util.module_from_spec()` instead.

```python
imp.reload(module)
```

Reload a previously imported `module`. The argument must be a module object, so it must have been successfully imported before. This is useful if you have edited the module source file using an external editor and want to try out the new version without leaving the Python interpreter. The return value is the module object (the same as the `module` argument).

When `reload(module)` is executed:
• Python modules’ code is recompiled and the module-level code reexecuted, defining a new set of objects which are bound to names in the module’s dictionary. The init function of extension modules is not called a second time.

• As with all other objects in Python the old objects are only reclaimed after their reference counts drop to zero.

• The names in the module namespace are updated to point to any new or changed objects.

• Other references to the old objects (such as names external to the module) are not rebound to refer to the new objects and must be updated in each namespace where they occur if that is desired.

There are a number of other caveats:

When a module is reloaded, its dictionary (containing the module’s global variables) is retained. Redefinitions of names will override the old definitions, so this is generally not a problem. If the new version of a module does not define a name that was defined by the old version, the old definition remains. This feature can be used to the module’s advantage if it maintains a global table or cache of objects — with a try statement it can test for the table’s presence and skip its initialization if desired:

```python
try:
    cache
except NameError:
    cache = {}
```

It is legal though generally not very useful to reload built-in or dynamically loaded modules, except for sys, __main__ and builtins. In many cases, however, extension modules are not designed to be initialized more than once, and may fail in arbitrary ways when reloaded.
If a module imports objects from another module using `from ... import ...`, calling `reload()` for the other module does not redefine the objects imported from it — one way around this is to re-execute the `from` statement, another is to use `import` and qualified names (`module.*name*`) instead.

If a module instantiates instances of a class, reloading the module that defines the class does not affect the method definitions of the instances — they continue to use the old class definition. The same is true for derived classes.

*Changed in version 3.3:* Relies on both `__name__` and `__loader__` being defined on the module being reloaded instead of just `__name__`.

*Deprecated since version 3.4:* Use `importlib.reload()` instead.

The following functions are conveniences for handling PEP 3147 byte-compiled file paths.

*New in version 3.2.*

```python
imp.cache_from_source(path, debug_override=None)
```

Return the PEP 3147 path to the byte-compiled file associated with the source `path`. For example, if `path` is `/foo/bar/baz.py` the return value would be `/foo/bar/__pycache__/baz.cpython-32.pyc` for Python 3.2. The `cpython-32` string comes from the current magic tag (see `get_tag()`; if `sys.implementation.cache_tag` is not defined then `NotImplementedError` will be raised). By passing in `True` or `False` for `debug_override` you can override the system's value for
___debug___, leading to optimized bytecode.

`path` need not exist.

*Changed in version 3.3:* If `sys.implementation.cache_tag` is `None`, then `NotImplementedError` is raised.

*Deprecated since version 3.4:* Use `importlib.util.cache_from_source()` instead.

*Changed in version 3.5:* The `debug_override` parameter no longer creates a `.pyo` file.

```python
imp. source_from_cache(path)
```

Given the `path` to a PEP 3147 file name, return the associated source code file path. For example, if `path` is `/foo/bar/__pycache__/baz.cpython-32.pyc` the returned path would be `/foo/bar/baz.py`. `path` need not exist, however if it does not conform to PEP 3147 format, a `ValueError` is raised. If `sys.implementation.cache_tag` is not defined, `NotImplementedError` is raised.

*Changed in version 3.3:* Raise `NotImplementedError` when `sys.implementation.cache_tag` is not defined.

*Deprecated since version 3.4:* Use `importlib.util.source_from_cache()` instead.

```python
imp. get_tag()
```

Return the PEP 3147 magic tag string matching this version of Python's magic number, as returned by `get_magic()`.

*Deprecated since version 3.4:* Use
sys.implementation.cache_tag directly starting in Python 3.3.

The following functions help interact with the import system’s internal locking mechanism. Locking semantics of imports are an implementation detail which may vary from release to release. However, Python ensures that circular imports work without any deadlocks.

\[ \text{imp}. \text{lock\_held}() \]

Return `True` if the global import lock is currently held, else `False`. On platforms without threads, always return `False`.

On platforms with threads, a thread executing an import first holds a global import lock, then sets up a per-module lock for the rest of the import. This blocks other threads from importing the same module until the original import completes, preventing other threads from seeing incomplete module objects constructed by the original thread. An exception is made for circular imports, which by construction have to expose an incomplete module object at some point.

* Changed in version 3.3: The locking scheme has changed to per-module locks for the most part. A global import lock is kept for some critical tasks, such as initializing the per-module locks.

* Deprecated since version 3.4.

\[ \text{imp}. \text{acquire\_lock}() \]

Acquire the interpreter’s global import lock for the current thread. This lock should be used by import hooks to ensure thread-safety when importing modules.
Once a thread has acquired the import lock, the same thread may acquire it again without blocking; the thread must release it once for each time it has acquired it.

On platforms without threads, this function does nothing.

*Changed in version 3.3:* The locking scheme has changed to per-module locks for the most part. A global import lock is kept for some critical tasks, such as initializing the per-module locks.

*Deprecated since version 3.4.*

```python
imp.release_lock()
```
Release the interpreter’s global import lock. On platforms without threads, this function does nothing.

*Changed in version 3.3:* The locking scheme has changed to per-module locks for the most part. A global import lock is kept for some critical tasks, such as initializing the per-module locks.

*Deprecated since version 3.4.*

The following constants with integer values, defined in this module, are used to indicate the search result of `find_module()`.

```python
imp.PY_SOURCE
```
The module was found as a source file.

*Deprecated since version 3.3.*

```python
imp.PY_COMPILED
```
The module was found as a compiled code object file.

*Deprecated since version 3.3.*
imp. **C_EXTENSION**
The module was found as dynamically loadable shared library.

*Deprecated since version 3.3.*

imp. **PKG_DIRECTORY**
The module was found as a package directory.

*Deprecated since version 3.3.*

imp. **C_BUILTIN**
The module was found as a built-in module.

*Deprecated since version 3.3.*

imp. **PY_FROZEN**
The module was found as a frozen module.

*Deprecated since version 3.3.*

```
class imp. NullImporter(path_string)
```

The *NullImporter* type is a [PEP 302](https://www.python.org/dev/peps/pep-0302) import hook that handles non-directory path strings by failing to find any modules. Calling this type with an existing directory or empty string raises `ImportError`. Otherwise, a *NullImporter* instance is returned.

Instances have only one method:

```
find_module(fullname[, path])
```

This method always returns `None`, indicating that the requested module could not be found.

*Changed in version 3.3:* `None` is inserted into `sys.path_importer_cache` instead of an instance of
NullImporter.

*Deprecated since version 3.4:* Insert `None` into `sys.path_importer_cache` instead.
36.2.1. Examples

The following function emulates what was the standard import statement up to Python 1.4 (no hierarchical module names). (This implementation wouldn’t work in that version, since find_module() has been extended and load_module() has been added in 1.4.)

```python
import imp
import sys

def __import__(name, globals=None, locals=None, fromlist=[]):
    # Fast path: see if the module has already been
    try:
        return sys.modules[name]
    except KeyError:
        pass

    # If any of the following calls raises an except
    # there's a problem we can't handle -- let the caller
    fp, pathname, description = imp.find_module(name,
      [os.curdir, os.curdir, os.pardir])
    try:
        return imp.load_module(name, fp, pathname, description)
    finally:
        # Since we may exit via an exception, close
        if fp:
            fp.close()
```
37. Undocumented Modules

Here’s a quick listing of modules that are currently undocumented, but that should be documented. Feel free to contribute documentation for them! (Send via email to docs@python.org.)

The idea and original contents for this chapter were taken from a posting by Fredrik Lundh; the specific contents of this chapter have been substantially revised.
37.1. Platform specific modules

These modules are used to implement the `os.path` module, and are not documented beyond this mention. There’s little need to document these.

`ntpath`
--- Implementation of `os.path` on Win32 and Win64 platforms.

`posixpath`
--- Implementation of `os.path` on POSIX.
1. Extending Python with C or C++

It is quite easy to add new built-in modules to Python, if you know how to program in C. Such extension modules can do two things that can’t be done directly in Python: they can implement new built-in object types, and they can call C library functions and system calls.

To support extensions, the Python API (Application Programmers Interface) defines a set of functions, macros and variables that provide access to most aspects of the Python run-time system. The Python API is incorporated in a C source file by including the header "Python.h".

The compilation of an extension module depends on its intended use as well as on your system setup; details are given in later chapters.

**Note:** The C extension interface is specific to CPython, and extension modules do not work on other Python implementations. In many cases, it is possible to avoid writing C extensions and preserve portability to other implementations. For example, if your use case is calling C library functions or system calls, you should consider using the `ctypes` module or the `cffi` library rather than writing custom C code. These modules let you write Python code to interface with C code and are more portable between implementations of Python than writing and compiling a C extension module.
1.1. A Simple Example

Let's create an extension module called spam (the favorite food of Monty Python fans...) and let's say we want to create a Python interface to the C library function `system()`. [1] This function takes a null-terminated character string as argument and returns an integer. We want this function to be callable from Python as follows:

```python
>>> import spam
>>> status = spam.system("ls -l")
```

Begin by creating a file `spammodule.c`. (Historically, if a module is called spam, the C file containing its implementation is called `spammodule.c`; if the module name is very long, like spammify, the module name can be just `spammify.c`.)

The first line of our file can be:

```c
#include <Python.h>
```

which pulls in the Python API (you can add a comment describing the purpose of the module and a copyright notice if you like).

**Note:** Since Python may define some pre-processor definitions which affect the standard headers on some systems, you *must* include `Python.h` before any standard headers are included.

All user-visible symbols defined by `Python.h` have a prefix of Py or PY, except those defined in standard header files. For convenience, and since they are used extensively by the Python interpreter, "Python.h" includes a few standard header files: `<stdio.h>`,
<string.h>, <errno.h>, and <stdlib.h>. If the latter header file does not exist on your system, it declares the functions malloc(), free() and realloc() directly.

The next thing we add to our module file is the C function that will be called when the Python expression `spam.system(string)` is evaluated (we’ll see shortly how it ends up being called):

```c
static PyObject *
spam_system(PyObject *self, PyObject *args) {
    const char *command;
    int sts;

    if (!PyArg_ParseTuple(args, "s", &command))
        return NULL;

    sts = system(command);
    return PyLong_FromLong(sts);
}
```

There is a straightforward translation from the argument list in Python (for example, the single expression "ls -l") to the arguments passed to the C function. The C function always has two arguments, conventionally named `self` and `args`.

The `self` argument points to the module object for module-level functions; for a method it would point to the object instance.

The `args` argument will be a pointer to a Python tuple object containing the arguments. Each item of the tuple corresponds to an argument in the call’s argument list. The arguments are Python objects — in order to do anything with them in our C function we have to convert them to C values. The function `PyArg_ParseTuple()` in the Python API checks the argument types and converts them to C values. It uses a
template string to determine the required types of the arguments as well as the types of the C variables into which to store the converted values. More about this later.

`PyArg_ParseTuple()` returns true (nonzero) if all arguments have the right type and its components have been stored in the variables whose addresses are passed. It returns false (zero) if an invalid argument list was passed. In the latter case it also raises an appropriate exception so the calling function can return `NULL` immediately (as we saw in the example).
1.2. Intermezzo: Errors and Exceptions

An important convention throughout the Python interpreter is the following: when a function fails, it should set an exception condition and return an error value (usually a NULL pointer). Exceptions are stored in a static global variable inside the interpreter; if this variable is NULL no exception has occurred. A second global variable stores the “associated value” of the exception (the second argument to raise). A third variable contains the stack traceback in case the error originated in Python code. These three variables are the C equivalents of the result in Python of \texttt{sys.exc_info()} (see the section on module \texttt{sys} in the Python Library Reference). It is important to know about them to understand how errors are passed around.

The Python API defines a number of functions to set various types of exceptions.

The most common one is \texttt{PyErr_SetString()}. Its arguments are an exception object and a C string. The exception object is usually a predefined object like \texttt{PyExc_ZeroDivisionError}. The C string indicates the cause of the error and is converted to a Python string object and stored as the “associated value” of the exception.

Another useful function is \texttt{PyErr_SetFromErrno()}, which only takes an exception argument and constructs the associated value by inspection of the global variable \texttt{errno}. The most general function is \texttt{PyErr_SetObject()}, which takes two object arguments, the exception and its associated value. You don’t need to \texttt{Py_INCREF()} the objects passed to any of these functions.

You can test non-destructively whether an exception has been set with
**PyErr_Occurred()**. This returns the current exception object, or *NULL* if no exception has occurred. You normally don’t need to call `PyErr_Occurred()` to see whether an error occurred in a function call, since you should be able to tell from the return value.

When a function *f* that calls another function *g* detects that the latter fails, *f* should itself return an error value (usually *NULL* or -1). It should *not* call one of the `PyErr_*()` functions — one has already been called by *g*. *f*’s caller is then supposed to also return an error indication to *its* caller, again *without* calling `PyErr_*()`, and so on — the most detailed cause of the error was already reported by the function that first detected it. Once the error reaches the Python interpreter’s main loop, this aborts the currently executing Python code and tries to find an exception handler specified by the Python programmer.

(There are situations where a module can actually give a more detailed error message by calling another `PyErr_*()` function, and in such cases it is fine to do so. As a general rule, however, this is not necessary, and can cause information about the cause of the error to be lost: most operations can fail for a variety of reasons.)

To ignore an exception set by a function call that failed, the exception condition must be cleared explicitly by calling `PyErr_Clear()`. The only time C code should call `PyErr_Clear()` is if it doesn’t want to pass the error on to the interpreter but wants to handle it completely by itself (possibly by trying something else, or pretending nothing went wrong).

Every failing `malloc()` call must be turned into an exception — the direct caller of `malloc()` (or `realloc()`) must call `PyErr_NoMemory()` and return a failure indicator itself. All the
object-creating functions (for example, `PyLong_FromLong()`)
already do this, so this note is only relevant to those who call
`malloc()` directly.

Also note that, with the important exception of
`PyArg_ParseTuple()` and friends, functions that return an integer
status usually return a positive value or zero for success and -1 for
failure, like Unix system calls.

Finally, be careful to clean up garbage (by making `Py_XDECREF()` or
`Py_DECREF()` calls for objects you have already created) when you
return an error indicator!

The choice of which exception to raise is entirely yours. There are
predeclared C objects corresponding to all built-in Python exceptions,
such as `PyExc_ZeroDivisionError`, which you can use directly.
Of course, you should choose exceptions wisely — don’t use
`PyExc_TypeError` to mean that a file couldn’t be opened (that
should probably be `PyExc_IOError`). If something’s wrong with the
argument list, the `PyArg_ParseTuple()` function usually raises
`PyExc_TypeError`. If you have an argument whose value must be in
a particular range or must satisfy other conditions, `PyExc_ValueError` is appropriate.

You can also define a new exception that is unique to your module.
For this, you usually declare a static object variable at the beginning of
your file:

```c
static PyObject *SpamError;
```

and initialize it in your module’s initialization function
(`PyInit_spam()`) with an exception object (leaving out the error
checking for now):

```c
PyMODINIT_FUNC
PyInit_spam(void)
{
    PyObject *m;

    m = PyModule_Create(&spammodule);
    if (m == NULL)
        return NULL;

    SpamError = PyErr_NewException("spam.error", NULL);
    Py_INCREF(SpamError);
    PyModule_AddObject(m, "error", SpamError);
    return m;
}
```

Note that the Python name for the exception object is spam.error. The `PyErr_NewException()` function may create a class with the base class being `Exception` (unless another class is passed in instead of `NULL`), described in Built-in Exceptions.

Note also that the SpamError variable retains a reference to the newly created exception class; this is intentional! Since the exception could be removed from the module by external code, an owned reference to the class is needed to ensure that it will not be discarded, causing SpamError to become a dangling pointer. Should it become a dangling pointer, C code which raises the exception could cause a core dump or other unintended side effects.

We discuss the use of `PyMODINIT_FUNC` as a function return type later in this sample.

The spam.error exception can be raised in your extension module
using a call to `PyErr_SetString()` as shown below:

```c
static PyObject *
spam_system(PyObject *self, PyObject *args)
{
    const char *command;
    int sts;

    if (!PyArg_ParseTuple(args, "s", &command))
        return NULL;
    sts = system(command);
    if (sts < 0) {
        PyErr_SetString(SpamError, "System command failed");
        return NULL;
    }
    return PyLong_FromLong(sts);
}
```
1.3. Back to the Example

Going back to our example function, you should now be able to understand this statement:

```c
if (!PyArg_ParseTuple(args, "s", &command))
    return NULL;
```

It returns `NULL` (the error indicator for functions returning object pointers) if an error is detected in the argument list, relying on the exception set by `PyArg_ParseTuple()`. Otherwise the string value of the argument has been copied to the local variable `command`. This is a pointer assignment and you are not supposed to modify the string to which it points (so in Standard C, the variable `command` should properly be declared as `const char *command`).

The next statement is a call to the Unix function `system()`, passing it the string we just got from `PyArg_ParseTuple()`:

```c
sts = system(command);
```

Our `spam.system()` function must return the value of `sts` as a Python object. This is done using the function `PyLong_FromLong()`.

```c
return PyLong_FromLong(sts);
```

In this case, it will return an integer object. (Yes, even integers are objects on the heap in Python!)

If you have a C function that returns no useful argument (a function returning `void`), the corresponding Python function must return `None`. You need this idiom to do so (which is implemented by the
Py_RETURN_NONE macro):

```c
Py_INCREF(Py_None);
return Py_None;
```

Py_None is the C name for the special Python object None. It is a genuine Python object rather than a NULL pointer, which means “error” in most contexts, as we have seen.
1.4. The Module’s Method Table and Initialization Function

I promised to show how spam_system() is called from Python programs. First, we need to list its name and address in a “method table”:

```c
static PyMethodDef SpamMethods[] = {
    ...
    {"system", spam_system, METH_VARARGS,
        "Execute a shell command."},
    ...
    {NULL, NULL, 0, NULL}    /* Sentinel */
};
```

Note the third entry (METH_VARARGS). This is a flag telling the interpreter the calling convention to be used for the C function. It should normally always be METH_VARARGS or METH_VARARGS | METH_KEYWORDS; a value of 0 means that an obsolete variant of PyArg_ParseTuple() is used.

When using only METH_VARARGS, the function should expect the Python-level parameters to be passed in as a tuple acceptable for parsing via PyArg_ParseTuple(); more information on this function is provided below.

The METH_KEYWORDS bit may be set in the third field if keyword arguments should be passed to the function. In this case, the C function should accept a third PyObject * parameter which will be a dictionary of keywords. Use PyArg_ParseTupleAndKeywords() to parse the arguments to such a function.
The method table must be referenced in the module definition structure:

```c
static struct PyModuleDef spammodule = {
    PyModuleDef_HEAD_INIT,
    "spam", /* name of module */
    spam_doc, /* module documentation, may be NULL */
    -1, /* size of per-interpreter state of the module, or -1 if the module keeps state in global variables. */
    SpamMethods
};
```

This structure, in turn, must be passed to the interpreter in the module’s initialization function. The initialization function must be named `PyInit_name()`, where `name` is the name of the module, and should be the only non-static item defined in the module file:

```c
PyMODINIT_FUNC
PyInit_spam(void)
{
    return PyModule_Create(&spammodule);
}
```

Note that `PyMODINIT_FUNC` declares the function as `PyObject *` return type, declares any special linkage declarations required by the platform, and for C++ declares the function as `extern "C"`.

When the Python program imports module spam for the first time, `PyInit_spam()` is called. (See below for comments about embedding Python.) It calls `PyModule_Create()`, which returns a module object, and inserts built-in function objects into the newly created module based upon the table (an array of `PyMethodDef` structures) found in the module definition. `PyModule_Create()`
returns a pointer to the module object that it creates. It may abort with a fatal error for certain errors, or return NULL if the module could not be initialized satisfactorily. The init function must return the module object to its caller, so that it then gets inserted into sys.modules.

When embedding Python, the PyInit_spam() function is not called automatically unless there's an entry in the PyImport_InitTab table. To add the module to the initialization table, use PyImport_AppendInittab(), optionally followed by an import of the module:

```c
int main(int argc, char *argv[]) {
    wchar_t *program = Py_DecodeLocale(argv[0], NULL);
    if (program == NULL) {
        fprintf(stderr, "Fatal error: cannot decode argv[0]"
                exit(1);
    }

    /* Add a built-in module, before Py_Initialize */
    PyImport_AppendInittab("spam", PyInit_spam);

    /* Pass argv[0] to the Python interpreter */
    Py_SetProgramName(program);

    /* Initialize the Python interpreter. Required. */
    Py_Initialize();

    /* Optionally import the module; alternatively, import can be deferred until the embedded script imports it. */
    PyImport_ImportModule("spam");

    ...
```
PyMem_RawFree(program);
   return 0;
}

Note: Removing entries from sys.modules or importing compiled modules into multiple interpreters within a process (or following a fork() without an intervening exec()) can create problems for some extension modules. Extension module authors should exercise caution when initializing internal data structures.

A more substantial example module is included in the Python source distribution as Modules/xxmodule.c. This file may be used as a template or simply read as an example.

Note: Unlike our spam example, xxmodule uses multi-phase initialization (new in Python 3.5), where a PyModuleDef structure is returned from PyInit_spam, and creation of the module is left to the import machinery. For details on multi-phase initialization, see PEP 489.
1.5. Compilation and Linkage

There are two more things to do before you can use your new extension: compiling and linking it with the Python system. If you use dynamic loading, the details may depend on the style of dynamic loading your system uses; see the chapters about building extension modules (chapter Building C and C++ Extensions) and additional information that pertains only to building on Windows (chapter Building C and C++ Extensions on Windows) for more information about this.

If you can't use dynamic loading, or if you want to make your module a permanent part of the Python interpreter, you will have to change the configuration setup and rebuild the interpreter. Luckily, this is very simple on Unix: just place your file (spammodule.c for example) in the Modules/ directory of an unpacked source distribution, add a line to the file Modules/Setup.local describing your file:

```plaintext
spam spammodule.o
```

and rebuild the interpreter by running `make` in the toplevel directory. You can also run `make` in the Modules/ subdirectory, but then you must first rebuild Makefile there by running `make` Makefile'. (This is necessary each time you change the Setup file.)

If your module requires additional libraries to link with, these can be listed on the line in the configuration file as well, for instance:

```plaintext
spam spammodule.o -lX11
```
1.6. Calling Python Functions from C

So far we have concentrated on making C functions callable from Python. The reverse is also useful: calling Python functions from C. This is especially the case for libraries that support so-called “callback” functions. If a C interface makes use of callbacks, the equivalent Python often needs to provide a callback mechanism to the Python programmer; the implementation will require calling the Python callback functions from a C callback. Other uses are also imaginable.

Fortunately, the Python interpreter is easily called recursively, and there is a standard interface to call a Python function. (I won’t dwell on how to call the Python parser with a particular string as input — if you’re interested, have a look at the implementation of the `-c` command line option in `Modules/main.c` from the Python source code.)

Calling a Python function is easy. First, the Python program must somehow pass you the Python function object. You should provide a function (or some other interface) to do this. When this function is called, save a pointer to the Python function object (be careful to `Py_INCREF()` it!) in a global variable — or wherever you see fit. For example, the following function might be part of a module definition:

```c
static PyObject *my_callback = NULL;

static PyObject *
my_set_callback(PyObject *dummy, PyObject *args)
{
    PyObject *result = NULL;
    PyObject *temp;

    if (PyArg_ParseTuple(args, "O:set_callback", &te
if (!PyCallable_Check(temp)) {
    PyErr_SetString(PyExc_TypeError, "parameter must be callable" );
    return NULL;
}
Py_XINCREF(temp); /* Add a reference */
Py_XDECREF(my_callback); /* Dispose of previous callback */
my_callback = temp; /* Remember new callback */
/* Boilerplate to return "None" */
Py_INCREF(Py_None);
result = Py_None;
}
return result;

This function must be registered with the interpreter using the METH_VARARGS flag; this is described in section The Module's Method Table and Initialization Function. The PyArg_ParseTuple() function and its arguments are documented in section Extracting Parameters in Extension Functions.

The macros Py_XINCREF() and Py_XDECREF() increment/decrement the reference count of an object and are safe in the presence of NULL pointers (but note that temp will not be NULL in this context). More info on them in section Reference Counts.

Later, when it is time to call the function, you call the C function PyObject_CallObject(). This function has two arguments, both pointers to arbitrary Python objects: the Python function, and the argument list. The argument list must always be a tuple object, whose length is the number of arguments. To call the Python function with no arguments, pass in NULL, or an empty tuple; to call it with one argument, pass a singleton tuple. Py_BuildValue() returns a tuple when its format string consists of zero or more format codes between
parentheses. For example:

```c
int arg;
PyObject *arglist;
PyObject *result;
...
arg = 123;
...
/* Time to call the callback */
arglist = Py_BuildValue("(i)", arg);
result = PyObject_CallObject(my_callback, arglist);
Py_DECREF(arglist);
```

`PyObject_CallObject()` returns a Python object pointer: this is the return value of the Python function. `PyObject_CallObject()` is “reference-count-neutral” with respect to its arguments. In the example a new tuple was created to serve as the argument list, which is `Py_DECREF()`-ed immediately after the `PyObject_CallObject()` call.

The return value of `PyObject_CallObject()` is “new”: either it is a brand new object, or it is an existing object whose reference count has been incremented. So, unless you want to save it in a global variable, you should somehow `Py_DECREF()` the result, even (especially!) if you are not interested in its value.

Before you do this, however, it is important to check that the return value isn't `NULL`. If it is, the Python function terminated by raising an exception. If the C code that called `PyObject_CallObject()` is called from Python, it should now return an error indication to its Python caller, so the interpreter can print a stack trace, or the calling Python code can handle the exception. If this is not possible or desirable, the exception should be cleared by calling
PyErr_Clear(). For example:

```c
if (result == NULL)
    return NULL; /* Pass error back */
...use result...
Py_DECREF(result);
```

Depending on the desired interface to the Python callback function, you may also have to provide an argument list to PyObject_CallObject(). In some cases the argument list is also provided by the Python program, through the same interface that specified the callback function. It can then be saved and used in the same manner as the function object. In other cases, you may have to construct a new tuple to pass as the argument list. The simplest way to do this is to call Py_BuildValue(). For example, if you want to pass an integral event code, you might use the following code:

```c
PyObject *arglist;
...
arglist = Py_BuildValue("(l)", eventcode);
result = PyObject_CallObject(my_callback, arglist);
Py_DECREF(arglist);
if (result == NULL)
    return NULL; /* Pass error back */
/* Here maybe use the result */
Py_DECREF(result);
```

Note the placement of Py_DECREF(arglist) immediately after the call, before the error check! Also note that strictly speaking this code is not complete: Py_BuildValue() may run out of memory, and this should be checked.

You may also call a function with keyword arguments by using PyObject_Call(), which supports arguments and keyword
arguments. As in the above example, we use `Py_BuildValue()` to construct the dictionary.

```c
PyObject *dict;
...
dict = Py_BuildValue("{s:i}", "name", val);
result = PyObject_Call(my_callback, NULL, dict);
Py_DECREF(dict);
if (result == NULL)
    return NULL; /* Pass error back */
/* Here maybe use the result */
Py_DECREF(result);
```
1.7. Extracting Parameters in Extension Functions

The PyArg_ParseTuple() function is declared as follows:

```c
int PyArg_ParseTuple(PyObject *arg, const char *format
```

The `arg` argument must be a tuple object containing an argument list passed from Python to a C function. The `format` argument must be a format string, whose syntax is explained in Parsing arguments and building values in the Python/C API Reference Manual. The remaining arguments must be addresses of variables whose type is determined by the format string.

Note that while PyArg_ParseTuple() checks that the Python arguments have the required types, it cannot check the validity of the addresses of C variables passed to the call: if you make mistakes there, your code will probably crash or at least overwrite random bits in memory. So be careful!

Note that any Python object references which are provided to the caller are borrowed references; do not decrement their reference count!

Some example calls:

```c
#define PY_SSIZE_T_CLEAN  /* Make "s#" use Py_ssize_t */
#include <Python.h>

int ok;
int i, j;
```
long k, l;
const char *s;
Py_ssize_t size;

ok = PyArg_ParseTuple(args, ""); /* No arguments */
    /* Python call: f() */

ok = PyArg_ParseTuple(args, "s", &s); /* A string */
    /* Possible Python call: f('whoops!') */

ok = PyArg_ParseTuple(args, "lls", &k, &l, &s); /* Two longs and a string */
    /* Possible Python call: f(1, 2, 'three') */

ok = PyArg_ParseTuple(args, "(ii)s#", &i, &j, &s, &size);
    /* A pair of ints and a string, whose size is also returned */
    /* Possible Python call: f((1, 2), 'three') */

{
    const char *file;
    const char *mode = "r";
    int bufsize = 0;
    ok = PyArg_ParseTuple(args, "s|si", &file, &mode);
        /* A string, and optionally another string and an integer */
        /* Possible Python calls: */
    f('spam')
    f('spam', 'w')
    f('spam', 'wb', 100000) */
}

{
    int left, top, right, bottom, h, v;
    ok = PyArg_ParseTuple(args, "((ii)(ii))(ii)",
        &left, &top, &right, &bottom, &h, &v);
/* A rectangle and a point */
/* Possible Python call:
   f(((0, 0), (400, 300)), (10, 10)) */
}

{
Py_complex c;
ok = PyArg_ParseTuple(args, "D:myfunction", &c);
/* a complex, also providing a function name for */
/* Possible Python call: myfunction(1+2j) */
}
1.8. Keyword Parameters for Extension Functions

The `PyArg_ParseTupleAndKeywords()` function is declared as follows:

```c
int PyArg_ParseTupleAndKeywords(PyObject *arg, PyObject const char *format,
                                PyObject **kwdict, PyObject *kwlist);
```

The `arg` and `format` parameters are identical to those of the `PyArg_ParseTuple()` function. The `kwdict` parameter is the dictionary of keywords received as the third parameter from the Python runtime. The `kwlist` parameter is a `NULL`-terminated list of strings which identify the parameters; the names are matched with the type information from `format` from left to right. On success, `PyArg_ParseTupleAndKeywords()` returns true, otherwise it returns false and raises an appropriate exception.

**Note:** Nested tuples cannot be parsed when using keyword arguments! Keyword parameters passed in which are not present in the `kwlist` will cause `TypeError` to be raised.

Here is an example module which uses keywords, based on an example by Geoff Philbrick (philbrick@hks.com):

```c
#include "Python.h"

static PyObject *
keywdarg_parrot(PyObject *self, PyObject *args, PyObject *kwdict, PyObject *kwlist) {
    int voltage;
```
char *state = "a stiff";
char *action = "voom";
char *type = "Norwegian Blue";

static char *kwlist[] = {"voltage", "state", "action"};

if (!PyArg_ParseTupleAndKeywords(args, keywds, "i|sss", &voltage, &state, &action))
    return NULL;

printf("-- This parrot wouldn't %s if you put %i Volts through it.\n", state, voltage);
printf("-- Lovely plumage, the %s -- It's %s!\n", action, type);

Py_RETURN_NONE;

static PyMethodDef keywdarg_methods[] = {
    /* The cast of the function is necessary since PyCFunction values only take two PyObject* parameters, and keyword arguments take three. */
    {"parrot", (PyCFunction)keywdarg_parrot, METH_VARARGS,
     "Print a lovely skit to standard output."},
    {NULL, NULL, 0, NULL} /* sentinel */
};

static struct PyModuleDef keywdargmodule = {
    PyModuleDef_HEAD_INIT,
    "keywdarg",
    NULL,
    -1,
    keywdarg_methods
};

PyMODINIT_FUNC
PyInit_keywdarg(void)
return PyModule_Create(&keywdargmodule);
}
1.9. Building Arbitrary Values

This function is the counterpart to `PyArg_ParseTuple()`. It is declared as follows:

```c
PyObject *Py_BuildValue(const char *format, ...);
```

It recognizes a set of format units similar to the ones recognized by `PyArg_ParseTuple()`, but the arguments (which are input to the function, not output) must not be pointers, just values. It returns a new Python object, suitable for returning from a C function called from Python.

One difference with `PyArg_ParseTuple()`: while the latter requires its first argument to be a tuple (since Python argument lists are always represented as tuples internally), `Py_BuildValue()` does not always build a tuple. It builds a tuple only if its format string contains two or more format units. If the format string is empty, it returns `None`; if it contains exactly one format unit, it returns whatever object is described by that format unit. To force it to return a tuple of size 0 or one, parenthesize the format string.

Examples (to the left the call, to the right the resulting Python value):

```c
Py_BuildValue(""")               None
Py_BuildValue("i", 123)           123
Py_BuildValue("iii", 123, 456, 789) (123, 456, 789)
Py_BuildValue("s", "hello")      'hello'
Py_BuildValue("y", "hello")      b'hello'
Py_BuildValue("ss", "hello", "world") ('hello', 'world')
Py_BuildValue("s#", "hello", 4)   'hell'
Py_BuildValue("y#", "hello", 4)   b'hell'
Py_BuildValue("()")              ()
```
Py_BuildValue("(i)", 123)  
(123,)

Py_BuildValue("(ii)", 123, 456)  
(123, 456)

Py_BuildValue("(i,i)", 123, 456)  
(123, 456)

Py_BuildValue("[i,i]", 123, 456)  
[123, 456]

Py_BuildValue("{s:i,s:i}",  
   "abc", 123, "def", 456)  
{'abc': 123, 'def': 456}

Py_BuildValue("((ii)(ii)) (ii)",  
   1, 2, 3, 4, 5, 6)  
(((1, 2), (3, 4)), (5, 6))
1.10. Reference Counts

In languages like C or C++, the programmer is responsible for dynamic allocation and deallocation of memory on the heap. In C, this is done using the functions `malloc()` and `free()`. In C++, the operators `new` and `delete` are used with essentially the same meaning and we’ll restrict the following discussion to the C case.

Every block of memory allocated with `malloc()` should eventually be returned to the pool of available memory by exactly one call to `free()`. It is important to call `free()` at the right time. If a block’s address is forgotten but `free()` is not called for it, the memory it occupies cannot be reused until the program terminates. This is called a *memory leak*. On the other hand, if a program calls `free()` for a block and then continues to use the block, it creates a conflict with re-use of the block through another `malloc()` call. This is called *using freed memory*. It has the same bad consequences as referencing uninitialized data — core dumps, wrong results, mysterious crashes.

Common causes of memory leaks are unusual paths through the code. For instance, a function may allocate a block of memory, do some calculation, and then free the block again. Now a change in the requirements for the function may add a test to the calculation that detects an error condition and can return prematurely from the function. It’s easy to forget to free the allocated memory block when taking this premature exit, especially when it is added later to the code. Such leaks, once introduced, often go undetected for a long time: the error exit is taken only in a small fraction of all calls, and most modern machines have plenty of virtual memory, so the leak only becomes apparent in a long-running process that uses the leaking function frequently. Therefore, it’s important to prevent leaks from
happening by having a coding convention or strategy that minimizes this kind of errors.

Since Python makes heavy use of `malloc()` and `free()`, it needs a strategy to avoid memory leaks as well as the use of freed memory. The chosen method is called *reference counting*. The principle is simple: every object contains a counter, which is incremented when a reference to the object is stored somewhere, and which is decremented when a reference to it is deleted. When the counter reaches zero, the last reference to the object has been deleted and the object is freed.

An alternative strategy is called *automatic garbage collection*. (Sometimes, reference counting is also referred to as a garbage collection strategy, hence my use of “automatic” to distinguish the two.) The big advantage of automatic garbage collection is that the user doesn’t need to call `free()` explicitly. (Another claimed advantage is an improvement in speed or memory usage — this is no hard fact however.) The disadvantage is that for C, there is no truly portable automatic garbage collector, while reference counting can be implemented portably (as long as the functions `malloc()` and `free()` are available — which the C Standard guarantees). Maybe some day a sufficiently portable automatic garbage collector will be available for C. Until then, we’ll have to live with reference counts.

While Python uses the traditional reference counting implementation, it also offers a cycle detector that works to detect reference cycles. This allows applications to not worry about creating direct or indirect circular references; these are the weakness of garbage collection implemented using only reference counting. Reference cycles consist of objects which contain (possibly indirect) references to themselves, so that each object in the cycle has a reference count which is non-
zero. Typical reference counting implementations are not able to reclaim the memory belonging to any objects in a reference cycle, or referenced from the objects in the cycle, even though there are no further references to the cycle itself.

The cycle detector is able to detect garbage cycles and can reclaim them. The gc module exposes a way to run the detector (the `collect()` function), as well as configuration interfaces and the ability to disable the detector at runtime. The cycle detector is considered an optional component; though it is included by default, it can be disabled at build time using the `--without-cycle-gc` option to the `configure` script on Unix platforms (including Mac OS X). If the cycle detector is disabled in this way, the gc module will not be available.

1.10.1. Reference Counting in Python

There are two macros, `Py_INCREF(x)` and `Py_DECREF(x)`, which handle the incrementing and decrementing of the reference count. `Py_DECREF()` also frees the object when the count reaches zero. For flexibility, it doesn't call `free()` directly — rather, it makes a call through a function pointer in the object's type object. For this purpose (and others), every object also contains a pointer to its type object.

The big question now remains: when to use `Py_INCREF(x)` and `Py_DECREF(x)`? Let's first introduce some terms. Nobody “owns” an object; however, you can own a reference to an object. An object's reference count is now defined as the number of owned references to it. The owner of a reference is responsible for calling `Py_DECREF()` when the reference is no longer needed. Ownership of a reference can be transferred. There are three ways to dispose of an owned
reference: pass it on, store it, or call \texttt{Py\_DECREF()}. Forgetting to dispose of an owned reference creates a memory leak.

It is also possible to \textit{borrow} \cite{2} a reference to an object. The borrower of a reference should not call \texttt{Py\_DECREF()}. The borrower must not hold on to the object longer than the owner from which it was borrowed. Using a borrowed reference after the owner has disposed of it risks using freed memory and should be avoided completely. \cite{3}

The advantage of borrowing over owning a reference is that you don’t need to take care of disposing of the reference on all possible paths through the code — in other words, with a borrowed reference you don’t run the risk of leaking when a premature exit is taken. The disadvantage of borrowing over owning is that there are some subtle situations where in seemingly correct code a borrowed reference can be used after the owner from which it was borrowed has in fact disposed of it.

A borrowed reference can be changed into an owned reference by calling \texttt{Py\_INCREF()}. This does not affect the status of the owner from which the reference was borrowed — it creates a new owned reference, and gives full owner responsibilities (the new owner must dispose of the reference properly, as well as the previous owner).

\textbf{1.10.2. Ownership Rules}

Whenever an object reference is passed into or out of a function, it is part of the function’s interface specification whether ownership is transferred with the reference or not.

Most functions that return a reference to an object pass on ownership with the reference. In particular, all functions whose function it is to
create a new object, such as `PyLong_FromLong()` and `Py_BuildValue()`, pass ownership to the receiver. Even if the object is not actually new, you still receive ownership of a new reference to that object. For instance, `PyLong_FromLong()` maintains a cache of popular values and can return a reference to a cached item.

Many functions that extract objects from other objects also transfer ownership with the reference, for instance `PyObject_GetAttrString()`. The picture is less clear, here, however, since a few common routines are exceptions: `PyTuple_GetItem()`, `PyList_GetItem()`, `PyDict_GetItem()`, and `PyDict_GetItemString()` all return references that you borrow from the tuple, list or dictionary.

The function `PyImport_AddModule()` also returns a borrowed reference, even though it may actually create the object it returns: this is possible because an owned reference to the object is stored in `sys.modules`.

When you pass an object reference into another function, in general, the function borrows the reference from you — if it needs to store it, it will use `Py_INCREF()` to become an independent owner. There are exactly two important exceptions to this rule: `PyTuple_SetItem()` and `PyList_SetItem()`. These functions take over ownership of the item passed to them — even if they fail! (Note that `PyDict_SetItem()` and friends don’t take over ownership — they are “normal.”)

When a C function is called from Python, it borrows references to its arguments from the caller. The caller owns a reference to the object, so the borrowed reference’s lifetime is guaranteed until the function
returns. Only when such a borrowed reference must be stored or passed on, it must be turned into an owned reference by calling \texttt{Py_INCREF()}. 

The object reference returned from a C function that is called from Python must be an owned reference — ownership is transferred from the function to its caller.

### 1.10.3. Thin Ice

There are a few situations where seemingly harmless use of a borrowed reference can lead to problems. These all have to do with implicit invocations of the interpreter, which can cause the owner of a reference to dispose of it.

The first and most important case to know about is using \texttt{Py_DECREF()} on an unrelated object while borrowing a reference to a list item. For instance:

```c
void bug(PyObject *list)
{
    PyObject *item = PyTuple_GetItem(list, 0);

    PyTuple_SetItem(list, 1, PyLong_FromLong(0L));
    PyObject_Print(item, stdout, 0); /* BUG! */
}
```

This function first borrows a reference to \texttt{list[0]}, then replaces \texttt{list[1]} with the value \texttt{0}, and finally prints the borrowed reference. Looks harmless, right? But it’s not!

Let’s follow the control flow into \texttt{PyList_SetItem()}. The list owns
references to all its items, so when item 1 is replaced, it has to dispose of the original item 1. Now let's suppose the original item 1 was an instance of a user-defined class, and let's further suppose that the class defined a __del__() method. If this class instance has a reference count of 1, disposing of it will call its __del__() method.

Since it is written in Python, the __del__() method can execute arbitrary Python code. Could it perhaps do something to invalidate the reference to item in bug()? You bet! Assuming that the list passed into bug() is accessible to the __del__() method, it could execute a statement to the effect of del list[0], and assuming this was the last reference to that object, it would free the memory associated with it, thereby invalidating item.

The solution, once you know the source of the problem, is easy: temporarily increment the reference count. The correct version of the function reads:

```c
void no_bug(PyObject *list)
{
    PyObject *item = PyList_GetItem(list, 0);

    Py_INCREF(item);
    PyList_SetItem(list, 1, PyLong_FromLong(0L));
    PyObject_Print(item, stdout, 0);
    Py_DECREF(item);
}
```

This is a true story. An older version of Python contained variants of this bug and someone spent a considerable amount of time in a C debugger to figure out why his __del__() methods would fail...

The second case of problems with a borrowed reference is a variant
involving threads. Normally, multiple threads in the Python interpreter can't get in each other's way, because there is a global lock protecting Python's entire object space. However, it is possible to temporarily release this lock using the macro `Py_BEGIN_ALLOW_THREADS`, and to re-acquire it using `Py_END_ALLOW_THREADS`. This is common around blocking I/O calls, to let other threads use the processor while waiting for the I/O to complete. Obviously, the following function has the same problem as the previous one:

```c
void
bug(PyObject *list)
{
    PyObject *item = PyList_GetItem(list, 0);
    Py_BEGIN_ALLOW_THREADS
    ...some blocking I/O call...
    Py_END_ALLOW_THREADS
    PyObject_Print(item, stdout, 0); /* BUG! */
}
```

### 1.10.4. NULL Pointers

In general, functions that take object references as arguments do not expect you to pass them `NULL` pointers, and will dump core (or cause later core dumps) if you do so. Functions that return object references generally return `NULL` only to indicate that an exception occurred. The reason for not testing for `NULL` arguments is that functions often pass the objects they receive on to other function — if each function were to test for `NULL`, there would be a lot of redundant tests and the code would run more slowly.

It is better to test for `NULL` only at the “source:” when a pointer that may be `NULL` is received, for example, from `malloc()` or from a function that may raise an exception.
The macros `Py_INCREF()` and `Py_DECREF()` do not check for *NULL* pointers — however, their variants `Py_XINCR() and Py_XDECREF()` do.

The macros for checking for a particular object type (`PyType_Check()`) don’t check for *NULL* pointers — again, there is much code that calls several of these in a row to test an object against various different expected types, and this would generate redundant tests. There are no variants with *NULL* checking.

The C function calling mechanism guarantees that the argument list passed to C functions (`args` in the examples) is never *NULL* — in fact it guarantees that it is always a tuple. [4]

It is a severe error to ever let a *NULL* pointer “escape” to the Python user.
1.11. Writing Extensions in C++

It is possible to write extension modules in C++. Some restrictions apply. If the main program (the Python interpreter) is compiled and linked by the C compiler, global or static objects with constructors cannot be used. This is not a problem if the main program is linked by the C++ compiler. Functions that will be called by the Python interpreter (in particular, module initialization functions) have to be declared using `extern "C"`. It is unnecessary to enclose the Python header files in `extern "C" {...}` — they use this form already if the symbol `__cplusplus` is defined (all recent C++ compilers define this symbol).
1.12. Providing a C API for an Extension Module

Many extension modules just provide new functions and types to be used from Python, but sometimes the code in an extension module can be useful for other extension modules. For example, an extension module could implement a type “collection” which works like lists without order. Just like the standard Python list type has a C API which permits extension modules to create and manipulate lists, this new collection type should have a set of C functions for direct manipulation from other extension modules.

At first sight this seems easy: just write the functions (without declaring them static, of course), provide an appropriate header file, and document the C API. And in fact this would work if all extension modules were always linked statically with the Python interpreter. When modules are used as shared libraries, however, the symbols defined in one module may not be visible to another module. The details of visibility depend on the operating system; some systems use one global namespace for the Python interpreter and all extension modules (Windows, for example), whereas others require an explicit list of imported symbols at module link time (AIX is one example), or offer a choice of different strategies (most Unices). And even if symbols are globally visible, the module whose functions one wishes to call might not have been loaded yet!

Portability therefore requires not to make any assumptions about symbol visibility. This means that all symbols in extension modules should be declared static, except for the module’s initialization function, in order to avoid name clashes with other extension modules (as discussed in section The Module’s Method Table and Initialization...
Function). And it means that symbols that \textit{should} be accessible from other extension modules must be exported in a different way.

Python provides a special mechanism to pass C-level information (pointers) from one extension module to another one: Capsules. A Capsule is a Python data type which stores a pointer (\texttt{void *}). Capsules can only be created and accessed via their C API, but they can be passed around like any other Python object. In particular, they can be assigned to a name in an extension module's namespace. Other extension modules can then import this module, retrieve the value of this name, and then retrieve the pointer from the Capsule.

There are many ways in which Capsules can be used to export the C API of an extension module. Each function could get its own Capsule, or all C API pointers could be stored in an array whose address is published in a Capsule. And the various tasks of storing and retrieving the pointers can be distributed in different ways between the module providing the code and the client modules.

Whichever method you choose, it's important to name your Capsules properly. The function \texttt{PyCapsule\_New()} takes a name parameter (\texttt{const char *}); you're permitted to pass in a \texttt{NULL} name, but we strongly encourage you to specify a name. Properly named Capsules provide a degree of runtime type-safety; there is no feasible way to tell one unnamed Capsule from another.

In particular, Capsules used to expose C APIs should be given a name following this convention:

\begin{verbatim}
modulename.attributename
\end{verbatim}

The convenience function \texttt{PyCapsule\_Import()} makes it easy to load a C API provided via a Capsule, but only if the Capsule's name
matches this convention. This behavior gives C API users a high degree of certainty that the Capsule they load contains the correct C API.

The following example demonstrates an approach that puts most of the burden on the writer of the exporting module, which is appropriate for commonly used library modules. It stores all C API pointers (just one in the example!) in an array of void pointers which becomes the value of a Capsule. The header file corresponding to the module provides a macro that takes care of importing the module and retrieving its C API pointers; client modules only have to call this macro before accessing the C API.

The exporting module is a modification of the spam module from section A Simple Example. The function spam.system() does not call the C library function system() directly, but a function PySpam_System(), which would of course do something more complicated in reality (such as adding “spam” to every command). This function PySpam_System() is also exported to other extension modules.

The function PySpam_System() is a plain C function, declared static like everything else:

```c
static int PySpam_System(const char *command)
{
    return system(command);
}
```

The function spam_system() is modified in a trivial way:

```c
static PyObject *
```
```c
spam_system(PyObject *self, PyObject *args)
{
    const char *command;
    int sts;

    if (!PyArg_ParseTuple(args, "s", &command))
        return NULL;
    sts = PySpam_System(command);
    return PyLong_FromLong(sts);
}
```

In the beginning of the module, right after the line

```c
#include "Python.h"
```

two more lines must be added:

```c
#define SPAM_MODULE
#include "spammodule.h"
```

The #define is used to tell the header file that it is being included in the exporting module, not a client module. Finally, the module's initialization function must take care of initializing the C API pointer array:

```c
PyMODINIT_FUNC
PyInit_spam(void)
{
    PyObject *m;
    static void *PySpam_API[PySpam_API_pointers];
    PyObject *c_api_object;

    m = PyModule_Create(&spammodule);
    if (m == NULL)
        return NULL;
```
/* Initialize the C API pointer array */
PySpam_API[PySpam_System_NUM] = (void *)PySpam_System

/* Create a Capsule containing the API pointer array */
c_api_object = PyCapsule_New((void *)PySpam_API,
if (c_api_object != NULL)
    PyModule_AddObject(m, "_C_API", c_api_object)
return m;

Note that PySpam_API is declared static; otherwise the pointer array would disappear when PyInit_spam() terminates!

The bulk of the work is in the header file spammodule.h, which looks like this:

#ifndef Py_SPAMMODULE_H
#define Py_SPAMMODULE_H
#ifdef __cplusplus
extern "C" {
#endif

/* Header file for spammodule */

/* C API functions */
#define PySpam_System_NUM 0
#define PySpam_System_RETURN int
#define PySpam_SystemPROTO (const char *command)

/* Total number of C API pointers */
#define PySpam_API_pointers 1
All that a client module must do in order to have access to the function PySpam_System() is to call the function (or rather macro) import_spam() in its initialization function:

PyMODINIT_FUNC
The main disadvantage of this approach is that the file spammodule.h is rather complicated. However, the basic structure is the same for each function that is exported, so it has to be learned only once.

Finally it should be mentioned that Capsules offer additional functionality, which is especially useful for memory allocation and deallocation of the pointer stored in a Capsule. The details are described in the Python/C API Reference Manual in the section Capsules and in the implementation of Capsules (files Include/pycapsule.h and Objects/pycapsule.c in the Python source code distribution).

Footnotes

An interface for this function already exists in the standard module os — it was chosen as a simple and straightforward example.

The metaphor of “borrowing” a reference is not completely correct: the owner still has a copy of the reference.
Checking that the reference count is at least 1 does not work
— the reference count itself could be in freed memory and may
thus be reused for another object!

These guarantees don’t hold when you use the “old” style
calling convention — this is still found in much existing code.
2. Defining New Types

As mentioned in the last chapter, Python allows the writer of an extension module to define new types that can be manipulated from Python code, much like strings and lists in core Python.

This is not hard; the code for all extension types follows a pattern, but there are some details that you need to understand before you can get started.
2.1. The Basics

The Python runtime sees all Python objects as variables of type `PyObject*`, which serves as a “base type” for all Python objects. `PyObject` itself only contains the refcount and a pointer to the object’s “type object”. This is where the action is; the type object determines which (C) functions get called when, for instance, an attribute gets looked up on an object or it is multiplied by another object. These C functions are called “type methods”.

So, if you want to define a new object type, you need to create a new type object.

This sort of thing can only be explained by example, so here’s a minimal, but complete, module that defines a new type:

```c
#include <Python.h>

typedef struct {
    PyObject_HEAD
    /* Type-specific fields go here. */
} noddy_NoddyObject;

static PyTypeObject noddy_NoddyType = {
    PyVarObject_HEAD_INIT(NULL, 0)
    "noddy.Noddy",    /* tp_name */
    sizeof(noddy_NoddyObject), /* tp_basicsize */
    0,                  /* tp_itemsize */
    0,                  /* tp_dealloc */
    0,                  /* tp_print */
    0,                  /* tp_getattr */
    0,                  /* tp_setattr */
    0,                  /* tp_reserved */
    0,                  /* tp_repr */
};
```
```c
static PyModuleDef noddymodule = {
    PyModuleDef_HEAD_INIT,
    "noddy",
    "Example module that creates an extension type."
    -1,
    NULL, NULL, NULL, NULL, NULL
};

PyMODINIT_FUNC
PyInit_noddy(void)
{
    PyObject* m;

    noddy_NoddyType.tp_new = PyType_GenericNew;
    if (PyType_Ready(&noddy_NoddyType) < 0)
        return NULL;

    m = PyModule_Create(&noddymodule);
    if (m == NULL)
        return NULL;

    Py_INCREF(&noddy_NoddyType);
    PyModule_AddObject(m, "Noddy", (PyObject *)&noddy_NoddyType);
    return m;
}
```
Now that's quite a bit to take in at once, but hopefully bits will seem familiar from the last chapter.

The first bit that will be new is:

```c
typedef struct {
    PyObject_HEAD
} noddy_NoddyObject;
```

This is what a Noddy object will contain—in this case, nothing more than what every Python object contains—a field called `ob_base` of type `PyObject`. `PyObject` in turn, contains an `ob_refcnt` field and a pointer to a type object. These can be accessed using the macros `Py_REFCNT` and `Py_TYPE` respectively. These are the fields the `PyObject_HEAD` macro brings in. The reason for the macro is to standardize the layout and to enable special debugging fields in debug builds.

Note that there is no semicolon after the `PyObject_HEAD` macro; one is included in the macro definition. Be wary of adding one by accident; it's easy to do from habit, and your compiler might not complain, but someone else's probably will! (On Windows, MSVC is known to call this an error and refuse to compile the code.)

For contrast, let's take a look at the corresponding definition for standard Python floats:

```c
typedef struct {
    PyObject_HEAD
    double ob_fval;
} PyFloatObject;
```
Moving on, we come to the crunch — the type object.

```c
static PyTypeObject noddy_NoddyType = {
    PyVarObject_HEAD_INIT(NULL, 0)
    "noddy.Noddy", /* tp_name */
    sizeof(noddy_NoddyObject), /* tp_basicsize */
    0, /* tp_itemsize */
    0, /* tp_dealloc */
    0, /* tp_print */
    0, /* tp_getattr */
    0, /* tp_setattr */
    0, /* tp_as_async */
    0, /* tp_repr */
    0, /* tp_as_number */
    0, /* tp_as_sequence */
    0, /* tp_as_mapping */
    0, /* tp_hash */
    0, /* tp_call */
    0, /* tp_str */
    0, /* tp_getattro */
    0, /* tp_setattro */
    0, /* tp_as_buffer */
    Py_TPFLAGS_DEFAULT, /* tp_flags */
    "Noddy objects", /* tp_doc */
};
```

Now if you go and look up the definition of `PyTypeObject` in `object.h` you'll see that it has many more fields that the definition above. The remaining fields will be filled with zeros by the C compiler, and it's common practice to not specify them explicitly unless you need them.

This is so important that we're going to pick the top of it apart still further:
PyVarObject_HEAD_INIT(NULL, 0)

This line is a bit of a wart; what we’d like to write is:

PyVarObject_HEAD_INIT(&PyType_Type, 0)

as the type of a type object is “type”, but this isn’t strictly conforming C and some compilers complain. Fortunately, this member will be filled in for us by PyType_Ready().

"noddy.Noddy",
    /* tp_name */

The name of our type. This will appear in the default textual representation of our objects and in some error messages, for example:

```
>>> "" + noddy.new_noddy()
Traceback (most recent call last):
  File "<stdin>", line 1, in <module>
TypeError: cannot add type "noddy.Noddy" to string
```

Note that the name is a dotted name that includes both the module name and the name of the type within the module. The module in this case is noddy and the type is Noddy, so we set the type name to noddy.Noddy. One side effect of using an undotted name is that the pydoc documentation tool will not list the new type in the module documentation.

sizeof(noddy_NoddyObject), /* tp_basicsize */

This is so that Python knows how much memory to allocate when you call PyObject_New().
**Note:** If you want your type to be subclassable from Python, and your type has the same `tp_basicsize` as its base type, you may have problems with multiple inheritance. A Python subclass of your type will have to list your type first in its `__bases__`, or else it will not be able to call your type’s `__new__()` method without getting an error. You can avoid this problem by ensuring that your type has a larger value for `tp_basicsize` than its base type does. Most of the time, this will be true anyway, because either your base type will be `object`, or else you will be adding data members to your base type, and therefore increasing its size.

```
0,          /* tp_itemsize */
```

This has to do with variable length objects like lists and strings. Ignore this for now.

Skipping a number of type methods that we don’t provide, we set the class flags to `Py_TPFLAGS_DEFAULT`.

```
Py_TPFLAGS_DEFAULT,      /* tp_flags */
```

All types should include this constant in their flags. It enables all of the members defined until at least Python 3.3. If you need further members, you will need to OR the corresponding flags.

We provide a doc string for the type in `tp_doc`.

```
"Noddy objects",      /* tp_doc */
```

Now we get into the type methods, the things that make your objects different from the others. We aren’t going to implement any of these in this version of the module. We’ll expand this example later to have
more interesting behavior.

For now, all we want to be able to do is to create new Noddy objects. To enable object creation, we have to provide a \texttt{tp\_new} implementation. In this case, we can just use the default implementation provided by the API function \texttt{PyType\_GenericNew()}. We'd like to just assign this to the \texttt{tp\_new} slot, but we can't, for portability sake, On some platforms or compilers, we can't statically initialize a structure member with a function defined in another C module, so, instead, we'll assign the \texttt{tp\_new} slot in the module initialization function just before calling \texttt{PyType\_Ready()}:

\begin{verbatim}
noddy_NoddyType.tp\_new = PyType\_GenericNew;
if (PyType\_Ready(&noddy_NoddyType) < 0)
  return;
\end{verbatim}

All the other type methods are \texttt{NULL}, so we'll go over them later — that's for a later section!

Everything else in the file should be familiar, except for some code in \texttt{PyInit\_noddy()}:

\begin{verbatim}
if (PyType\_Ready(&noddy_NoddyType) < 0)
  return;
\end{verbatim}

This initializes the Noddy type, filing in a number of members, including \texttt{ob\_type} that we initially set to \texttt{NULL}.

\begin{verbatim}
PyModule\_AddObject(m, "Noddy", (PyObject *)&noddy_NoddyType);
\end{verbatim}

This adds the type to the module dictionary. This allows us to create Noddy instances by calling the Noddy class:
That's it! All that remains is to build it; put the above code in a file called `noddy.c` and

```python
from distutils.core import setup, Extension
setup(name="noddy", version="1.0",
      ext_modules=[Extension("noddy", ["noddy.c"])]
)
```

in a file called `setup.py`; then typing

```
$ python setup.py build
```

at a shell should produce a file `noddy.so` in a subdirectory; move to that directory and fire up Python — you should be able to `import noddy` and play around with Noddy objects.

That wasn't so hard, was it?

Of course, the current Noddy type is pretty uninteresting. It has no data and doesn’t do anything. It can’t even be subclassed.

### 2.1.1. Adding data and methods to the Basic example

Let's extend the basic example to add some data and methods. Let's also make the type usable as a base class. We'll create a new module, `noddy2` that adds these capabilities:

```c
#include <Python.h>
#include "structmember.h"
```
typedef struct {
    PyObject_HEAD
    PyObject *first; /* first name */
    PyObject *last;  /* last name */
    int number;
} Noddy;

static void
Noddy_dealloc(Noddy* self)
{
    Py_XDECREF(self->first);
    Py_XDECREF(self->last);
    Py_TYPE(self)->tp_free((PyObject*)self);
}

static PyObject *
Noddy_new(PyTypeObject *type, PyObject *args, PyObject *kwargs)
{
    Noddy *self;

    self = (Noddy *)type->tp_alloc(type, 0);
    if (self != NULL) {
        self->first = PyUnicode_FromString(""");
        if (self->first == NULL) {
            Py_DECREF(self);
            return NULL;
        }

        self->last = PyUnicode_FromString(""");
        if (self->last == NULL) {
            Py_DECREF(self);
            return NULL;
        }

        self->number = 0;
    }

    return self;
}
```c
return (PyObject *)self;
}

static int Noddy_init(Noddy *self, PyObject *args, PyObject *kwds)
{
    PyObject *first=NULL, *last=NULL, *tmp;

    static char *kwlist[] = {"first", "last", "number"};

    if (! PyArg_ParseTupleAndKeywords(args, kwds, "|OOi", &first, &last, &self->number))
        return -1;

    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_XDECREF(tmp);
    }

    if (last) {
        tmp = self->last;
        Py_INCREF(last);
        self->last = last;
        Py_XDECREF(tmp);
    }

    return 0;
}

static PyMemberDef Noddy_members[] = {
    {"first", T_OBJECT_EX, offsetof(Noddy, first), 0, "first name"},
};
```
static PyObject *
Noddy_name(Noddy* self)
{
    if (self->first == NULL) {
        PyErr_SetString(PyExc_AttributeError, "first"
        return NULL;
    }

    if (self->last == NULL) {
        PyErr_SetString(PyExc_AttributeError, "last"
        return NULL;
    }

    return PyUnicode_FromFormat("%S %S", self->first
}

static PyMethodDef Noddy_methods[] = {
    {"name", (PyCFunction)Noddy_name, METH_NOARGS,
      "Return the name, combining the first and last
    },
    {NULL} /* Sentinel */
};

static PyTypeObject NoddyType = {
    PyVarObject_HEAD_INIT(NULL, 0)
    "noddy.Noddy",          /* tp_name */
    sizeof(Noddy),          /* tp_basicsize */
    0,                      /* tp_itemsize */
    (destructor)Noddy_dealloc, /* tp_dealloc */
    0,                      /* tp_print */
    {0} /* tp_getattr */,
    {0} /* tp_setattr */,
    {0} /* tp_reserved */
};

0,          /* tp_getattr */
0,          /* tp_setattr */
0,          /* tp_reserved */
0,          /* tp_repr */
0,          /* tp_as_number */
0,          /* tp_as_sequence */
0,          /* tp_as_mapping */
0,          /* tp_hash */
0,          /* tp_call */
0,          /* tp_str */
0,          /* tp_getattro */
0,          /* tp_setattro */
0,          /* tp_as_buffer */
Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE,
                 "Noddy objects",
0,          /* tp_flags */
0,          /* tp_doc */
0,          /* tp_traverse */
0,          /* tp_clear */
0,          /* tp_richcompare */
0,          /* tp_weaklistoffset */
0,          /* tp_iter */
0,          /* tp_iternext */
Noddy_methods,
Noddy_members,
0,          /* tp_getset */
0,          /* tp_base */
0,          /* tp_dict */
0,          /* tp_descr_get */
0,          /* tp_descr_set */
0,          /* tp_dictoffset */
Noddy_init,
Noddy_new,
};

static PyModuleDef noddy2module = {
PyModuleDef_HEAD_INIT,
This version of the module has a number of changes.

We've added an extra include:

```c
#include <structmember.h>
```

This include provides declarations that we use to handle attributes, as described a bit later.

The name of the Noddy object structure has been shortened to Noddy. The type object name has been shortened to NoddyType.
The Noddy type now has three data attributes, first, last, and number. The first and last variables are Python strings containing first and last names. The number attribute is an integer.

The object structure is updated accordingly:

```c
typedef struct {
    PyObject_HEAD
    PyObject *first;
    PyObject *last;
    int number;
} Noddy;
```

Because we now have data to manage, we have to be more careful about object allocation and deallocation. At a minimum, we need a deallocation method:

```c
static void
Noddy_dealloc(Noddy* self)
{
    Py_XDECREF(self->first);
    Py_XDECREF(self->last);
    Py_TYPE(self)->tp_free((PyObject*)self);
}
```

which is assigned to the tp_dealloc member:

```
(destructor)Noddy_dealloc, /*tp_dealloc*/
```

This method decrements the reference counts of the two Python attributes. We use Py_XDECREF() here because the first and last members could be NULL. It then calls the tp_free member of the object's type to free the object's memory. Note that the object's type might not be NoddyType, because the object may be an
instance of a subclass.

We want to make sure that the first and last names are initialized to empty strings, so we provide a new method:

```c
static PyObject *
Noddy_new(PyTypeObject *type, PyObject *args, PyObject *kwds)
{
    Noddy *self;

    self = (Noddy *)type->tp_alloc(type, 0);
    if (self != NULL) {
        self->first = PyUnicode_FromString("");
        if (self->first == NULL) {
            Py_DECREF(self);
            return NULL;
        }
        self->last = PyUnicode_FromString("");
        if (self->last == NULL) {
            Py_DECREF(self);
            return NULL;
        }
        self->number = 0;
    }
    return (PyObject *)self;
}
```

and install it in the `tp_new` member:

```c
Noddy_new,       /* tp_new */
```

The new member is responsible for creating (as opposed to initializing)
objects of the type. It is exposed in Python as the `__new__() method. See the paper titled “Unifying types and classes in Python” for a detailed discussion of the `__new__() method. One reason to implement a new method is to assure the initial values of instance variables. In this case, we use the new method to make sure that the initial values of the members first and last are not NULL. If we didn’t care whether the initial values were NULL, we could have used `PyType_GenericNew()` as our new method, as we did before. `PyType_GenericNew()` initializes all of the instance variable members to NULL.

The new method is a static method that is passed the type being instantiated and any arguments passed when the type was called, and that returns the new object created. New methods always accept positional and keyword arguments, but they often ignore the arguments, leaving the argument handling to initializer methods. Note that if the type supports subclassing, the type passed may not be the type being defined. The new method calls the `tp_alloc` slot to allocate memory. We don’t fill the `tp_alloc` slot ourselves. Rather `PyType_Ready()` fills it for us by inheriting it from our base class, which is object by default. Most types use the default allocation.

**Note:** If you are creating a co-operative `tp_new` (one that calls a base type’s `tp_new` or `__new__()`), you must not try to determine what method to call using method resolution order at runtime. Always statically determine what type you are going to call, and call its `tp_new` directly, or via `type->tp_base->tp_new`. If you do not do this, Python subclasses of your type that also inherit from other Python-defined classes may not work correctly. (Specifically, you may not be able to create instances of such subclasses without getting a `TypeError`.)
We provide an initialization function:

```c
static int Noddy_init(Noddy *self, PyObject *args, PyObject *kwds)
{
    PyObject *first=NULL, *last=NULL, *tmp;

    static char *kwlist[] = {"first", "last", "number"};

    if (!PyArg_ParseTupleAndKeywords(args, kwds, "|OOi",
                                      &first, &last,
                                      &self->number))
        return -1;

    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_XDECREF(tmp);
    }

    if (last) {
        tmp = self->last;
        Py_INCREF(last);
        self->last = last;
        Py_XDECREF(tmp);
    }

    return 0;
}
```

by filling the `tp_init` slot.

```
(initproc)Noddy_init,    /* tp_init */
```
The `tp_init` slot is exposed in Python as the `__init__()` method. It is used to initialize an object after it's created. Unlike the new method, we can't guarantee that the initializer is called. The initializer isn't called when unpickling objects and it can be overridden. Our initializer accepts arguments to provide initial values for our instance. Initializers always accept positional and keyword arguments. Initializers should return either 0 on success or -1 on error.

Initializers can be called multiple times. Anyone can call the `__init__()` method on our objects. For this reason, we have to be extra careful when assigning the new values. We might be tempted, for example to assign the `first` member like this:

```python
if (first) {
    Py_XDECREF(self->first);
    Py_INCREF(first);
    self->first = first;
}
```

But this would be risky. Our type doesn't restrict the type of the `first` member, so it could be any kind of object. It could have a destructor that causes code to be executed that tries to access the `first` member. To be paranoid and protect ourselves against this possibility, we almost always reassign members before decrementing their reference counts. When don't we have to do this?

- when we absolutely know that the reference count is greater than 1
- when we know that deallocation of the object [1] will not cause any calls back into our type's code
- when decrementing a reference count in a `tp_dealloc` handler when garbage-collections is not supported [2]
We want to expose our instance variables as attributes. There are a number of ways to do that. The simplest way is to define member definitions:

```c
static PyMemberDef Noddy_members[] = {
    {"first", T_OBJECT_EX, offsetof(Noddy, first), 0, "first name"},
    {"last", T_OBJECT_EX, offsetof(Noddy, last), 0, "last name"},
    {"number", T_INT, offsetof(Noddy, number), 0, "noddy number"},
    {NULL} /* Sentinel */
};
```

and put the definitions in the `tp_members` slot:

```c
Noddy_members, /* tp_members */
```

Each member definition has a member name, type, offset, access flags and documentation string. See the Generic Attribute Management section below for details.

A disadvantage of this approach is that it doesn’t provide a way to restrict the types of objects that can be assigned to the Python attributes. We expect the first and last names to be strings, but any Python objects can be assigned. Further, the attributes can be deleted, setting the C pointers to `NULL`. Even though we can make sure the members are initialized to non-`NULL` values, the members can be set to `NULL` if the attributes are deleted.

We define a single method, `name()`, that outputs the objects name as the concatenation of the first and last names.
The method is implemented as a C function that takes a Noddy (or Noddy subclass) instance as the first argument. Methods always take an instance as the first argument. Methods often take positional and keyword arguments as well, but in this case we don’t take any and don’t need to accept a positional argument tuple or keyword argument dictionary. This method is equivalent to the Python method:

```python
def name(self):
    return "%s %s" % (self.first, self.last)
```

Note that we have to check for the possibility that our first and last members are `NULL`. This is because they can be deleted, in which case they are set to `NULL`. It would be better to prevent deletion of these attributes and to restrict the attribute values to be strings. We’ll see how to do that in the next section.

Now that we’ve defined the method, we need to create an array of method definitions:
And assign them to the `tp_methods` slot:

```python
Noddy_methods,  /* tp_methods */
```

Note that we used the `METH_NOARGS` flag to indicate that the method is passed no arguments.

Finally, we'll make our type usable as a base class. We've written our methods carefully so far so that they don't make any assumptions about the type of the object being created or used, so all we need to do is to add the `Py_TPFLAGS_BASETYPE` to our class flag definition:

```python
Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE, /*tp_flags*/
```

We rename `PyInit_noddy()` to `PyInit_noddy2()` and update the module name in the `PyModuleDef` struct.

Finally, we update our `setup.py` file to build the new module:

```python
from distutils.core import setup, Extension
setup(name="noddy", version="1.0",
      ext_modules=[
          Extension("noddy", ["noddy.c"]),
          Extension("noddy2", ["noddy2.c"]),
      ])
```
2.1.2. Providing finer control over data attributes

In this section, we’ll provide finer control over how the first and last attributes are set in the Noddy example. In the previous version of our module, the instance variables first and last could be set to non-string values or even deleted. We want to make sure that these attributes always contain strings.

```c
#include <Python.h>
#include "structmember.h"

typedef struct {
    PyObject_HEAD
    PyObject *first;
    PyObject *last;
    int number;
} Noddy;

static void
Noddy_dealloc(Noddy* self)
{
    Py_XDECREF(self->first);
    Py_XDECREF(self->last);
    Py_TYPE(self)->tp_free((PyObject*)self);
}

static PyObject *
Noddy_new(PyTypeObject *type, PyObject *args, PyObject *)
{
    Noddy *self;

    self = (Noddy *)type->tp_alloc(type, 0);
    if (self != NULL) {
        self->first = PyUnicode_FromString("");
        if (self->first == NULL) {
            Py_XDECREF(self->first);
            Py_TYPE(self)->tp_free((PyObject*)self);
        }
    }
    return self;
}
```
Py_DECREF(self);
return NULL;
}

self->last = PyUnicode_FromString("");
if (self->last == NULL) {
    Py_DECREF(self);
    return NULL;
}

self->number = 0;
}

return (PyObject *)self;

static int Noddy_init(Noddy *self, PyObject *args, PyObject *kwds)
{
    PyObject *first=NULL, *last=NULL, *tmp;

    static char *kwlist[] = {"first", "last", "number"};

    if (! PyArg_ParseTupleAndKeywords(args, kwds, "|SSi", &first, &last, &self->number))
    {
        return -1;
    }

    if (first) {
        tmp = self->first;
        Py_INCREF(first);
        self->first = first;
        Py_DECREF(tmp);
    }

    if (last) {
        tmp = self->last;
        Py_INCREF(last);
        self->last = last;
        Py_DECREF(tmp);
    }

    return 0;
}
Py_INCREF(last);
self->last = last;
Py_DECREF(tmp);
}

return 0;
}

static PyMemberDef Noddy_members[] = {
    {"number", T_INT, offsetof(Noddy, number), 0,
     "noddy number"},
    {NULL} /* Sentinel */
};

0,            /* tp_dictoffset */
(initproc)Noddy_init,     /* tp_init */
0,            /* tp_alloc */
Noddy_new,         /* tp_new */
};

static PyModuleDef noddy3module = {
    PyModuleDef_HEAD_INIT,
    "noddy3",
    "Example module that creates an extension type."
-1,
    NULL, NULL, NULL, NULL, NULL, NULL
};

PyMODINIT_FUNC
PyInit_noddy3(void)
{

To provide greater control, over the first and last attributes, we'll use custom getter and setter functions. Here are the functions for getting and setting the first attribute:

```c
Noddy_getfirst(Noddy *self, void *closure)
{
    Py_INCREF(self->first);
    return self->first;
}

static int
Noddy_setfirst(Noddy *self, PyObject *value, void *closure)
{
    if (value == NULL) {
        PyErr_SetString(PyExc_TypeError, "Cannot delete
    return -1;
}

    if (!PyUnicode_Check(value)) {
        PyErr_SetString(PyExc_TypeError,
            "The first attribute value must
    return -1;
```
The getter function is passed a Noddy object and a “closure”, which is void pointer. In this case, the closure is ignored. (The closure supports an advanced usage in which definition data is passed to the getter and setter. This could, for example, be used to allow a single set of getter and setter functions that decide the attribute to get or set based on data in the closure.)

The setter function is passed the Noddy object, the new value, and the closure. The new value may be NULL, in which case the attribute is being deleted. In our setter, we raise an error if the attribute is deleted or if the attribute value is not a string.

We create an array of `PyGetSetDef` structures:

```c
static PyGetSetDef Noddy_getseters[] = {
    {"first",
     (getter)Noddy_getfirst, (setter)Noddy_setfirst,
     "first name",
     NULL},
    {"last",
     (getter)Noddy_getlast, (setter)Noddy_setlast,
     "last name",
     NULL},
    {NULL} /* Sentinel */
};
```
and register it in the \texttt{tp\_getset} slot:

\begin{verbatim}
Noddy\_getseters,    /* \texttt{tp\_getset} */
\end{verbatim}

to register our attribute getters and setters.

The last item in a \texttt{PyGetSetDef} structure is the closure mentioned above. In this case, we aren't using the closure, so we just pass \texttt{NULL}.

We also remove the member definitions for these attributes:

\begin{verbatim}
static PyMemberDef Noddy\_members[] = {
    {"number", T\_INT, offsetof(Noddy, number), 0,
     "noddy number"},
    {NULL}    /* Sentinel */
};
\end{verbatim}

We also need to update the \texttt{tp\_init} handler to only allow strings [3] to be passed:

\begin{verbatim}
static int Noddy\_init(Noddy *self, PyObject *args, PyObject *kwds)
{
    PyObject *first=NULL, *last=NULL, *tmp;

    static char *kwlist[] = {"first", "last", "number"};

    if (! PyArg\_ParseTupleAndKeywords(args, kwds, "|
                    &first, &last, &self->number)
        return -1;

    if (first) {
        tmp = self->first;
        Py\_INCREF(first);
    }
\end{verbatim}
With these changes, we can assure that the first and last members are never NULL so we can remove checks for NULL values in almost all cases. This means that most of the `Py_XDECREF()` calls can be converted to `Py_DECREF()` calls. The only place we can’t change these calls is in the deallocator, where there is the possibility that the initialization of these members failed in the constructor.

We also rename the module initialization function and module name in the initialization function, as we did before, and we add an extra definition to the `setup.py` file.

### 2.1.3. Supporting cyclic garbage collection

Python has a cyclic-garbage collector that can identify unneeded objects even when their reference counts are not zero. This can happen when objects are involved in cycles. For example, consider:

```python
>>> l = []
>>> l.append(l)
```
In this example, we create a list that contains itself. When we delete it, it still has a reference from itself. Its reference count doesn’t drop to zero. Fortunately, Python’s cyclic-garbage collector will eventually figure out that the list is garbage and free it.

In the second version of the Noddy example, we allowed any kind of object to be stored in the first or last attributes. [4] This means that Noddy objects can participate in cycles:

```python
>>> import noddy2
>>> n = noddy2.Noddy()
>>> l = [n]
>>> n.first = l
```

This is pretty silly, but it gives us an excuse to add support for the cyclic-garbage collector to the Noddy example. To support cyclic garbage collection, types need to fill two slots and set a class flag that enables these slots:

```c
#include <Python.h>
#include "structmember.h"

typedef struct {
    PyObject_HEAD
    PyObject *first;
    PyObject *last;
    int number;
} Noddy;

static int
Noddy_traverse(Noddy *self, visitproc visit, void *arg)
{
    int vret;
```
if (self->first) {
    vret = visit(self->first, arg);
    if (vret != 0)
        return vret;
}
if (self->last) {
    vret = visit(self->last, arg);
    if (vret != 0)
        return vret;
}
return 0;
}

static int
Noddy_clear(Noddy *self)
{
    PyObject *tmp;

    tmp = self->first;
    self->first = NULL;
    Py_XDECREF(tmp);

    tmp = self->last;
    self->last = NULL;
    Py_XDECREF(tmp);

    return 0;
}

static void
Noddy_dealloc(Noddy* self)
{
    PyObject_GC_UnTrack(self);
    Noddy_clear(self);
    Py_TYPE(self)->tp_free((PyObject*)self);
static PyObject *
Noddy_new(PyTypeObject *type, PyObject *args, PyObject *kwds)
{
    Noddy *self;

    self = (Noddy *)type->tp_alloc(type, 0);
    if (self != NULL) {
        self->first = PyUnicode_FromString("");           
        if (self->first == NULL) {
            Py_DECREF(self);
            return NULL;
        }
    }

    self->last = PyUnicode_FromString("");       
    if (self->last == NULL) {
        Py_DECREF(self);
        return NULL;
    }

    self->number = 0;
}

    return (PyObject *)self;
}

static int
Noddy_init(Noddy *self, PyObject *args, PyObject *kwds)
{
    PyObject *first=NULL, *last=NULL, *tmp;

    static char *kwlist[] = {"first", "last", "number"};

    if (! PyArg_ParseTupleAndKeywords(args, kwds, "|OOi"
                                         &first, &last, &self->number)
return -1;

if (first) {
    tmp = self->first;
    Py_INCREF(first);
    self->first = first;
    Py_XDECREF(tmp);
}

if (last) {
    tmp = self->last;
    Py_INCREF(last);
    self->last = last;
    Py_XDECREF(tmp);
}

return 0;

static PyMemberDef Noddy_members[] = {
    {"first", T_OBJECT_EX, offsetof(Noddy, first), 0,
     "first name"},
    {"last", T_OBJECT_EX, offsetof(Noddy, last), 0,
     "last name"},
    {"number", T_INT, offsetof(Noddy, number), 0,
     "noddy number"},
    {NULL} /* Sentinel */
};

static PyObject *
Noddy_name(Noddy* self)
{
    if (self->first == NULL) {
        PyErr_SetString(PyExc_AttributeError, "first");
        return NULL;
    }
    return NULL;
}
if (self->last == NULL) {
    PyErr_SetString(PyExc_AttributeError, "last"
    return NULL;
}

return PyUnicode_FromFormat("%S %S", self->first

static PyMethodDef Noddy_methods[] = {
    {"name", (PyCFunction)Noddy_name, METH_NOARGS,
    "Return the name, combining the first and last
    },
    {NULL} /* Sentinel */
};

static PyTypeObject NoddyType = {
    PyVarObject_HEAD_INIT(NULL, 0)
    "noddy.Noddy",
    /* tp_name */
    sizeof(Noddy),
    /* tp_basicsize */
    0,
    /* tp_itemsize */
    (destructor)Noddy_dealloc, /* tp_dealloc */
    0,
    /* tp_print */
    0,
    /* tp_getattr */
    0,

    0,
    /* tp_call */
    0,
    /* tp_str */
    0,
    /* tp_getattro */
    0,
    /* tp_setattro */
    0,
    /* tp_as_buffer */
    Py_TPFLAGS_DEFAULT |
Py_TPFLAGS_BASETYPE | Py_TPFLAGS_HAVE_GC, /* tp_flags */
"Noddy objects", /* tp_doc */
(traverseproc)Noddy_traverse, /* tp_traverse */
(inquiry)Noddy_clear, /* tp_clear */
0, /* tp_richcompare */
0, /* tp_weaklistoffset */
0, /* tp_iter */
0, /* tp_iernext */
Noddy_methods, /* tp_methods */
Noddy_members, /* tp_members */
0, /* tp_getset */
0, /* tp_base */
0, /* tp_dict */
0, /* tp_descr_get */
0, /* tp_descr_set */
0, /* tp_dictoffset */
(initproc)Noddy_init, /* tp_init */
0, /* tp_alloc */
Noddy_new, /* tp_new */
};

static PyModuleDef noddy4module = {
    PyModuleDef_HEAD_INIT,
    "noddy4",
    "Example module that creates an extension type.",
    -1,
    NULL, NULL, NULL, NULL
};

PyMODINIT_FUNC
PyInit_noddy4(void)
{
    PyObject* m;

    if (PyType_Ready(&NoddyType) < 0)
        return NULL;
The traversal method provides access to subobjects that could participate in cycles:

```c
static int Noddy_traverse(Noddy *self, visitproc visit, void *arg)
{
    int vret;

    if (self->first) {
        vret = visit(self->first, arg);
        if (vret != 0)
            return vret;
    }

    if (self->last) {
        vret = visit(self->last, arg);
        if (vret != 0)
            return vret;
    }

    return 0;
}
```

For each subobject that can participate in cycles, we need to call the visit() function, which is passed to the traversal method. The
visit() function takes as arguments the subobject and the extra argument arg passed to the traversal method. It returns an integer value that must be returned if it is non-zero.

Python provides a Py_VISIT() macro that automates calling visit functions. With Py_VISIT(), Noddy_traverse() can be simplified:

```c
static int
Noddy_traverse(Noddy *self, visitproc visit, void *arg)
{
    Py_VISIT(self->first);
    Py_VISIT(self->last);
    return 0;
}
```

**Note:** Note that the tp_traverse implementation must name its arguments exactly visit and arg in order to use Py_VISIT(). This is to encourage uniformity across these boring implementations.

We also need to provide a method for clearing any subobjects that can participate in cycles.

```c
static int
Noddy_clear(Noddy *self)
{
    PyObject *tmp;

    tmp = self->first;
    self->first = NULL;
    Py_XDECREF(tmp);

    tmp = self->last;
    self->last = NULL;
    Py_XDECREF(tmp);
```
Notice the use of a temporary variable in Noddy_clear(). We use the temporary variable so that we can set each member to NULL before decrementing its reference count. We do this because, as was discussed earlier, if the reference count drops to zero, we might cause code to run that calls back into the object. In addition, because we now support garbage collection, we also have to worry about code being run that triggers garbage collection. If garbage collection is run, our tp_traverse handler could get called. We can't take a chance of having Noddy_traverse() called when a member's reference count has dropped to zero and its value hasn't been set to NULL.

Python provides a Py_CLEAR() that automates the careful decrementing of reference counts. With Py_CLEAR(), the Noddy_clear() function can be simplified:

```c
static int
Noddy_clear(Noddy *self)
{
    Py_CLEAR(self->first);
    Py_CLEAR(self->last);
    return 0;
}
```

Note that Noddy_dealloc() may call arbitrary functions through __del__ method or weakref callback. It means circular GC can be triggered inside the function. Since GC assumes reference count is not zero, we need to untrack the object from GC by calling PyObject_GC_UnTrack() before clearing members. Here is reimplemented deallocator which uses PyObject_GC_UnTrack()
and Noddy_clear().

```c
static void
Noddy_dealloc(Noddy* self)
{
    PyObject_GC_UnTrack(self);
    Noddy_clear(self);
    Py_TYPE(self)->tp_free((PyObject*)self);
}
```

Finally, we add the `Py_TPFLAGS_HAVE_GC` flag to the class flags:

```
Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE | Py_TPFLAGS_HAVE_GC
```

That's pretty much it. If we had written custom `tp_alloc` or `tp_free` slots, we'd need to modify them for cyclic-garbage collection. Most extensions will use the versions automatically provided.

### 2.1.4. Subclassing other types

It is possible to create new extension types that are derived from existing types. It is easiest to inherit from the built in types, since an extension can easily use the `PyTypeObject` it needs. It can be difficult to share these `PyTypeObject` structures between extension modules.

In this example we will create a Shoddy type that inherits from the built-in `list` type. The new type will be completely compatible with regular lists, but will have an additional `increment()` method that increases an internal counter.

```python
>>> import shoddy
```
```python
>>> s = shoddy.Shoddy(range(3))
>>> s.extend(s)
>>> print(len(s))
6
>>> print(s.increment())
1
>>> print(s.increment())
2
```
return 0;
}

static PyTypeObject ShoddyType = {
    PyVarObject_HEAD_INIT(NULL, 0)
    "shoddy.Shoddy",
    sizeof(Shoddy),
    0,
    0,
    0,
    0,
    0,
    0,
    0,
    0,
    0,
    Py_TPFLAGS_DEFAULT | Py_TPFLAGS_BASETYPE,
    Shoddy_methods,
    0,
    0,
    0,
    }
As you can see, the source code closely resembles the Noddy
examples in previous sections. We will break down the main differences between them.

typedef struct {
    PyListObject list;
    int state;
} Shoddy;

The primary difference for derived type objects is that the base type's object structure must be the first value. The base type will already include the `PyObject_HEAD()` at the beginning of its structure.

When a Python object is a Shoddy instance, its `PyObject*` pointer can be safely cast to both `PyListObject*` and `Shoddy*`.

```
static int
Shoddy_init(Shoddy *self, PyObject *args, PyObject *)
{
    if (PyList_Type.tp_init((PyObject *)self, args, 
                 return -1);
    self->state = 0;
    return 0;
}
```

In the `__init__` method for our type, we can see how to call through to the `__init__` method of the base type.

This pattern is important when writing a type with custom new and dealloc methods. The new method should not actually create the memory for the object with `tp_alloc`, that will be handled by the base class when calling its `tp_new`.

When filling out the `PyTypeObject()` for the Shoddy type, you see
a slot for `tp_base()`. Due to cross platform compiler issues, you can't fill that field directly with the `PyList_Type()`; it can be done later in the module's `init()` function.

```c
PyMODINIT_FUNC
PyInit_shoddy(void)
{
    PyObject *m;

    ShoddyType.tp_base = &PyList_Type;
    if (PyType_Ready(&ShoddyType) < 0)
        return NULL;

    m = PyModule_Create(&shoddymodule);
    if (m == NULL)
        return NULL;

    Py_INCREF(&ShoddyType);
    PyModule_AddObject(m, "Shoddy", (PyObject *) &Sh
    return m;
}
```

Before calling `PyType_Ready()`, the type structure must have the `tp_base` slot filled in. When we are deriving a new type, it is not necessary to fill out the `tp_alloc` slot with `PyType_GenericNew()` – the allocate function from the base type will be inherited.

After that, calling `PyType_Ready()` and adding the type object to the module is the same as with the basic Noddy examples.
2.2. Type Methods

This section aims to give a quick fly-by on the various type methods you can implement and what they do.

Here is the definition of `PyTypeObject`, with some fields only used in debug builds omitted:

```c
typedef struct _typeobject {
    PyObject_VAR_HEAD
    const char  *tp_name; /* For printing, in format "<module>.<name>" */
    Py_ssize_t   tp_basicsize, tp_itemsize; /* For allocation */
    /* Methods to implement standard operations */
    destructor   tp_dealloc;
    printfunc    tp_print;
    getattrofunc tp_getattro;
    setattrfunc   tp_setattr;
    PyAsyncMethods *tp_as_async; /* formerly known as tp_compare (Python 2)
                                  or tp_reserved (Python 3) */
    reprfunc     tp_repr;

    /* Method suites for standard classes */
    PyNumberMethods *tp_as_number;
    PySequenceMethods *tp_as_sequence;
    PyMappingMethods *tp_as_mapping;

    /* More standard operations (here for binary compatibility) */
    hashfunc     tp_hash;
    ternaryfunc  tp_call;
    reprfunc     tp_str;
    getattrofunc tp_getattro;
} PyTypeObject;
```
setattrofunc tp_setattro;

/* Functions to access object as input/output buffer */
PyBufferProcs *tp_as_buffer;

/* Flags to define presence of optional/expanded features */
unsigned long tp_flags;

const char *tp_doc; /* Documentation string */

/* call function for all accessible objects */
traverseproc tp_traverse;

/* delete references to contained objects */
inquiry tp_clear;

/* rich comparisons */
richcmpfunc tp_richcompare;

/* weak reference enabler */
Py_ssize_t tp_weaklistoffset;

/* Iterators */
getiterfunc tp_iter;
iternextfunc tp_iternext;

/* Attribute descriptor and subclassing stuff */
struct PyMethodDef *tp_methods;
struct PyMemberDef *tp_members;
struct PyGetSetDef *tp_getset;
struct _typeobject *tp_base;
PyObject *tp_dict;
descrgetfunc tp_descr_get;
descrsetfunc tp_descr_set;
Py_ssize_t tp_dictoffset;
initproc tp_init;
allocfunc tp_alloc;
newfunc tp_new;
freefunc tp_free; /* Low-level free-memory routine */
inquiry tp_is_gc; /* For PyObject_IS_GC */
PyObject *tp_bases;
PyObject *tp_mro; /* method resolution order */
PyObject *tp_cache;
PyObject *tp_subclasses;
PyObject *tp_weaklist;
destructor tp_del;

/* Type attribute cache version tag. Added in version 2.6 */
unsigned int tp_version_tag;

destructor tp_finalize;

} PyTypeObject;

Now that’s a lot of methods. Don’t worry too much though - if you have a type you want to define, the chances are very good that you will only implement a handful of these.

As you probably expect by now, we’re going to go over this and give more information about the various handlers. We won’t go in the order they are defined in the structure, because there is a lot of historical baggage that impacts the ordering of the fields; be sure your type initialization keeps the fields in the right order! It’s often easiest to find an example that includes all the fields you need (even if they’re initialized to 0) and then change the values to suit your new type.

const char *tp_name; /* For printing */

The name of the type - as mentioned in the last section, this will appear in various places, almost entirely for diagnostic purposes. Try to choose something that will be helpful in such a situation!
These fields tell the runtime how much memory to allocate when new objects of this type are created. Python has some built-in support for variable length structures (think: strings, lists) which is where the `tp_itemsize` field comes in. This will be dealt with later.

```c
const char *tp_doc;
```

Here you can put a string (or its address) that you want returned when the Python script references `obj.__doc__` to retrieve the doc string.

Now we come to the basic type methods—the ones most extension types will implement.

### 2.2.1. Finalization and De-allocation

```c
void newdatatype_dealloc(newdatatypeobject * obj) {
    free(obj->obj_UnderlyingDatatypePtr);
    Py_TYPE(obj)->tp_free(obj);
}
```
One important requirement of the deallocator function is that it leaves any pending exceptions alone. This is important since deallocators are frequently called as the interpreter unwinds the Python stack; when the stack is unwound due to an exception (rather than normal returns), nothing is done to protect the deallocators from seeing that an exception has already been set. Any actions which a deallocator performs which may cause additional Python code to be executed may detect that an exception has been set. This can lead to misleading errors from the interpreter. The proper way to protect against this is to save a pending exception before performing the unsafe action, and restoring it when done. This can be done using the `PyErr_Fetch()` and `PyErr_Restore()` functions:

```c
static void my_dealloc(PyObject *obj) {
    MyObject *self = (MyObject *) obj;
    PyObject *cbresult;

    if (self->my_callback != NULL) {
        PyObject *err_type, *err_value, *err_traceback;

        /* This saves the current exception state */
        PyErr_Fetch(&err_type, &err_value, &err_traceback);

        cbresult = PyObject_CallObject(self->my_callback,
                                         self->my_callback);

        if (cbresult == NULL)
            PyErr_WriteUnraisable(self->my_callback);
        else
            Py_DECREF(cbresult);

        /* This restores the saved exception state */
        PyErr_Restore(err_type, err_value, err_traceback);
        Py_DECREF(self->my_callback);
    }
}
```
Py_TYPE(obj)->tp_free((PyObject*)self);

**Note:** There are limitations to what you can safely do in a deallocator function. First, if your type supports garbage collection (using `tp_traverse` and/or `tp_clear`), some of the object’s members can have been cleared or finalized by the time `tp_dealloc` is called. Second, in `tp_dealloc`, your object is in an unstable state: its reference count is equal to zero. Any call to a non-trivial object or API (as in the example above) might end up calling `tp_dealloc` again, causing a double free and a crash.

Starting with Python 3.4, it is recommended not to put any complex finalization code in `tp_dealloc`, and instead use the new `tp_finalize` type method.

**See also:** [PEP 442](https://www.python.org/dev/peps/pep-0442/) explains the new finalization scheme.

### 2.2.2. Object Presentation

In Python, there are two ways to generate a textual representation of an object: the `repr()` function, and the `str()` function. (The `print()` function just calls `str()`.) These handlers are both optional.

```
reprfunc tp_repr;
reprfunc tp_str;
```

The `tp_repr` handler should return a string object containing a representation of the instance for which it is called. Here is a simple
example:

```c
static PyObject *
newdatatype_repr(newdatatypeobject * obj)
{
    return PyUnicode_FromFormat("Repr-ified_newdatatype{{size:%d}}", obj->obj_UnderlyingDatatypePtr);
}
```

If no `tp_repr` handler is specified, the interpreter will supply a representation that uses the type’s `tp_name` and a uniquely-identifying value for the object.

The `tp_str` handler is to `str()` what the `tp_repr` handler described above is to `repr()`; that is, it is called when Python code calls `str()` on an instance of your object. Its implementation is very similar to the `tp_repr` function, but the resulting string is intended for human consumption. If `tp_str` is not specified, the `tp_repr` handler is used instead.

Here is a simple example:

```c
static PyObject *
newdatatype_str(newdatatypeobject * obj)
{
    return PyUnicode_FromFormat("Stringified_newdatatype{{size:%d}}", obj->obj_UnderlyingDatatypePtr);
}
```

2.2.3. Attribute Management

For every object which can support attributes, the corresponding type
must provide the functions that control how the attributes are resolved. There needs to be a function which can retrieve attributes (if any are defined), and another to set attributes (if setting attributes is allowed). Removing an attribute is a special case, for which the new value passed to the handler is NULL.

Python supports two pairs of attribute handlers; a type that supports attributes only needs to implement the functions for one pair. The difference is that one pair takes the name of the attribute as a char*, while the other accepts a PyObject*. Each type can use whichever pair makes more sense for the implementation’s convenience.

```c
getattrfunc tp_getattr; /* char * version */
setattrfunc tp_setattr;
/* ... */
getattrofunc tp_getattro; /* PyObject * version */
setattrofunc tp_setattro;
```

If accessing attributes of an object is always a simple operation (this will be explained shortly), there are generic implementations which can be used to provide the PyObject* version of the attribute management functions. The actual need for type-specific attribute handlers almost completely disappeared starting with Python 2.2, though there are many examples which have not been updated to use some of the new generic mechanism that is available.

2.2.3.1. Generic Attribute Management

Most extension types only use simple attributes. So, what makes the attributes simple? There are only a couple of conditions that must be met:
1. The name of the attributes must be known when `PyType_Ready()` is called.
2. No special processing is needed to record that an attribute was looked up or set, nor do actions need to be taken based on the value.

Note that this list does not place any restrictions on the values of the attributes, when the values are computed, or how relevant data is stored.

When `PyType_Ready()` is called, it uses three tables referenced by the type object to create descriptors which are placed in the dictionary of the type object. Each descriptor controls access to one attribute of the instance object. Each of the tables is optional; if all three are `NULL`, instances of the type will only have attributes that are inherited from their base type, and should leave the `tp_getattro` and `tp_setattro` fields `NULL` as well, allowing the base type to handle attributes.

The tables are declared as three fields of the type object:

```c
struct PyMethodDef *tp_methods;
struct PyMemberDef *tp_members;
struct PyGetSetDef *tp_getset;
```

If `tp_methods` is not `NULL`, it must refer to an array of `PyMethodDef` structures. Each entry in the table is an instance of this structure:

```c
typedef struct PyMethodDef {
    const char *ml_name;    /* method name */
    PyCFunction ml_meth;    /* implementation function */
    int ml_flags;            /* flags */
    const char *ml_doc;      /* docstring */
} PyMethodDef;
```
One entry should be defined for each method provided by the type; no entries are needed for methods inherited from a base type. One additional entry is needed at the end; it is a sentinel that marks the end of the array. The ml_name field of the sentinel must be NULL.

The second table is used to define attributes which map directly to data stored in the instance. A variety of primitive C types are supported, and access may be read-only or read-write. The structures in the table are defined as:

```c
typedef struct PyMemberDef {
    char *name;
    int type;
    int offset;
    int flags;
    char *doc;
} PyMemberDef;
```

For each entry in the table, a descriptor will be constructed and added to the type which will be able to extract a value from the instance structure. The type field should contain one of the type codes defined in the structmember.h header; the value will be used to determine how to convert Python values to and from C values. The flags field is used to store flags which control how the attribute can be accessed.

The following flag constants are defined in structmember.h; they may be combined using bitwise-OR.

<table>
<thead>
<tr>
<th>Constant</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>READONLY</td>
<td>Never writable.</td>
</tr>
<tr>
<td>READ_RESTRICTED</td>
<td>Not readable in restricted mode.</td>
</tr>
<tr>
<td>-----------------------</td>
<td>----------------------------------</td>
</tr>
<tr>
<td>WRITE_RESTRICTED</td>
<td>Not writable in restricted mode.</td>
</tr>
<tr>
<td>RESTRICTED</td>
<td>Not readable or writable in restricted mode.</td>
</tr>
</tbody>
</table>

An interesting advantage of using the `tp_members` table to build descriptors that are used at runtime is that any attribute defined this way can have an associated doc string simply by providing the text in the table. An application can use the introspection API to retrieve the descriptor from the class object, and get the doc string using its `__doc__` attribute.

As with the `tp_methods` table, a sentinel entry with a name value of `NULL` is required.

### 2.2.3.2. Type-specific Attribute Management

For simplicity, only the `char*` version will be demonstrated here; the type of the name parameter is the only difference between the `char*` and `PyObject*` flavors of the interface. This example effectively does the same thing as the generic example above, but does not use the generic support added in Python 2.2. It explains how the handler functions are called, so that if you do need to extend their functionality, you'll understand what needs to be done.

The `tp_getattr` handler is called when the object requires an attribute look-up. It is called in the same situations where the `__getattr__()` method of a class would be called.

Here is an example:

```python
static PyObject *
```
newdatatype_getattr(newdatatypeobject *obj, char *name)
{
    if (strcmp(name, "data") == 0)
    {
        return PyLong_FromLong(obj->data);
    }
    PyErr_Format(PyExc_AttributeError,
        "'%.50s' object has no attribute '%
        tp->tp_name, name);
    return NULL;
}

The \texttt{tp\_setattr} handler is called when the \texttt{\_\_setattr\_\_()} or
\texttt{\_\_delattr\_\_()} method of a class instance would be called. When
an attribute should be deleted, the third parameter will be \texttt{NULL}. Here
is an example that simply raises an exception; if this were really all you
wanted, the \texttt{tp\_setattr} handler should be set to \texttt{NULL}.

static int
newdatatype_setattr(newdatatypeobject *obj, char *name)
{
    (void)PyErr_Format(PyExc_RuntimeError, "Read-only
    return -1;
}

2.2.4. Object Comparison

richcmpfunc tp_richcompare;

The \texttt{tp\_richcompare} handler is called when comparisons are
needed. It is analogous to the \texttt{rich comparison methods}, like
__lt__(), and also called by PyObject_RichCompare() and PyObject_RichCompareBool().

This function is called with two Python objects and the operator as arguments, where the operator is one of Py_EQ, Py_NE, Py_LE, Py_GT, Py_LT or Py_GT. It should compare the two objects with respect to the specified operator and return Py_True or Py_False if the comparison is successful, Py_NotImplemented to indicate that comparison is not implemented and the other object’s comparison method should be tried, or NULL if an exception was set.

Here is a sample implementation, for a datatype that is considered equal if the size of an internal pointer is equal:

```c
static PyObject *
newdatatype_richcmp(PyObject *obj1, PyObject *obj2,
{  
    PyObject *result;
    int c, size1, size2;

    /* code to make sure that both arguments are of newdatatype omitted */

    size1 = obj1->obj_UnderlyingDatatypePtr->size;
    size2 = obj2->obj_UnderlyingDatatypePtr->size;

    switch (op) {
    case Py_LT: c = size1 < size2; break;
    case Py_LE: c = size1 <= size2; break;
    case Py_EQ: c = size1 == size2; break;
    case Py_NE: c = size1 != size2; break;
    case Py_GT: c = size1 > size2; break;
    case Py_GE: c = size1 >= size2; break;
    }
    result = c ? Py_True : Py_False;
```
2.2.5. Abstract Protocol Support

Python supports a variety of abstract ‘protocols;’ the specific interfaces provided to use these interfaces are documented in Abstract Objects Layer.

A number of these abstract interfaces were defined early in the development of the Python implementation. In particular, the number, mapping, and sequence protocols have been part of Python since the beginning. Other protocols have been added over time. For protocols which depend on several handler routines from the type implementation, the older protocols have been defined as optional blocks of handlers referenced by the type object. For newer protocols there are additional slots in the main type object, with a flag bit being set to indicate that the slots are present and should be checked by the interpreter. (The flag bit does not indicate that the slot values are non-NULL. The flag may be set to indicate the presence of a slot, but a slot may still be unfilled.)

```c
PyNumberMethods *tp_as_number;
PySequenceMethods *tp_as_sequence;
PyMappingMethods *tp_as_mapping;
```

If you wish your object to be able to act like a number, a sequence, or a mapping object, then you place the address of a structure that implements the C type `PyNumberMethods`, `PySequenceMethods`, or `PyMappingMethods`, respectively. It is up to you to fill in this structure with appropriate values. You can find examples of the use of
each of these in the Objects directory of the Python source distribution.

```c
hashfunc tp_hash;
```

This function, if you choose to provide it, should return a hash number for an instance of your data type. Here is a moderately pointless example:

```c
static long newdatatype_hash(newdatatypeobject *obj)
{
    long result;
    result = obj->obj_UnderlyingDatatypePtr->size;
    result = result * 3;
    return result;
}
```

```c
ternaryfunc tp_call;
```

This function is called when an instance of your data type is “called”, for example, if `obj1` is an instance of your data type and the Python script contains `obj1('hello')`, the `tp_call` handler is invoked.

This function takes three arguments:

1. `arg1` is the instance of the data type which is the subject of the call. If the call is `obj1('hello')`, then `arg1` is `obj1`.
2. `arg2` is a tuple containing the arguments to the call. You can use `PyArg_ParseTuple()` to extract the arguments.
3. `arg3` is a dictionary of keyword arguments that were passed. If this is non-NULL and you support keyword arguments, use `PyArg_ParseTupleAndKeywords()` to extract the arguments.
   If you do not want to support keyword arguments and this is non-
NULL, raise a TypeError with a message saying that keyword arguments are not supported.

Here is a desultory example of the implementation of the call function.

```c
/* Implement the call function. * 
 * obj1 is the instance receiving the call. 
 * obj2 is a tuple containing the arguments to the case 3 strings. */
static PyObject *
newdatatype_call(newdatatypeobject *obj, PyObject *args
{    
    PyObject *result;
    char *arg1;
    char *arg2;
    char *arg3;

    if (!PyArg_ParseTuple(args, "sss:call", &arg1, &
        return NULL;
    }
    result = PyUnicode_FromFormat(
        "Returning -- value: [%d] arg1: [%s] arg2: 
        obj->obj_UnderlyingDatatypePtr->size, 
        arg1, arg2, arg3);
    return result;
}

/* Iterators */
getiterfunc tp_iter;
iternextfunc tp_iternext;
```

These functions provide support for the iterator protocol. Any object which wishes to support iteration over its contents (which may be generated during iteration) must implement the tp_iter handler.
Objects which are returned by a `tp_iter` handler must implement both the `tp_iter` and `tp_iternext` handlers. Both handlers take exactly one parameter, the instance for which they are being called, and return a new reference. In the case of an error, they should set an exception and return `NULL`.

For an object which represents an iterable collection, the `tp_iter` handler must return an iterator object. The iterator object is responsible for maintaining the state of the iteration. For collections which can support multiple iterators which do not interfere with each other (as lists and tuples do), a new iterator should be created and returned. Objects which can only be iterated over once (usually due to side effects of iteration) should implement this handler by returning a new reference to themselves, and should also implement the `tp_iternext` handler. File objects are an example of such an iterator.

Iterator objects should implement both handlers. The `tp_iter` handler should return a new reference to the iterator (this is the same as the `tp_iter` handler for objects which can only be iterated over destructively). The `tp_iternext` handler should return a new reference to the next object in the iteration if there is one. If the iteration has reached the end, it may return `NULL` without setting an exception or it may set `StopIteration`; avoiding the exception can yield slightly better performance. If an actual error occurs, it should set an exception and return `NULL`.

### 2.2.6. Weak Reference Support

One of the goals of Python’s weak-reference implementation is to allow any type to participate in the weak reference mechanism without
incurring the overhead on those objects which do not benefit by weak referencing (such as numbers).

For an object to be weakly referencable, the extension must include a `PyObject*` field in the instance structure for the use of the weak reference mechanism; it must be initialized to `NULL` by the object's constructor. It must also set the `tp_weaklistoffset` field of the corresponding type object to the offset of the field. For example, the instance type is defined with the following structure:

```c
typedef struct {
    PyObject_HEAD
    PyClassObject  *in_class;    /* The class object */
    PyObject       *in_dict;     /* A dictionary */
    PyObject       *in_weakreflist; /* List of weak references */
} PyInstanceObject;
```

The statically-declared type object for instances is defined this way:

```c
PyTypeObject PyInstance_Type = {
    PyVarObject_HEAD_INIT(&PyType_Type, 0)
    0,
    "module.instance",

    /* Lots of stuff omitted for brevity... */

    Py_TPFLAGS_DEFAULT,
    0, /* tp_new */
    0, /* tp_free */
    0, /* tp_print */
    0, /* tp_getattr */
    0, /* tp_setattr */
    offsetof(PyInstanceObject, in_weakreflist), /* tp_compare */
};
```
The type constructor is responsible for initializing the weak reference list to NULL:

```c
static PyObject *
instance_new() {
    /* Other initialization stuff omitted for brevity */
    self->in_weakreflist = NULL;
    return (PyObject *) self;
}
```

The only further addition is that the destructor needs to call the weak reference manager to clear any weak references. This is only required if the weak reference list is non-NULL:

```c
static void
instance_dealloc(PyInstanceObject *inst)
{
    /* Allocate temporaries if needed, but do not begin destruction just yet. */

    if (inst->in_weakreflist != NULL)
        PyObject_ClearWeakRefs((PyObject *) inst);

    /* Proceed with object destruction normally. */
}
```

2.2.7. More Suggestions

Remember that you can omit most of these functions, in which case you provide 0 as a value. There are type definitions for each of the
functions you must provide. They are in `object.h` in the Python include directory that comes with the source distribution of Python.

In order to learn how to implement any specific method for your new data type, do the following: Download and unpack the Python source distribution. Go to the `Objects` directory, then search the C source files for `tp_` plus the function you want (for example, `tp_richcompare`). You will find examples of the function you want to implement.

When you need to verify that an object is an instance of the type you are implementing, use the `PyObject_TypeCheck()` function. A sample of its use might be something like the following:

```c
if (!PyObject_TypeCheck(some_object, &MyType)) {
    PyErr_SetString(PyExc_TypeError, "arg #1 not a mything");
    return NULL;
}
```

Footnotes

[1] This is true when we know that the object is a basic type, like a string or a float.

We relied on this in the `tp_dealloc` handler in this example, because our type doesn’t support garbage collection. Even if a type supports garbage collection, there are calls that can be made to “untrack” the object from garbage collection, however, these calls are advanced and not covered here.

[2] We now know that the first and last members are strings, so perhaps we could be less careful about decrementing their reference counts, however, we accept instances of string subclasses. Even though deallocating normal strings won’t call
back into our objects, we can’t guarantee that deallocating an instance of a string subclass won’t call back into our objects.

Even in the third version, we aren’t guaranteed to avoid cycles. Instances of string subclasses are allowed and string subclasses could allow cycles even if normal strings don’t.
3. Building C and C++ Extensions

A C extension for CPython is a shared library (e.g. a .so file on Linux, .pyd on Windows), which exports an initialization function.

To be importable, the shared library must be available on PYTHONPATH, and must be named after the module name, with an appropriate extension. When using distutils, the correct filename is generated automatically.

The initialization function has the signature:

`PyObject* PyInit_modulename(void)`

It returns either a fully-initialized module, or a `PyModuleDef` instance. See Initializing C modules for details.

For modules with ASCII-only names, the function must be named `PyInit_<modulename>`, with `<modulename>` replaced by the name of the module. When using Multi-phase initialization, non-ASCII module names are allowed. In this case, the initialization function name is `PyInitU_<modulename>`, with `<modulename>` encoded using Python’s `punycode` encoding with hyphens replaced by underscores. In Python:

```python
def initfunc_name(name):
    try:
        suffix = b'_' + name.encode('ascii')
    except UnicodeEncodeError:
        suffix = b'U_' + name.encode('punycode').replace(b'-', b'_')
    return b'PyInit' + suffix
```
It is possible to export multiple modules from a single shared library by defining multiple initialization functions. However, importing them requires using symbolic links or a custom importer, because by default only the function corresponding to the filename is found. See the “Multiple modules in one library” section in PEP 489 for details.
3.1. Building C and C++ Extensions with distutils

Extension modules can be built using distutils, which is included in Python. Since distutils also supports creation of binary packages, users don’t necessarily need a compiler and distutils to install the extension.

A distutils package contains a driver script, `setup.py`. This is a plain Python file, which, in the most simple case, could look like this:

```python
from distutils.core import setup, Extension

module1 = Extension('demo',
                     sources = ['demo.c'])

setup (name = 'PackageName',
       version = '1.0',
       description = 'This is a demo package',
       ext_modules = [module1])
```

With this `setup.py`, and a file `demo.c`, running

```
python setup.py build
```

will compile `demo.c`, and produce an extension module named `demo` in the `build` directory. Depending on the system, the module file will end up in a subdirectory `build/lib.system`, and may have a name like `demo.so` or `demo.pyd`.

In the `setup.py`, all execution is performed by calling the `setup` function. This takes a variable number of keyword arguments, of which
the example above uses only a subset. Specifically, the example specifies meta-information to build packages, and it specifies the contents of the package. Normally, a package will contain additional modules, like Python source modules, documentation, subpackages, etc. Please refer to the distutils documentation in *Distributing Python Modules (Legacy version)* to learn more about the features of distutils; this section explains building extension modules only.

It is common to pre-compute arguments to setup(), to better structure the driver script. In the example above, the `ext_modules` argument to `setup()` is a list of extension modules, each of which is an instance of the Extension. In the example, the instance defines an extension named `demo` which is build by compiling a single source file, `demo.c`.

In many cases, building an extension is more complex, since additional preprocessor defines and libraries may be needed. This is demonstrated in the example below.

```python
from distutils.core import setup, Extension

module1 = Extension('demo',
    define_macros = [(("MAJOR_VERSION", 1),
                     ("MINOR_VERSION", 0)),
    include_dirs = ['/usr/local/include'],
    libraries = ['tcl83'],
    library_dirs = ['/usr/local/lib'],
    sources = ['demo.c'])

setup (name = 'PackageName',
    version = '1.0',
    description = 'This is a demo package',
    author = 'Martin v. Loewis',
    author_email = 'martin@v.loewis.de',
```
In this example, `setup()` is called with additional meta-information, which is recommended when distribution packages have to be built. For the extension itself, it specifies preprocessor defines, include directories, library directories, and libraries. Depending on the compiler, distutils passes this information in different ways to the compiler. For example, on Unix, this may result in the compilation commands

```
gcc -DNDEBUG -g -O3 -Wall -Wstrict-prototypes -fPIC
gcc -shared build/temp.linux-i686-2.2/demo.o -L/usr/
```

These lines are for demonstration purposes only; distutils users should trust that distutils gets the invocations right.
3.2. Distributing your extension modules

When an extension has been successfully built, there are three ways to use it.

End-users will typically want to install the module, they do so by running

```
python setup.py install
```

Module maintainers should produce source packages; to do so, they run

```
python setup.py sdist
```

In some cases, additional files need to be included in a source distribution; this is done through a MANIFEST.in file; see Specifying the files to distribute for details.

If the source distribution has been built successfully, maintainers can also create binary distributions. Depending on the platform, one of the following commands can be used to do so.

```
python setup.py bdist_wininst
python setup.py bdist_rpm
python setup.py bdist_dumb
```
4. Building C and C++ Extensions on Windows

This chapter briefly explains how to create a Windows extension module for Python using Microsoft Visual C++, and follows with more detailed background information on how it works. The explanatory material is useful for both the Windows programmer learning to build Python extensions and the Unix programmer interested in producing software which can be successfully built on both Unix and Windows.

Module authors are encouraged to use the distutils approach for building extension modules, instead of the one described in this section. You will still need the C compiler that was used to build Python; typically Microsoft Visual C++.

**Note:** This chapter mentions a number of filenames that include an encoded Python version number. These filenames are represented with the version number shown as XY; in practice, 'X' will be the major version number and 'Y' will be the minor version number of the Python release you’re working with. For example, if you are using Python 2.2.1, XY will actually be 22.
4.1. A Cookbook Approach

There are two approaches to building extension modules on Windows, just as there are on Unix: use the distutils package to control the build process, or do things manually. The distutils approach works well for most extensions; documentation on using distutils to build and package extension modules is available in Distributing Python Modules (Legacy version). If you find you really need to do things manually, it may be instructive to study the project file for the winsound standard library module.
4.2. Differences Between Unix and Windows

Unix and Windows use completely different paradigms for run-time loading of code. Before you try to build a module that can be dynamically loaded, be aware of how your system works.

In Unix, a shared object (.so) file contains code to be used by the program, and also the names of functions and data that it expects to find in the program. When the file is joined to the program, all references to those functions and data in the file’s code are changed to point to the actual locations in the program where the functions and data are placed in memory. This is basically a link operation.

In Windows, a dynamic-link library (.dll) file has no dangling references. Instead, an access to functions or data goes through a lookup table. So the DLL code does not have to be fixed up at runtime to refer to the program’s memory; instead, the code already uses the DLL’s lookup table, and the lookup table is modified at runtime to point to the functions and data.

In Unix, there is only one type of library file (.a) which contains code from several object files (.o). During the link step to create a shared object file (.so), the linker may find that it doesn’t know where an identifier is defined. The linker will look for it in the object files in the libraries; if it finds it, it will include all the code from that object file.

In Windows, there are two types of library, a static library and an import library (both called .lib). A static library is like a Unix .a file; it contains code to be included as necessary. An import library is basically used only to reassure the linker that a certain identifier is
legal, and will be present in the program when the DLL is loaded. So the linker uses the information from the import library to build the lookup table for using identifiers that are not included in the DLL. When an application or a DLL is linked, an import library may be generated, which will need to be used for all future DLLs that depend on the symbols in the application or DLL.

Suppose you are building two dynamic-load modules, B and C, which should share another block of code A. On Unix, you would not pass A.a to the linker for B.so and C.so; that would cause it to be included twice, so that B and C would each have their own copy. In Windows, building A.dll will also build A.lib. You do pass A.lib to the linker for B and C. A.lib does not contain code; it just contains information which will be used at runtime to access A’s code.

In Windows, using an import library is sort of like using import spam; it gives you access to spam’s names, but does not create a separate copy. On Unix, linking with a library is more like from spam import *; it does create a separate copy.
4.3. Using DLLs in Practice

Windows Python is built in Microsoft Visual C++; using other compilers may or may not work (though Borland seems to). The rest of this section is MSVC++ specific.

When creating DLLs in Windows, you must pass pythonXY.lib to the linker. To build two DLLs, spam and ni (which uses C functions found in spam), you could use these commands:

```
cl /LD /I/python/include spam.c ../libs/pythonXY.lib
cl /LD /I/python/include ni.c spam.lib ../libs/pythonXY.lib
```

The first command created three files: spam.obj, spam.dll and spam.lib. Spam.dll does not contain any Python functions (such as `PyArg_ParseTuple()`), but it does know how to find the Python code thanks to pythonXY.lib.

The second command created ni.dll (and .obj and .lib), which knows how to find the necessary functions from spam, and also from the Python executable.

Not every identifier is exported to the lookup table. If you want any other modules (including Python) to be able to see your identifiers, you have to say `declspec(dllexport)`, as in `void _declspec(dllexport) initspam(void)` or `PyObject _declspec(dllexport) *NiGetSpamData(void)`.

Developer Studio will throw in a lot of import libraries that you do not really need, adding about 100K to your executable. To get rid of them, use the Project Settings dialog, Link tab, to specify `ignore default`
libraries. Add the correct `msvcrtxx.lib` to the list of libraries.
1. Embedding Python in Another Application

The previous chapters discussed how to extend Python, that is, how to extend the functionality of Python by attaching a library of C functions to it. It is also possible to do it the other way around: enrich your C/C++ application by embedding Python in it. Embedding provides your application with the ability to implement some of the functionality of your application in Python rather than C or C++. This can be used for many purposes; one example would be to allow users to tailor the application to their needs by writing some scripts in Python. You can also use it yourself if some of the functionality can be written in Python more easily.

Embedding Python is similar to extending it, but not quite. The difference is that when you extend Python, the main program of the application is still the Python interpreter, while if you embed Python, the main program may have nothing to do with Python — instead, some parts of the application occasionally call the Python interpreter to run some Python code.

So if you are embedding Python, you are providing your own main program. One of the things this main program has to do is initialize the Python interpreter. At the very least, you have to call the function Py_Initialize(). There are optional calls to pass command line arguments to Python. Then later you can call the interpreter from any part of the application.

There are several different ways to call the interpreter: you can pass a string containing Python statements to PyRun_SimpleString(), or
you can pass a stdio file pointer and a file name (for identification in error messages only) to `PyRun_SimpleFile()`. You can also call the lower-level operations described in the previous chapters to construct and use Python objects.

**See also:**

**Python/C API Reference Manual**

The details of Python’s C interface are given in this manual. A great deal of necessary information can be found here.
1.1. Very High Level Embedding

The simplest form of embedding Python is the use of the very high level interface. This interface is intended to execute a Python script without needing to interact with the application directly. This can for example be used to perform some operation on a file.

```c
#include <Python.h>

int main(int argc, char *argv[]) {
    wchar_t *program = Py_DecodeLocale(argv[0], NULL);
    if (program == NULL) {
        fprintf(stderr, "Fatal error: cannot decode argv[0]");
        exit(1);
    }
    Py_SetProgramName(program); /* optional but recommended */
    Py_Initialize();
    PyRun_SimpleString("from time import time,ctime
                        print('Today is', ctime(time()))
                        if (Py_FinalizeEx() < 0) {
                            exit(120);
                        }
    PyMem_RawFree(program);
    return 0;
}
```

The `Py_SetProgramName()` function should be called before `Py_Initialize()` to inform the interpreter about paths to Python run-time libraries. Next, the Python interpreter is initialized with `Py_Initialize()`, followed by the execution of a hard-coded Python script that prints the date and time. Afterwards, the
\texttt{Py\_FinalizeEx()} call shuts the interpreter down, followed by the end of the program. In a real program, you may want to get the Python script from another source, perhaps a text-editor routine, a file, or a database. Getting the Python code from a file can better be done by using the \texttt{PyRun\_SimpleFile()} function, which saves you the trouble of allocating memory space and loading the file contents.
1.2. Beyond Very High Level Embedding: An overview

The high level interface gives you the ability to execute arbitrary pieces of Python code from your application, but exchanging data values is quite cumbersome to say the least. If you want that, you should use lower level calls. At the cost of having to write more C code, you can achieve almost anything.

It should be noted that extending Python and embedding Python is quite the same activity, despite the different intent. Most topics discussed in the previous chapters are still valid. To show this, consider what the extension code from Python to C really does:

1. Convert data values from Python to C,
2. Perform a function call to a C routine using the converted values, and
3. Convert the data values from the call from C to Python.

When embedding Python, the interface code does:

1. Convert data values from C to Python,
2. Perform a function call to a Python interface routine using the converted values, and
3. Convert the data values from the call from Python to C.

As you can see, the data conversion steps are simply swapped to accommodate the different direction of the cross-language transfer. The only difference is the routine that you call between both data conversions. When extending, you call a C routine, when embedding, you call a Python routine.

This chapter will not discuss how to convert data from Python to C and
vice versa. Also, proper use of references and dealing with errors is assumed to be understood. Since these aspects do not differ from extending the interpreter, you can refer to earlier chapters for the required information.
1.3. Pure Embedding

The first program aims to execute a function in a Python script. Like in the section about the very high level interface, the Python interpreter does not directly interact with the application (but that will change in the next section).

The code to run a function defined in a Python script is:

```c
#include <Python.h>

int main(int argc, char *argv[]) {
    PyObject *pName, *pModule, *pDict, *pFunc;
    PyObject *pArgs, *pValue;
    int i;

    if (argc < 3) {
        fprintf(stderr,"Usage: call pythonfile funcname [args]
        return 1;
    }

    Py_Initialize();
    pName = PyUnicode_DecodeFSDefault(argv[1]);
    /* Error checking of pName left out */

    pModule = PyImport_Import(pName);
    Py_DECREF(pName);

    if (pModule != NULL) {
        pFunc = PyObject_GetAttrString(pModule, argv[2]);
        /* pFunc is a new reference */
        if (pFunc && PyCallable_Check(pFunc)) {
```
pArgs = PyTuple_New(argc - 3);
for (i = 0; i < argc - 3; ++i) {
    pValue = PyLong_FromLong(atoi(argv[i]);
    if (!pValue) {
        Py_DECREF(pArgs);
        Py_DECREF(pModule);
        fprintf(stderr, "Cannot convert
        return 1;
    } /* pValue reference stolen here: */
    PyTuple_SetItem(pArgs, i, pValue);
}
pValue = PyObject_CallObject(pFunc, pArgs);
Py_DECREF(pArgs);
if (pValue != NULL) {
    printf("Result of call: %ld\n", PyLong_AsLong(pValue));
    Py_DECREF(pValue);
} else {
    Py_DECREF(pFunc);
    Py_DECREF(pModule);
    PyErr_Print();
    fprintf(stderr, "Call failed\n");
    return 1;
}
else {
    if (PyErr_Occurred())
        PyErr_Print();
    fprintf(stderr, "Cannot find function \"
}
Py_XDECREF(pFunc);
Py_DECREF(pModule);
else {
    PyErr_Print();
    fprintf(stderr, "Failed to load \"%s\"\n", a
This code loads a Python script using `argv[1]`, and calls the function named in `argv[2]`. Its integer arguments are the other values of the `argv` array. If you compile and link this program (let's call the finished executable `call`), and use it to execute a Python script, such as:

```python
def multiply(a, b):
    print("Will compute", a, "times", b)
    c = 0
    for i in range(0, a):
        c = c + b
    return c
```

then the result should be:

```
$ call multiply multiply 3 2
Will compute 3 times 2
Result of call: 6
```

Although the program is quite large for its functionality, most of the code is for data conversion between Python and C, and for error reporting. The interesting part with respect to embedding Python starts with

```c
def multiply(a, b):
    print("Will compute", a, "times", b)
    c = 0
    for i in range(0, a):
        c = c + b
    return c
```
pModule = PyImport_Import(pName);

After initializing the interpreter, the script is loaded using `PyImport_Import()`. This routine needs a Python string as its argument, which is constructed using the `PyUnicode_FromString()` data conversion routine.

```c
pFunc = PyObject_GetAttrString(pModule, argv[2]); /* pFunc is a new reference */

if (pFunc && PyCallable_Check(pFunc)) {
    ...
}
Py_XDECREFP(pFunc);
```

Once the script is loaded, the name we're looking for is retrieved using `PyObject_GetAttrString()`. If the name exists, and the object returned is callable, you can safely assume that it is a function. The program then proceeds by constructing a tuple of arguments as normal. The call to the Python function is then made with:

```c
pValue = PyObject_CallObject(pFunc, pArgs);
```

Upon return of the function, `pValue` is either `NULL` or it contains a reference to the return value of the function. Be sure to release the reference after examining the value.
1.4. Extending Embedded Python

Until now, the embedded Python interpreter had no access to functionality from the application itself. The Python API allows this by extending the embedded interpreter. That is, the embedded interpreter gets extended with routines provided by the application. While it sounds complex, it is not so bad. Simply forget for a while that the application starts the Python interpreter. Instead, consider the application to be a set of subroutines, and write some glue code that gives Python access to those routines, just like you would write a normal Python extension. For example:

```c
static int numargs=0;

/* Return the number of arguments of the application command line */
static PyObject *
emb_numargs(PyObject *self, PyObject *args)
{
    if (!PyArg_ParseTuple(args, ":numargs"))
        return NULL;
    return PyLong_FromLong(numargs);
}

static PyMethodDef EmbMethods[] = {
    {"numargs", emb_numargs, METH_VARARGS,
     "Return the number of arguments received by the process.
     
     {NULL, NULL, 0, NULL}
    };

static PyModuleDef EmbModule = {
    PyModuleDef_HEAD_INIT, "emb", NULL, -1, EmbMethods
    NULL, NULL, NULL, NULL, NULL
};
```
```c
static PyObject*
PyInit_emb(void)
{
    return PyModule_Create(&EmbModule);
}
```

Insert the above code just above the `main()` function. Also, insert the following two statements before the call to `Py_Initialize()`:

```c
numargs = argc;
PyImport_AppendInittab("emb", &PyInit_emb);
```

These two lines initialize the `numargs` variable, and make the `emb.numargs()` function accessible to the embedded Python interpreter. With these extensions, the Python script can do things like

```python
import emb
print("Number of arguments", emb.numargs())
```

In a real application, the methods will expose an API of the application to Python.
1.5. Embedding Python in C++

It is also possible to embed Python in a C++ program; precisely how this is done will depend on the details of the C++ system used; in general you will need to write the main program in C++, and use the C++ compiler to compile and link your program. There is no need to recompile Python itself using C++. 
1.6. Compiling and Linking under Unix-like systems

It is not necessarily trivial to find the right flags to pass to your compiler (and linker) in order to embed the Python interpreter into your application, particularly because Python needs to load library modules implemented as C dynamic extensions (.so files) linked against it.

To find out the required compiler and linker flags, you can execute the pythonX.Y-config script which is generated as part of the installation process (a python3-config script may also be available). This script has several options, of which the following will be directly useful to you:

- **pythonX.Y-config --cflags** will give you the recommended flags when compiling:

  ```
  $ /opt/bin/python3.4-config --cflags
  -I/opt/include/python3.4m -I/opt/include/python3
  ```

- **pythonX.Y-config --ldflags** will give you the recommended flags when linking:

  ```
  $ /opt/bin/python3.4-config --ldflags
  -L/opt/lib/python3.4/config-3.4m -lpthread -ldl
  ```

**Note:** To avoid confusion between several Python installations (and especially between the system Python and your own compiled Python), it is recommended that you use the absolute path to pythonX.Y-config, as in the above example.
If this procedure doesn’t work for you (it is not guaranteed to work for all Unix-like platforms; however, we welcome bug reports) you will have to read your system’s documentation about dynamic linking and/or examine Python’s Makefile (use `sysconfig.get_makefile_filename()` to find its location) and compilation options. In this case, the `sysconfig` module is a useful tool to programmatically extract the configuration values that you will want to combine together. For example:

```python
>>> import sysconfig
>>> sysconfig.get_config_var('LIBS')
'-lpthread -ldl -lutil'
>>> sysconfig.get_config_var('LINKFORSHARED')
'-Xlinker -export-dynamic'
```
Introduction

The Application Programmer’s Interface to Python gives C and C++ programmers access to the Python interpreter at a variety of levels. The API is equally usable from C++, but for brevity it is generally referred to as the Python/C API. There are two fundamentally different reasons for using the Python/C API. The first reason is to write extension modules for specific purposes; these are C modules that extend the Python interpreter. This is probably the most common use. The second reason is to use Python as a component in a larger application; this technique is generally referred to as embedding Python in an application.

Writing an extension module is a relatively well-understood process, where a “cookbook” approach works well. There are several tools that automate the process to some extent. While people have embedded Python in other applications since its early existence, the process of embedding Python is less straightforward than writing an extension.

Many API functions are useful independent of whether you’re embedding or extending Python; moreover, most applications that embed Python will need to provide a custom extension as well, so it’s probably a good idea to become familiar with writing an extension before attempting to embed Python in a real application.
Include Files

All function, type and macro definitions needed to use the Python/C API are included in your code by the following line:

```
#include "Python.h"
```

This implies inclusion of the following standard headers: `<stdio.h>`, `<string.h>`, `<errno.h>`, `<limits.h>`, `<assert.h>` and `<stdlib.h>` (if available).

**Note:** Since Python may define some pre-processor definitions which affect the standard headers on some systems, you must include `Python.h` before any standard headers are included.

All user visible names defined by Python.h (except those defined by the included standard headers) have one of the prefixes `Py` or `_Py`. Names beginning with `_Py` are for internal use by the Python implementation and should not be used by extension writers. Structure member names do not have a reserved prefix.

**Important:** user code should never define names that begin with `Py` or `_Py`. This confuses the reader, and jeopardizes the portability of the user code to future Python versions, which may define additional names beginning with one of these prefixes.

The header files are typically installed with Python. On Unix, these are located in the directories `prefix/include/pythonversion/` and `exec_prefix/include/pythonversion/`, where `prefix` and `exec_prefix` are defined by the corresponding parameters to Python’s `configure` script and `version` is `%d.%d`.
On Windows, the headers are installed in `prefix/include`, where `prefix` is the installation directory specified to the installer.

To include the headers, place both directories (if different) on your compiler's search path for includes. Do not place the parent directories on the search path and then use `#include <pythonX.Y/Python.h>`; this will break on multi-platform builds since the platform independent headers under `prefix` include the platform specific headers from `exec_prefix`.

C++ users should note that though the API is defined entirely using C, the header files do properly declare the entry points to be `extern "C"`, so there is no need to do anything special to use the API from C++. 
Objects, Types and Reference Counts

Most Python/C API functions have one or more arguments as well as a return value of type `PyObject*`. This type is a pointer to an opaque data type representing an arbitrary Python object. Since all Python object types are treated the same way by the Python language in most situations (e.g., assignments, scope rules, and argument passing), it is only fitting that they should be represented by a single C type. Almost all Python objects live on the heap: you never declare an automatic or static variable of type `PyObject`, only pointer variables of type `PyObject*` can be declared. The sole exception are the type objects; since these must never be deallocated, they are typically static `PyTypeObject` objects.

All Python objects (even Python integers) have a *type* and a *reference count*. An object’s type determines what kind of object it is (e.g., an integer, a list, or a user-defined function; there are many more as explained in *The standard type hierarchy*). For each of the well-known types there is a macro to check whether an object is of that type; for instance, `PyList_Check(a)` is true if (and only if) the object pointed to by `a` is a Python list.

Reference Counts

The reference count is important because today’s computers have a finite (and often severely limited) memory size; it counts how many different places there are that have a reference to an object. Such a place could be another object, or a global (or static) C variable, or a local variable in some C function. When an object’s reference count becomes zero, the object is deallocated. If it contains references to other objects, their reference count is decremented. Those other
objects may be deallocated in turn, if this decrement makes their reference count become zero, and so on. (There's an obvious problem with objects that reference each other here; for now, the solution is “don't do that.”)

Reference counts are always manipulated explicitly. The normal way is to use the macro \texttt{Py\_INCREF()} to increment an object's reference count by one, and \texttt{Py\_DECREF()} to decrement it by one. The \texttt{Py\_DECREF()} macro is considerably more complex than the incref one, since it must check whether the reference count becomes zero and then cause the object's deallocator to be called. The deallocator is a function pointer contained in the object's type structure. The type-specific deallocator takes care of decrementing the reference counts for other objects contained in the object if this is a compound object type, such as a list, as well as performing any additional finalization that's needed. There's no chance that the reference count can overflow; at least as many bits are used to hold the reference count as there are distinct memory locations in virtual memory (assuming \texttt{sizeof(Py\_ssize\_t) >= sizeof(void*)}). Thus, the reference count increment is a simple operation.

It is not necessary to increment an object's reference count for every local variable that contains a pointer to an object. In theory, the object's reference count goes up by one when the variable is made to point to it and it goes down by one when the variable goes out of scope. However, these two cancel each other out, so at the end the reference count hasn't changed. The only real reason to use the reference count is to prevent the object from being deallocated as long as our variable is pointing to it. If we know that there is at least one other reference to the object that lives at least as long as our variable, there is no need to increment the reference count temporarily. An important situation where this arises is in objects that are passed as
arguments to C functions in an extension module that are called from Python; the call mechanism guarantees to hold a reference to every argument for the duration of the call.

However, a common pitfall is to extract an object from a list and hold on to it for a while without incrementing its reference count. Some other operation might conceivably remove the object from the list, decrementing its reference count and possible deallocating it. The real danger is that innocent-looking operations may invoke arbitrary Python code which could do this; there is a code path which allows control to flow back to the user from a `Py_DECREF()`, so almost any operation is potentially dangerous.

A safe approach is to always use the generic operations (functions whose name begins with `PyObject_`, `PyNumber_`, `PySequence_` or `PyMapping_`). These operations always increment the reference count of the object they return. This leaves the caller with the responsibility to call `Py_DECREF()` when they are done with the result; this soon becomes second nature.

Reference Count Details

The reference count behavior of functions in the Python/C API is best explained in terms of ownership of references. Ownership pertains to references, never to objects (objects are not owned: they are always shared). “Owning a reference” means being responsible for calling `Py_DECREF` on it when the reference is no longer needed. Ownership can also be transferred, meaning that the code that receives ownership of the reference then becomes responsible for eventually decref’ing it by calling `Py_DECREF()` or `Py_XDECREF()` when it’s no longer needed—or passing on this responsibility (usually to its caller). When a function passes ownership of a reference on to its caller, the
caller is said to receive a *new* reference. When no ownership is transferred, the caller is said to *borrow* the reference. Nothing needs to be done for a borrowed reference.

Conversely, when a calling function passes in a reference to an object, there are two possibilities: the function *steals* a reference to the object, or it does not. *Stealing a reference* means that when you pass a reference to a function, that function assumes that it now owns that reference, and you are not responsible for it any longer.

Few functions steal references; the two notable exceptions are `PyList_SetItem()` and `PyTuple_SetItem()`, which steal a reference to the item (but not to the tuple or list into which the item is put!). These functions were designed to steal a reference because of a common idiom for populating a tuple or list with newly created objects; for example, the code to create the tuple `(1, 2, "three")` could look like this (forgetting about error handling for the moment; a better way to code this is shown below):

```c
PyObject *t;

t = PyTuple_New(3);
PyTuple_SetItem(t, 0, PyLong_FromLong(1L));
PyTuple_SetItem(t, 1, PyLong_FromLong(2L));
PyTuple_SetItem(t, 2, PyUnicode_FromString("three"));
```

Here, `PyLong_FromLong()` returns a new reference which is immediately stolen by `PyTuple_SetItem()`. When you want to keep using an object although the reference to it will be stolen, use `Py_INCREF()` to grab another reference before calling the reference-stealing function.

Incidentally, `PyTuple_SetItem()` is the *only* way to set tuple items;
PySequence_SetItem() and PyObject_SetItem() refuse to do this since tuples are an immutable data type. You should only use PyTuple_SetItem() for tuples that you are creating yourself.

Equivalent code for populating a list can be written using PyList_New() and PyList_SetItem().

However, in practice, you will rarely use these ways of creating and populating a tuple or list. There’s a generic function, Py_BuildValue(), that can create most common objects from C values, directed by a format string. For example, the above two blocks of code could be replaced by the following (which also takes care of the error checking):

```c
PyObject *tuple, *list;

tuple = Py_BuildValue("(iis)", 1, 2, "three");
list = Py_BuildValue("[iis]", 1, 2, "three");
```

It is much more common to use PyObject_SetItem() and friends with items whose references you are only borrowing, like arguments that were passed in to the function you are writing. In that case, their behaviour regarding reference counts is much saner, since you don’t have to increment a reference count so you can give a reference away (“have it be stolen”). For example, this function sets all items of a list (actually, any mutable sequence) to a given item:

```c
int set_all(PyObject *target, PyObject *item)
{
    Py_ssize_t i, n;
    
    n = PyObject_Length(target);
    if (n < 0)
The situation is slightly different for function return values. While passing a reference to most functions does not change your ownership responsibilities for that reference, many functions that return a reference to an object give you ownership of the reference. The reason is simple: in many cases, the returned object is created on the fly, and the reference you get is the only reference to the object. Therefore, the generic functions that return object references, like `PyObject_GetItem()` and `PySequence_GetItem()`, always return a new reference (the caller becomes the owner of the reference).

It is important to realize that whether you own a reference returned by a function depends on which function you call only — the plumage (the type of the object passed as an argument to the function) doesn’t enter into it! Thus, if you extract an item from a list using `PyList_GetItem()`, you don’t own the reference — but if you obtain the same item from the same list using `PySequence_GetItem()` (which happens to take exactly the same arguments), you do own a reference to the returned object.
Here is an example of how you could write a function that computes the sum of the items in a list of integers; once using PyList_GetItem(), and once using PySequence_GetItem().

```c
long sum_list(PyObject *list)
{
    Py_ssize_t i, n;
    long total = 0, value;
    PyObject *item;

    n = PyList_Size(list);
    if (n < 0)
        return -1; /* Not a list */
    for (i = 0; i < n; i++) {
        item = PyList_GetItem(list, i); /* Can't fail
        if (!PyLong_Check(item)) continue; /* Skip non-integers
        value = PyLong_AsLong(item);
        if (value == -1 && PyErr_Occurred())
            /* Integer too big to fit in a C long, bail out */
            return -1;
        total += value;
    }
    return total;
}
```

```c
long sum_sequence(PyObject *sequence)
{
    Py_ssize_t i, n;
    long total = 0, value;
    PyObject *item;
    n = PySequence_Length(sequence);
    if (n < 0)
        return -1; /* Has no length */
```
for (i = 0; i < n; i++) {
    item = PySequence_GetItem(sequence, i);
    if (item == NULL)
        return -1; /* Not a sequence, or other failure */
    if (PyLong_Check(item)) {
        value = PyLong_AsLong(item);
        Py_DECREF(item);
        if (value == -1 && PyErr_Occurred())
            /* Integer too big to fit in a C long */
            return -1;
        total += value;
    } else {
        Py_DECREF(item); /* Discard reference ownership */
    }
}
return total;

Types

There are few other data types that play a significant role in the Python/C API; most are simple C types such as int, long, double and char*. A few structure types are used to describe static tables used to list the functions exported by a module or the data attributes of a new object type, and another is used to describe the value of a complex number. These will be discussed together with the functions that use them.
Exceptions

The Python programmer only needs to deal with exceptions if specific error handling is required; unhandled exceptions are automatically propagated to the caller, then to the caller’s caller, and so on, until they reach the top-level interpreter, where they are reported to the user accompanied by a stack traceback.

For C programmers, however, error checking always has to be explicit. All functions in the Python/C API can raise exceptions, unless an explicit claim is made otherwise in a function’s documentation. In general, when a function encounters an error, it sets an exception, discards any object references that it owns, and returns an error indicator. If not documented otherwise, this indicator is either NULL or -1, depending on the function’s return type. A few functions return a Boolean true/false result, with false indicating an error. Very few functions return no explicit error indicator or have an ambiguous return value, and require explicit testing for errors with PyErr_Occurred(). These exceptions are always explicitly documented.

Exception state is maintained in per-thread storage (this is equivalent to using global storage in an unthreaded application). A thread can be in one of two states: an exception has occurred, or not. The function PyErr_Occurred() can be used to check for this: it returns a borrowed reference to the exception type object when an exception has occurred, and NULL otherwise. There are a number of functions to set the exception state: PyErr_SetString() is the most common (though not the most general) function to set the exception state, and PyErr_Clear() clears the exception state.

The full exception state consists of three objects (all of which can be
NULL): the exception type, the corresponding exception value, and the traceback. These have the same meanings as the Python result of sys.exc_info(); however, they are not the same: the Python objects represent the last exception being handled by a Python try … except statement, while the C level exception state only exists while an exception is being passed on between C functions until it reaches the Python bytecode interpreter’s main loop, which takes care of transferring it to sys.exc_info() and friends.

Note that starting with Python 1.5, the preferred, thread-safe way to access the exception state from Python code is to call the function sys.exc_info(), which returns the per-thread exception state for Python code. Also, the semantics of both ways to access the exception state have changed so that a function which catches an exception will save and restore its thread's exception state so as to preserve the exception state of its caller. This prevents common bugs in exception handling code caused by an innocent-looking function overwriting the exception being handled; it also reduces the often unwanted lifetime extension for objects that are referenced by the stack frames in the traceback.

As a general principle, a function that calls another function to perform some task should check whether the called function raised an exception, and if so, pass the exception state on to its caller. It should discard any object references that it owns, and return an error indicator, but it should not set another exception — that would overwrite the exception that was just raised, and lose important information about the exact cause of the error.

A simple example of detecting exceptions and passing them on is shown in the sum_sequence() example above. It so happens that this example doesn’t need to clean up any owned references when it
detects an error. The following example function shows some error cleanup. First, to remind you why you like Python, we show the equivalent Python code:

```python
def incr_item(dict, key):
    try:
        item = dict[key]
    except KeyError:
        item = 0
    dict[key] = item + 1
```

Here is the corresponding C code, in all its glory:

```c
int incr_item(PyObject *dict, PyObject *key)
{
    /* Objects all initialized to NULL for Py_XDECREF */
    PyObject *item = NULL, *const_one = NULL, *incremented_item;
    int rv = -1; /* Return value initialized to -1 (failure) */

    item = PyObject_GetItem(dict, key);
    if (item == NULL) {
        /* Handle KeyError only: */
        if (!PyErr_ExceptionMatches(PyExc_KeyError))
            goto error;

        /* Clear the error and use zero: */
        PyErr_Clear();
        item = PyLong_FromLong(0L);
        if (item == NULL)
            goto error;
    }

    const_one = PyLong_FromLong(1L);
    if (const_one == NULL)
        goto error;

```
incremented_item = PyNumber_Add(item, const_one)

if (incremented_item == NULL)
    goto error;

if (PyObject_SetItem(dict, key, incremented_item)
    goto error;
rv = 0; /* Success */
/* Continue with cleanup code */

error:
/* Cleanup code, shared by success and failure path */

/* Use Py_XDECREF() to ignore NULL references */
Py_XDECREF(item);
Py_XDECREF(const_one);
Py_XDECREF(incremented_item);

return rv; /* -1 for error, 0 for success */
}

This example represents an endorsed use of the goto statement in C. It illustrates the use of PyErr_ExceptionMatches() and PyErr_Clear() to handle specific exceptions, and the use of Py_XDECREF() to dispose of owned references that may be NULL (note the 'X' in the name; Py_DECREF() would crash when confronted with a NULL reference). It is important that the variables used to hold owned references are initialized to NULL for this to work; likewise, the proposed return value is initialized to -1 (failure) and only set to success after the final call made is successful.
Embedding Python

The one important task that only embedders (as opposed to extension writers) of the Python interpreter have to worry about is the initialization, and possibly the finalization, of the Python interpreter. Most functionality of the interpreter can only be used after the interpreter has been initialized.

The basic initialization function is `Py_Initialize()`. This initializes the table of loaded modules, and creates the fundamental modules `builtins`, `__main__`, and `sys`. It also initializes the module search path (`sys.path`).

`Py_Initialize()` does not set the “script argument list” (`sys.argv`). If this variable is needed by Python code that will be executed later, it must be set explicitly with a call to `PySys_SetArgvEx(argc, argv, updatepath)` after the call to `Py_Initialize()`.

On most systems (in particular, on Unix and Windows, although the details are slightly different), `Py_Initialize()` calculates the module search path based upon its best guess for the location of the standard Python interpreter executable, assuming that the Python library is found in a fixed location relative to the Python interpreter executable. In particular, it looks for a directory named `lib/pythonX.Y` relative to the parent directory where the executable named `python` is found on the shell command search path (the environment variable `PATH`).

For instance, if the Python executable is found in `/usr/local/bin/python`, it will assume that the libraries are in
/usr/local/lib/pythonX.Y. (In fact, this particular path is also the “fallback” location, used when no executable file named python is found along PATH.) The user can override this behavior by setting the environment variable PYTHONHOME, or insert additional directories in front of the standard path by setting PYTHONPATH.

The embedding application can steer the search by calling Py_SetProgramName(file) before calling Py_Initialize(). Note that PYTHONHOME still overrides this and PYTHONPATH is still inserted in front of the standard path. An application that requires total control has to provide its own implementation of Py_GetPath(), Py_GetPrefix(), Py_GetExecPrefix(), and Py_GetProgramFullPath() (all defined in Modules/getpath.c).

Sometimes, it is desirable to “uninitialize” Python. For instance, the application may want to start over (make another call to Py_Initialize()) or the application is simply done with its use of Python and wants to free memory allocated by Python. This can be accomplished by calling Py_FinalizeEx(). The function Py_IsInitialized() returns true if Python is currently in the initialized state. More information about these functions is given in a later chapter. Notice that Py_FinalizeEx() does not free all memory allocated by the Python interpreter, e.g. memory allocated by extension modules currently cannot be released.
Debugging Builds

Python can be built with several macros to enable extra checks of the interpreter and extension modules. These checks tend to add a large amount of overhead to the runtime so they are not enabled by default.

A full list of the various types of debugging builds is in the file Misc/SpecialBuilds.txt in the Python source distribution. Builds are available that support tracing of reference counts, debugging the memory allocator, or low-level profiling of the main interpreter loop. Only the most frequently-used builds will be described in the remainder of this section.

Compiling the interpreter with the Py_DEBUG macro defined produces what is generally meant by “a debug build” of Python. Py_DEBUG is enabled in the Unix build by adding --with-pydebug to the ./configure command. It is also implied by the presence of the not-Python-specific _DEBUG macro. When Py_DEBUG is enabled in the Unix build, compiler optimization is disabled.

In addition to the reference count debugging described below, the following extra checks are performed:

- Extra checks are added to the object allocator.
- Extra checks are added to the parser and compiler.
- Downcasts from wide types to narrow types are checked for loss of information.
- A number of assertions are added to the dictionary and set implementations. In addition, the set object acquires a test_c_api() method.
- Sanity checks of the input arguments are added to frame creation.
- The storage for ints is initialized with a known invalid pattern to
catch reference to uninitialized digits.
- Low-level tracing and extra exception checking are added to the runtime virtual machine.
- Extra checks are added to the memory arena implementation.
- Extra debugging is added to the thread module.

There may be additional checks not mentioned here.

Defining Py_TRACE_REFS enables reference tracing. When defined, a circular doubly linked list of active objects is maintained by adding two extra fields to every PyObject. Total allocations are tracked as well. Upon exit, all existing references are printed. (In interactive mode this happens after every statement run by the interpreter.) Implied by Py_DEBUG.

Please refer to Misc/SpecialBuilds.txt in the Python source distribution for more detailed information.
Stable Application Binary Interface

Traditionally, the C API of Python will change with every release. Most changes will be source-compatible, typically by only adding API, rather than changing existing API or removing API (although some interfaces do get removed after being deprecated first).

Unfortunately, the API compatibility does not extend to binary compatibility (the ABI). The reason is primarily the evolution of struct definitions, where addition of a new field, or changing the type of a field, might not break the API, but can break the ABI. As a consequence, extension modules need to be recompiled for every Python release (although an exception is possible on Unix when none of the affected interfaces are used). In addition, on Windows, extension modules link with a specific pythonXY.dll and need to be recompiled to link with a newer one.

Since Python 3.2, a subset of the API has been declared to guarantee a stable ABI. Extension modules wishing to use this API (called “limited API”) need to define Py_LIMITED_API. A number of interpreter details then become hidden from the extension module; in return, a module is built that works on any 3.x version (x>=2) without recompilation.

In some cases, the stable ABI needs to be extended with new functions. Extension modules wishing to use these new APIs need to set Py_LIMITED_API to the PY_VERSION_HEX value (see API and ABI Versioning) of the minimum Python version they want to support (e.g. 0x03030000 for Python 3.3). Such modules will work on all subsequent Python releases, but fail to load (because of missing symbols) on the older releases.
As of Python 3.2, the set of functions available to the limited API is documented in PEP 384. In the C API documentation, API elements that are not part of the limited API are marked as “Not part of the limited API.”
The Very High Level Layer

The functions in this chapter will let you execute Python source code given in a file or a buffer, but they will not let you interact in a more detailed way with the interpreter.

Several of these functions accept a start symbol from the grammar as a parameter. The available start symbols are Py_eval_input, Py_file_input, and Py_single_input. These are described following the functions which accept them as parameters.

Note also that several of these functions take FILE* parameters. One particular issue which needs to be handled carefully is that the FILE structure for different C libraries can be different and incompatible. Under Windows (at least), it is possible for dynamically linked extensions to actually use different libraries, so care should be taken that FILE* parameters are only passed to these functions if it is certain that they were created by the same library that the Python runtime is using.

```c
int Py_Main(int argc, wchar_t **argv)
```

The main program for the standard interpreter. This is made available for programs which embed Python. The `argc` and `argv` parameters should be prepared exactly as those which are passed to a C program’s `main()` function (converted to wchar_t according to the user’s locale). It is important to note that the argument list may be modified (but the contents of the strings pointed to by the argument list are not). The return value will be \(0\) if the interpreter exits normally (i.e., without an exception), \(1\) if the interpreter exits due to an exception, or \(2\) if the parameter list does not represent a
valid Python command line.

Note that if an otherwise unhandled `SystemExit` is raised, this function will not return 1, but exit the process, as long as `Py_InspectFlag` is not set.

```c
int PyRun_AnyFile(FILE *fp, const char *filename)
    This is a simplified interface to `PyRun_AnyFileExFlags()` below, leaving `closeit` set to 0 and `flags` set to NULL.

int PyRun_AnyFileFlags(FILE *fp, const char *filename, PyCompilerFlags *flags)
    This is a simplified interface to `PyRun_AnyFileExFlags()` below, leaving the `closeit` argument set to 0.

int PyRun_AnyFileEx(FILE *fp, const char *filename, int closeit)
    This is a simplified interface to `PyRun_AnyFileExFlags()` below, leaving the `flags` argument set to NULL.

int PyRun_AnyFileExFlags(FILE *fp, const char *filename, int closeit, PyCompilerFlags *flags)
    If `fp` refers to a file associated with an interactive device (console or terminal input or Unix pseudo-terminal), return the value of `PyRun_InteractiveLoop()`, otherwise return the result of `PyRun_SimpleFile()`. `filename` is decoded from the filesystem encoding (`sys.getfilesystemencoding()`). If `filename` is `NULL`, this function uses "???" as the filename.

int PyRun_SimpleString(const char *command)
    This is a simplified interface to `PyRun_SimpleStringFlags()` below, leaving the `PyCompilerFlags*` argument set to NULL.
int **PyRun_SimpleStringFlags**(const char *command, PyCompilerFlags *flags)

Executes the Python source code from command in the __main__ module according to the flags argument. If __main__ does not already exist, it is created. Returns 0 on success or -1 if an exception was raised. If there was an error, there is no way to get the exception information. For the meaning of flags, see below.

Note that if an otherwise unhandled SystemExit is raised, this function will not return -1, but exit the process, as long as Py_InspectionFlag is not set.

int **PyRun_SimpleFile**(FILE *fp, const char *filename)

This is a simplified interface to PyRun_SimpleFileExFlags() below, leaving closeit set to 0 and flags set to NULL.

int **PyRun_SimpleFileEx**(FILE *fp, const char *filename, int closeit)

This is a simplified interface to PyRun_SimpleFileExFlags() below, leaving flags set to NULL.

int **PyRun_SimpleFileExFlags**(FILE *fp, const char *filename, int closeit, PyCompilerFlags *flags)

Similar to PyRun_SimpleStringFlags(), but the Python source code is read from fp instead of an in-memory string. filename should be the name of the file, it is decoded from the filesystem encoding (sys.getfilesystemencoding()). If closeit is true, the file is closed before PyRun_SimpleFileExFlags returns.

int **PyRun_InteractiveOne**(FILE *fp, const char *filename)

This is a simplified interface to
PyRun_InteractiveOneFlags() below, leaving flags set to NULL.

int PyRun_InteractiveOneFlags(FILE *fp, const char *filename, PyCompilerFlags *flags)

Read and execute a single statement from a file associated with an interactive device according to the flags argument. The user will be prompted using sys.ps1 and sys.ps2. filename is decoded from the filesystem encoding (sys.getfilesystemencoding()).

Returns 0 when the input was executed successfully, -1 if there was an exception, or an error code from the errcode.h include file distributed as part of Python if there was a parse error. (Note that errcode.h is not included by Python.h, so must be included specifically if needed.)

int PyRun_InteractiveLoop(FILE *fp, const char *filename)

This is a simplified interface to PyRun_InteractiveLoopFlags() below, leaving flags set to NULL.

int PyRun_InteractiveLoopFlags(FILE *fp, const char *filename, PyCompilerFlags *flags)

Read and execute statements from a file associated with an interactive device until EOF is reached. The user will be prompted using sys.ps1 and sys.ps2. filename is decoded from the filesystem encoding (sys.getfilesystemencoding()). Returns 0 at EOF.

int (*PyOS_InputHook)(void)

Can be set to point to a function with the prototype int func(void). The function will be called when Python's interpreter
prompt is about to become idle and wait for user input from the terminal. The return value is ignored. Overriding this hook can be used to integrate the interpreter’s prompt with other event loops, as done in the Modules/_tkinter.c in the Python source code.

```c
char* (*PyOS_ReadlineFunctionPointer)(FILE *, FILE *, const char *)
```

Can be set to point to a function with the prototype `char *func(FILE *stdin, FILE *stdout, char *prompt)`, overriding the default function used to read a single line of input at the interpreter’s prompt. The function is expected to output the string `prompt` if it’s not `NULL`, and then read a line of input from the provided standard input file, returning the resulting string. For example, The `readline` module sets this hook to provide line-editing and tab-completion features.

The result must be a string allocated by `PyMem_RawMalloc()` or `PyMem_RawRealloc()`, or `NULL` if an error occurred.

*Changed in version 3.4:* The result must be allocated by `PyMem_RawMalloc()` or `PyMem_RawRealloc()`, instead of being allocated by `PyMem_Malloc()` or `PyMem_Realloc()`.

```c
struct _node* PyParser_SimpleParseString(const char *str, int start)
```

This is a simplified interface to `PyParser_SimpleParseStringFlagsFilename()` below, leaving `filename` set to `NULL` and `flags` set to 0.

```c
struct _node* PyParser_SimpleParseStringFlags(const char *str, int start, int flags)
```

This is a simplified interface to
PyParser_SimpleParseStringFlagsFilename() below, leaving filename set to NULL.

struct _node* 
PyParser_SimpleParseStringFlagsFilename(const char *str, const char *filename, int start, int flags)

Parse Python source code from str using the start token start according to the flags argument. The result can be used to create a code object which can be evaluated efficiently. This is useful if a code fragment must be evaluated many times. filename is decoded from the filesystem encoding (sys.getfilesystemencoding()).

struct _node* PyParser_SimpleParseFile(FILE *fp, const char *filename, int start)

This is a simplified interface to PyParser_SimpleParseFileFlags() below, leaving flags set to 0.

struct _node* PyParser_SimpleParseFileFlags(FILE *fp, const char *filename, int start, int flags)

Similar to PyParser_SimpleParseStringFlagsFilename(), but the Python source code is read from fp instead of an in-memory string.

PyObject* PyRun_String(const char *str, int start, PyObject *globals, PyObject *locals)

This is a simplified interface to PyRun_StringFlags() below, leaving flags set to NULL.

PyObject* PyRun_StringFlags(const char *str, int start,
PyObject *`globals`, PyObject *`locals`, PyCompilerFlags *`flags`)

*Return value: New reference.*

Execute Python source code from `str` in the context specified by the objects `globals` and `locals` with the compiler flags specified by `flags`. `globals` must be a dictionary; `locals` can be any object that implements the mapping protocol. The parameter `start` specifies the start token that should be used to parse the source code.

Returns the result of executing the code as a Python object, or `NULL` if an exception was raised.

PyObject* **PyRun_File**(FILE *`fp`, const char *`filename`, int `start`,
PyObject *`globals`, PyObject *`locals`)

*Return value: New reference.*

This is a simplified interface to `PyRun_FileExFlags()` below, leaving `closeit` set to 0 and `flags` set to `NULL`.

PyObject* **PyRun_FileEx**(FILE *`fp`, const char *`filename`, int `start`,
PyObject *`globals`, PyObject *`locals`, int `closeit`)

*Return value: New reference.*

This is a simplified interface to `PyRun_FileExFlags()` below, leaving `flags` set to `NULL`.

PyObject* **PyRun_FileFlags**(FILE *`fp`, const char *`filename`,
int `start`, PyObject *`globals`, PyObject *`locals`, PyCompilerFlags *`flags`)

*Return value: New reference.*

This is a simplified interface to `PyRun_FileExFlags()` below, leaving `closeit` set to 0.

PyObject* **PyRun_FileExFlags**(FILE *`fp`, const char *`filename`,
int `start`, PyObject *`globals`, PyObject *`locals`, int `closeit`,
PyCompilerFlags *`flags`)

*Return value: New reference.*
Similar to `PyRun_StringFlags()`, but the Python source code is read from *fp* instead of an in-memory string. *filename* should be the name of the file, it is decoded from the filesystem encoding (`sys.getfilesystemencoding()`). If *closeit* is true, the file is closed before `PyRun_FileExFlags()` returns.

`PyObject* Py_CompileString(\text{const char *str, const char *filename, int start})`

*Return value: New reference.*
This is a simplified interface to `Py_CompileStringFlags()` below, leaving *flags* set to *NULL*.

`PyObject* Py_CompileStringFlags(\text{const char *str, const char *filename, int start, PyCompilerFlags *flags})`

*Return value: New reference.*
This is a simplified interface to `Py_CompileStringExFlags()` below, with *optimize* set to \texttt{-1}.

`PyObject* Py_CompileStringObject(\text{const char *str, PyObject *filename, int start, PyCompilerFlags *flags, int optimize})`

Parse and compile the Python source code in *str*, returning the resulting code object. The start token is given by *start*; this can be used to constrain the code which can be compiled and should be `Py_eval_input`, `Py_file_input`, or `Py_single_input`. The filename specified by *filename* is used to construct the code object and may appear in tracebacks or `SyntaxError` exception messages. This returns *NULL* if the code cannot be parsed or compiled.

The integer *optimize* specifies the optimization level of the compiler; a value of \texttt{-1} selects the optimization level of the interpreter as given by \texttt{-O} options. Explicit levels are \texttt{0} (no
optimization;  __debug__  is true), 1 (asserts are removed,  __debug__  is false) or 2 (docstrings are removed too).

New in version 3.4.

PyObject* Py_CompileStringExFlags (const char *str, const char *filename, int start, PyCompilerFlags *flags, int optimize)

Like  Py_CompileStringObject(),  but  filename  is a byte string decoded from the filesystem encoding (os.fsdecode()).

New in version 3.2.

PyObject* PyEval_EvalCode (PyObject *co, PyObject *globals, PyObject *locals)

This is a simplified interface to  PyEval_EvalCodeEx(),  with just the code object, and global and local variables. The other arguments are set to  NULL.

PyObject* PyEval_EvalCodeEx (PyObject *co, PyObject *globals, PyObject *locals, PyObject **args, int argcount, PyObject **kws, int kwcount, PyObject **defs, int defcount, PyObject *kwdefs, PyObject *closure)

Evaluate a precompiled code object, given a particular environment for its evaluation. This environment consists of a dictionary of global variables, a mapping object of local variables, arrays of arguments, keywords and defaults, a dictionary of default values for  keyword-only  arguments and a closure tuple of cells.

PyFrameObject
The C structure of the objects used to describe frame objects. The fields of this type are subject to change at any time.
**PyObject**\* **PyEval_EvalFrame**(PyFrameObject \*f)

Evaluate an execution frame. This is a simplified interface to **PyEval_EvalFrameEx()**, for backward compatibility.

**PyObject**\* **PyEval_EvalFrameEx**(PyFrameObject \*f, int *throwflag*)

This is the main, unvarnished function of Python interpretation. It is literally 2000 lines long. The code object associated with the execution frame \( f \) is executed, interpreting bytecode and executing calls as needed. The additional *throwflag* parameter can mostly be ignored - if true, then it causes an exception to immediately be thrown; this is used for the throw() methods of generator objects.

*Changed in version 3.4:* This function now includes a debug assertion to help ensure that it does not silently discard an active exception.

int **PyEval_MergeCompilerFlags**(PyCompilerFlags \*cf)

This function changes the flags of the current evaluation frame, and returns true on success, false on failure.

int **Py_eval_input**

The start symbol from the Python grammar for isolated expressions; for use with **Py_CompileString()**.

int **Py_file_input**

The start symbol from the Python grammar for sequences of statements as read from a file or other source; for use with **Py_CompileString()**. This is the symbol to use when compiling arbitrarily long Python source code.

int **Py_single_input**
The start symbol from the Python grammar for a single statement; for use with `Py_CompileString()`. This is the symbol used for the interactive interpreter loop.

```c
struct PyCompilerFlags
{
    int cf_flags;
}
```

`int CO_FUTURE_DIVISION`

This bit can be set in `flags` to cause division operator `/` to be interpreted as “true division” according to [PEP 238](https://www.python.org/dev/peps/pep-0238/).
Reference Counting

The macros in this section are used for managing reference counts of Python objects.

void `Py_INCREF(PyObject *o)`

Increment the reference count for object o. The object must not be `NULL`; if you aren’t sure that it isn’t `NULL`, use `Py_XINCREF()`.

void `Py_XINCREF(PyObject *o)`

Increment the reference count for object o. The object may be `NULL`, in which case the macro has no effect.

void `Py_DECREF(PyObject *o)`

Decrement the reference count for object o. The object must not be `NULL`; if you aren’t sure that it isn’t `NULL`, use `Py_XDECREF()`. If the reference count reaches zero, the object’s type’s deallocation function (which must not be `NULL`) is invoked.

**Warning:** The deallocation function can cause arbitrary Python code to be invoked (e.g. when a class instance with a `__del__()` method is deallocated). While exceptions in such code are not propagated, the executed code has free access to all Python global variables. This means that any object that is reachable from a global variable should be in a consistent state before `Py_DECREF()` is invoked. For example, code to delete an object from a list should copy a reference to the deleted object in a temporary variable, update the list data structure, and then call `Py_DECREF()` for the temporary variable.
void **Py_XDECREF**(PyObject *o)

Decrement the reference count for object o. The object may be *NULL*, in which case the macro has no effect; otherwise the effect is the same as for **Py_DECREF()**, and the same warning applies.

void **Py_CLEAR**(PyObject *o)

Decrement the reference count for object o. The object may be *NULL*, in which case the macro has no effect; otherwise the effect is the same as for **Py_DECREF()**, except that the argument is also set to *NULL*. The warning for **Py_DECREF()** does not apply with respect to the object passed because the macro carefully uses a temporary variable and sets the argument to *NULL* before decrementing its reference count.

It is a good idea to use this macro whenever decrementing the value of a variable that might be traversed during garbage collection.

The following functions are for runtime dynamic embedding of Python: **Py_IncRef**(PyObject *o), **Py_DecRef**(PyObject *o). They are simply exported function versions of **Py_XINCREF()** and **Py_XDECREF()**, respectively.

The following functions or macros are only for use within the interpreter core: _Py_Dealloc(), _Py_ForgetReference(), _Py_NewReference(), as well as the global variable _Py_RefTotal.
Exception Handling

The functions described in this chapter will let you handle and raise Python exceptions. It is important to understand some of the basics of Python exception handling. It works somewhat like the POSIX *errno* variable: there is a global indicator (per thread) of the last error that occurred. Most C API functions don’t clear this on success, but will set it to indicate the cause of the error on failure. Most C API functions also return an error indicator, usually *NULL* if they are supposed to return a pointer, or `-1` if they return an integer (exception: the `PyArg_*()` functions return `1` for success and `0` for failure).

Concretely, the error indicator consists of three object pointers: the exception’s type, the exception’s value, and the traceback object. Any of those pointers can be NULL if non-set (although some combinations are forbidden, for example you can’t have a non-NULL traceback if the exception type is NULL).

When a function must fail because some function it called failed, it generally doesn’t set the error indicator; the function it called already set it. It is responsible for either handling the error and clearing the exception or returning after cleaning up any resources it holds (such as object references or memory allocations); it should not continue normally if it is not prepared to handle the error. If returning due to an error, it is important to indicate to the caller that an error has been set. If the error is not handled or carefully propagated, additional calls into the Python/C API may not behave as intended and may fail in mysterious ways.

**Note:** The error indicator is **not** the result of `sys.exc_info()`. The former corresponds to an exception that is not yet caught (and is
therefore still propagating), while the latter returns an exception after it is caught (and has therefore stopped propagating).
Printing and clearing

void **PyErr_Clear()**

Clear the error indicator. If the error indicator is not set, there is no effect.

void **PyErr_PrintEx**(int set_sys_last_vars)

Print a standard traceback to `sys.stderr` and clear the error indicator. Call this function only when the error indicator is set. (Otherwise it will cause a fatal error!)

If `set_sys_last_vars` is nonzero, the variables `sys.last_type`, `sys.last_value` and `sys.last_traceback` will be set to the type, value and traceback of the printed exception, respectively.

void **PyErr_Print()**

Alias for **PyErr_PrintEx**(1).

void **PyErr_WriteUnraisable**(PyObject *obj)

This utility function prints a warning message to `sys.stderr` when an exception has been set but it is impossible for the interpreter to actually raise the exception. It is used, for example, when an exception occurs in an `__del__()` method.

The function is called with a single argument `obj` that identifies the context in which the unraisable exception occurred. If possible, the repr of `obj` will be printed in the warning message.
Raising exceptions

These functions help you set the current thread’s error indicator. For convenience, some of these functions will always return a NULL pointer for use in a return statement.

void **PyErr_SetString**(PyObject *type, const char *message)

This is the most common way to set the error indicator. The first argument specifies the exception type; it is normally one of the standard exceptions, e.g. PyExc_RuntimeError. You need not increment its reference count. The second argument is an error message; it is decoded from 'utf-8'.

void **PyErr_SetObject**(PyObject *type, PyObject *value)

This function is similar to PyErr_SetString() but lets you specify an arbitrary Python object for the “value” of the exception.

PyObject* **PyErr_Format**(PyObject *exception, const char *format, ...)

*Return value: Always NULL.*

This function sets the error indicator and returns NULL. exception should be a Python exception class. The format and subsequent parameters help format the error message; they have the same meaning and values as in PyUnicode_FromFormat(). format is an ASCII-encoded string.

PyObject* **PyErr_FormatV**(PyObject *exception, const char *format, va_list vars)

*Return value: Always NULL.*

Same as PyErr_Format(), but taking a va_list argument rather than a variable number of arguments.
New in version 3.5.

```c
void PyErr_SetNone(PyObject *type)
    This is a shorthand for PyErr_SetObject(type, Py_None).
```

```c
int PyErr_BadArgument()
    This is a shorthand for PyErr_SetString(PyExc_TypeError, message), where message indicates that a built-in operation was invoked with an illegal argument. It is mostly for internal use.
```

```c
PyObject* PyErr_NoMemory()
    Return value: Always NULL.
    This is a shorthand for PyErr_SetNone(PyExc_MemoryError); it returns NULL so an object allocation function can write return PyErr_NoMemory(); when it runs out of memory.
```

```c
PyObject* PyErr_SetFromErrno(PyObject *type)
    Return value: Always NULL.
    This is a convenience function to raise an exception when a C library function has returned an error and set the C variable errno. It constructs a tuple object whose first item is the integer errno value and whose second item is the corresponding error message (gotten from strerror()), and then calls PyErr_SetObject(type, object). On Unix, when the errno value is EINTR, indicating an interrupted system call, this calls PyErr_CheckSignals(), and if that set the error indicator, leaves it set to that. The function always returns NULL, so a wrapper function around a system call can write return PyErr_SetFromErrno(type); when the system call returns an error.
```

```c
PyObject*
```
**PyErr_SetFromErrnoWithFilenameObject** *(PyObject *type, PyObject *filenameObject)*

Similar to **PyErr_SetFromErrno()**, with the additional behavior that if `filenameObject` is not `NULL`, it is passed to the constructor of `type` as a third parameter. In the case of **OSError** exception, this is used to define the filename attribute of the exception instance.

**PyObject**

**PyErr_SetFromErrnoWithFilenameObjects** *(PyObject *type, PyObject *filenameObject, PyObject *filenameObject2)*

Similar to **PyErr_SetFromErrnoWithFilenameObject()**, but takes a second filename object, for raising errors when a function that takes two filenames fails.

*New in version 3.4.*

**PyObject**

**PyErr_SetFromErrnoWithFilename** *(PyObject *type, const char *filename)*

*Return value: Always NULL.*

Similar to **PyErr_SetFromErrnoWithFilenameObject()**, but the filename is given as a C string. `filename` is decoded from the filesystem encoding (`os.fsdecode()`).

**PyObject**

**PyErr_SetFromWindowsErr** *(int ierr)*

*Return value: Always NULL.*

This is a convenience function to raise **WindowsError**. If called with `ierr` of 0, the error code returned by a call to `GetLastError()` is used instead. It calls the Win32 function `FormatMessage()` to retrieve the Windows description of error code given by `ierr` or `GetLastError()`, then it constructs a tuple object whose first item is the `ierr` value and whose second item is
the corresponding error message (gotten from FormatMessage()), and then calls
PyErr_SetObject(PyExc_WindowsError, object). This function always returns NULL. Availability: Windows.

PyObject* PyErr_SetExcFromWindowsErr(PyObject *type, int ierr)

Return value: Always NULL.
Similar to PyErr_SetFromWindowsErr(), with an additional parameter specifying the exception type to be raised. Availability: Windows.

PyObject*
PyErr_SetFromWindowsErrWithFilename(int ierr, const char *filename)

Return value: Always NULL.
Similar to PyErr_SetFromWindowsErrWithFilenameObject(), but the filename is given as a C string. filename is decoded from the filesystem encoding (os.fsdecode()). Availability: Windows.

PyObject*
PyErr_SetExcFromWindowsErrWithFilenameObject(F
int ierr, PyObject *filename)

Similar to
PyErr_SetFromWindowsErrWithFilenameObject(), with an additional parameter specifying the exception type to be raised. Availability: Windows.

PyObject*
PyErr_SetExcFromWindowsErrWithFilenameObjects(}
int ierr, PyObject *filename, PyObject *filename2)

Similar to
PyObject*
PyErr_SetExcFromWindowsErrWithFilenameObject(PyObject *type, int ierr, const char *filename)

Return value: Always NULL.
Similar to PyErr_SetFromWindowsErrWithFilenameObject(), with an additional parameter specifying the exception type to be raised. Availability: Windows.

PyObject* PyErr_SetImportError(PyObject *msg, PyObject *name, PyObject *path)
This is a convenience function to raise ImportError. msg will be set as the exception’s message string. name and path, both of which can be NULL, will be set as the ImportError's respective name and path attributes.

New in version 3.3.

void PyErr_SyntaxLocationObject(PyObject *filename, int lineno, int col_offset)
Set file, line, and offset information for the current exception. If the current exception is not a SyntaxError, then it sets additional attributes, which make the exception printing subsystem think the exception is a SyntaxError.

New in version 3.4.

void PyErr_SyntaxLocationEx(const char *filename, int lineno, int col_offset)
Like `PyErr_SyntaxLocationObject()`, but `filename` is a byte string decoded from the filesystem encoding (`os.fsdecode()`).

*New in version 3.2.*

```c
void PyErr_SyntaxLocation(const char *filename, int lineno)
    Like PyErr_SyntaxLocationEx(), but the col_offset parameter is omitted.
```

```c
void PyErr_BadInternalCall()
    This is a shorthand for PyErr_SetString(PyExc_SystemError, message), where message indicates that an internal operation (e.g. a Python/C API function) was invoked with an illegal argument. It is mostly for internal use.
```
Issuing warnings

Use these functions to issue warnings from C code. They mirror similar functions exported by the Python `warnings` module. They normally print a warning message to `sys.stderr`; however, it is also possible that the user has specified that warnings are to be turned into errors, and in that case they will raise an exception. It is also possible that the functions raise an exception because of a problem with the warning machinery. The return value is 0 if no exception is raised, or -1 if an exception is raised. (It is not possible to determine whether a warning message is actually printed, nor what the reason is for the exception; this is intentional.) If an exception is raised, the caller should do its normal exception handling (for example, `Py_DECREF()`) owned references and return an error value.

```c
int PyErr_WarnEx(PyObject *category, const char *message, Py_ssize_t stack_level)

    Issue a warning message. The category argument is a warning category (see below) or NULL; the message argument is a UTF-8 encoded string. stack_level is a positive number giving a number of stack frames; the warning will be issued from the currently executing line of code in that stack frame. A stack_level of 1 is the function calling `PyErr_WarnEx()`, 2 is the function above that, and so forth.

    Warning categories must be subclasses of PyExc Warning; PyExc Warning is a subclass of PyExc Exception; the default warning category is PyExc_RuntimeWarning. The standard Python warning categories are available as global variables whose names are enumerated at `Standard Warning Categories`.
```
For information about warning control, see the documentation for the `warnings` module and the `-W` option in the command line documentation. There is no C API for warning control.

```python
PyObject*
PyErr_SetImportErrorSubclass(PyObject *msg, PyObject *name, PyObject *path)
```

Much like `PyErr_SetImportError()` but this function allows for specifying a subclass of `ImportError` to raise.

*New in version 3.6.*

```python
int PyErr_WarnExplicitObject(PyObject *category, PyObject *message, PyObject *filename, int lineno, PyObject *module, PyObject *registry)
```

Issue a warning message with explicit control over all warning attributes. This is a straightforward wrapper around the Python function `warnings.warn_explicit()`, see there for more information. The `module` and `registry` arguments may be set to `NULL` to get the default effect described there.

*New in version 3.4.*

```python
int PyErr_WarnExplicit(PyObject *category, const char *message, const char *filename, int lineno, const char *module, PyObject *registry)
```

Similar to `PyErr_WarnExplicitObject()` except that `message` and `module` are UTF-8 encoded strings, and `filename` is decoded from the filesystem encoding (`os.fsdecode()`).

```python
int PyErr_WarnFormat(PyObject *category, Py_ssize_t stack_level, const char *format, ...)
```

Function similar to `PyErr_WarnEx()`, but use
PyUnicode_FromFormat() to format the warning message. 
format is an ASCII-encoded string.

*New in version 3.2.*

```c
int PyErr_ResourceWarning(PyObject *source,
Py_ssize_t stack_level, const char *format, ...)  
Function similar to PyErr_WarnFormat(), but category is 
ResourceWarning and pass source to 
warnings.WarningMessage().

*New in version 3.6.*
Querying the error indicator

**PyObj**ect* PyErr_Occurred()**

*Return value: Borrowed reference.* Test whether the error indicator is set. If set, return the exception type (the first argument to the last call to one of the PyErr_Set* ( ) functions or to PyErr_Restore()). If not set, return NULL. You do not own a reference to the return value, so you do not need to Py_DECREF() it.

**Note:** Do not compare the return value to a specific exception; use PyErr_ExceptionMatches() instead, shown below. (The comparison could easily fail since the exception may be an instance instead of a class, in the case of a class exception, or it may be a subclass of the expected exception.)

```
int PyErr_ExceptionMatches(PyObject *exc)
```

Equivalent to PyErr_GivenExceptionMatches(PyErr_Occurred(), exc). This should only be called when an exception is actually set; a memory access violation will occur if no exception has been raised.

```
int PyErr_GivenExceptionMatches(PyObject *given, PyObject *exc)
```

Return true if the given exception matches the exception type in exc. If exc is a class object, this also returns true when given is an instance of a subclass. If exc is a tuple, all exception types in the tuple (and recursively in subtuples) are searched for a match.

```
void PyErr_Fetch(PyObject **ptype, PyObject **pvalue,
```
PyObject **ptraceback)

Retrieve the error indicator into three variables whose addresses are passed. If the error indicator is not set, set all three variables to NULL. If it is set, it will be cleared and you own a reference to each object retrieved. The value and traceback object may be NULL even when the type object is not.

Note: This function is normally only used by code that needs to catch exceptions or by code that needs to save and restore the error indicator temporarily, e.g.:

```c
{  
  PyObject *type, *value, *traceback;  
  PyErr_Fetch(&type, &value, &traceback);  

  /* ... code that might produce other errors ... */  
  PyErr_Restore(type, value, traceback);  
}
```

void PyErr_Restore(PyObject *type, PyObject *value, PyObject *traceback)

Set the error indicator from the three objects. If the error indicator is already set, it is cleared first. If the objects are NULL, the error indicator is cleared. Do not pass a NULL type and non-NULL value or traceback. The exception type should be a class. Do not pass an invalid exception type or value. (Violating these rules will cause subtle problems later.) This call takes away a reference to each object: you must own a reference to each object before the call and after the call you no longer own these references. (If you don’t understand this, don’t use this function. I warned you.)
**Note:** This function is normally only used by code that needs to save and restore the error indicator temporarily. Use `PyErr_Fetch()` to save the current error indicator.

```c
void PyErr_NormalizeException(PyObject** exc, PyObject** val, PyObject** tb)
```

Under certain circumstances, the values returned by `PyErr_Fetch()` below can be “unnormalized”, meaning that `*exc` is a class object but `*val` is not an instance of the same class. This function can be used to instantiate the class in that case. If the values are already normalized, nothing happens. The delayed normalization is implemented to improve performance.

**Note:** This function does not implicitly set the `__traceback__` attribute on the exception value. If setting the traceback appropriately is desired, the following additional snippet is needed:

```c
if (tb != NULL) {
    PyException_SetTraceback(val, tb);
}
```

```c
void PyErr_GetExcInfo(PyObject **ptype, PyObject **pvalue, PyObject **ptraceback)
```

Retrieve the exception info, as known from `sys.exc_info()`. This refers to an exception that was *already caught*, not to an exception that was freshly raised. Returns new references for the three objects, any of which may be `NULL`. Does not modify the exception info state.

**Note:** This function is not normally used by code that wants to
handle exceptions. Rather, it can be used when code needs to save and restore the exception state temporarily. Use `PyErr_SetExcInfo()` to restore or clear the exception state.

*New in version 3.3.*

```c
void PyErr_SetExcInfo(PyObject *type, PyObject *value, PyObject *traceback)
```

Set the exception info, as known from `sys.exc_info()`. This refers to an exception that was *already caught*, not to an exception that was freshly raised. This function steals the references of the arguments. To clear the exception state, pass `NULL` for all three arguments. For general rules about the three arguments, see `PyErr_Restore()`.

**Note:** This function is not normally used by code that wants to handle exceptions. Rather, it can be used when code needs to save and restore the exception state temporarily. Use `PyErr_GetExcInfo()` to read the exception state.

*New in version 3.3.*
Signal Handling

int **PyErr_CheckSignals()**

This function interacts with Python’s signal handling. It checks whether a signal has been sent to the processes and if so, invokes the corresponding signal handler. If the `signal` module is supported, this can invoke a signal handler written in Python. In all cases, the default effect for SIGINT is to raise the `KeyboardInterrupt` exception. If an exception is raised the error indicator is set and the function returns `-1`; otherwise the function returns `0`. The error indicator may or may not be cleared if it was previously set.

void **PyErr_SetInterrupt()**

This function simulates the effect of a SIGINT signal arriving — the next time **PyErr_CheckSignals()** is called, `KeyboardInterrupt` will be raised. It may be called without holding the interpreter lock.

int **PySignal_SetWakeupFd(int fd)**

This utility function specifies a file descriptor to which the signal number is written as a single byte whenever a signal is received. `fd` must be non-blocking. It returns the previous such file descriptor.

The value `-1` disables the feature; this is the initial state. This is equivalent to `signal.set_wakeup_fd()` in Python, but without any error checking. `fd` should be a valid file descriptor. The function should only be called from the main thread.

*Changed in version 3.5:* On Windows, the function now also supports socket handles.
Exception Classes

PyObject* PyErr_NewException(const char *name,
PyObject *base, PyObject *dict)

This utility function creates and returns a new exception class. The
name argument must be the name of the new exception, a C string
of the form module.classname. The base and dict arguments
are normally NULL. This creates a class object derived from
Exception (accessible in C as PyExc_Exception).

The __module__ attribute of the new class is set to the first part
(up to the last dot) of the name argument, and the class name is
set to the last part (after the last dot). The base argument can be
used to specify alternate base classes; it can either be only one
class or a tuple of classes. The dict argument can be used to
specify a dictionary of class variables and methods.

PyObject* PyErr_NewExceptionWithDoc(const char *name,
const char *doc, PyObject *base, PyObject *dict)

Same as PyErr_NewException(), except that the new
exception class can easily be given a docstring: If doc is non-
NULL, it will be used as the docstring for the exception class.

New in version 3.2.
Exception Objects

PyObject* PyException_GetTraceback(PyObject *ex)

Return the traceback associated with the exception as a new reference, as accessible from Python through __traceback__. If there is no traceback associated, this returns NULL.

int PyException_SetTraceback(PyObject *ex, PyObject *tb)
Set the traceback associated with the exception to tb. Use Py_None to clear it.

PyObject* PyException_GetContext(PyObject *ex)
Return the context (another exception instance during whose handling ex was raised) associated with the exception as a new reference, as accessible from Python through __context__. If there is no context associated, this returns NULL.

void PyException_SetContext(PyObject *ex, PyObject *ctx)
Set the context associated with the exception to ctx. Use NULL to clear it. There is no type check to make sure that ctx is an exception instance. This steals a reference to ctx.

PyObject* PyException_GetCause(PyObject *ex)
Return the cause (either an exception instance, or None, set by raise ... from ...) associated with the exception as a new reference, as accessible from Python through __cause__.

void PyException_SetCause(PyObject *ex, PyObject *cause)
Set the cause associated with the exception to cause. Use NULL to clear it. There is no type check to make sure that cause is either an
exception instance or None. This steals a reference to cause.

__suppress_context__ is implicitly set to True by this function.
Unicode Exception Objects

The following functions are used to create and modify Unicode exceptions from C.

PyObject* PyUnicodeDecodeError_Create(const char *encoding, const char *object, Py_ssize_t length, Py_ssize_t start, Py_ssize_t end, const char *reason)

Create a UnicodeDecodeError object with the attributes encoding, object, length, start, end and reason. encoding and reason are UTF-8 encoded strings.

PyObject* PyUnicodeEncodeError_Create(const char *encoding, const Py_UNICODE *object, Py_ssize_t length, Py_ssize_t start, Py_ssize_t end, const char *reason)

Create a UnicodeEncodeError object with the attributes encoding, object, length, start, end and reason. encoding and reason are UTF-8 encoded strings.

PyObject* PyUnicodeTranslateError_Create(const Py_UNICODE *object, Py_ssize_t length, Py_ssize_t start, Py_ssize_t end, const char *reason)

Create a UnicodeTranslateError object with the attributes object, length, start, end and reason. reason is a UTF-8 encoded string.

PyObject* PyUnicodeDecodeError_GetEncoding(PyObject *exc)

PyObject* PyUnicodeEncodeError_GetEncoding(PyObject *exc)

Return the encoding attribute of the given exception object.
PyUnicodeDecodeError_GetObject

*PyObject*  

Return the *object* attribute of the given exception object.

int PyUnicodeDecodeError_GetStart

*Py_ssize_t* *start*

Get the *start* attribute of the given exception object and place it into *start*. *start* must not be *NULL*. Return 0 on success, -1 on failure.

int PyUnicodeDecodeError_SetStart

*Py_ssize_t* *start*

Set the *start* attribute of the given exception object to *start*. Return 0 on success, -1 on failure.

int PyUnicodeDecodeError_GetEnd

*Py_ssize_t* *end*

Get the *end* attribute of the given exception object and place it into
*end. end must not be NULL. Return 0 on success, -1 on failure.

int PyUnicodeDecodeError_SetEnd(PyObject *exc, Py_ssize_t end)
int PyUnicodeEncodeError_SetEnd(PyObject *exc, Py_ssize_t end)
int PyUnicodeTranslateError_SetEnd(PyObject *exc, Py_ssize_t end)

Set the end attribute of the given exception object to end. Return 0 on success, -1 on failure.

PyObject*
PyUnicodeDecodeError_GetReason(PyObject *exc)
PyObject*
PyUnicodeEncodeError_GetReason(PyObject *exc)
PyObject*
PyUnicodeTranslateError_GetReason(PyObject *exc)

Return the reason attribute of the given exception object.

int PyUnicodeDecodeError_SetReason(PyObject *exc, const char *reason)
int PyUnicodeEncodeError_SetReason(PyObject *exc, const char *reason)
int PyUnicodeTranslateError_SetReason(PyObject *exc, const char *reason)

Set the reason attribute of the given exception object to reason. Return 0 on success, -1 on failure.
Recursion Control

These two functions provide a way to perform safe recursive calls at the C level, both in the core and in extension modules. They are needed if the recursive code does not necessarily invoke Python code (which tracks its recursion depth automatically).

int **Py_EnterRecursiveCall**(const char *where)
Marks a point where a recursive C-level call is about to be performed.

If USE_STACKCHECK is defined, this function checks if the OS stack overflowed using **PyOS_CheckStack()**. In this is the case, it sets a MemoryError and returns a nonzero value.

The function then checks if the recursion limit is reached. If this is the case, a RecursionError is set and a nonzero value is returned. Otherwise, zero is returned.

*where* should be a string such as "in instance check" to be concatenated to the RecursionError message caused by the recursion depth limit.

void **Py_LeaveRecursiveCall**()
Ends a **Py_EnterRecursiveCall**(). Must be called once for each successful invocation of **Py_EnterRecursiveCall**().

Properly implementing **tp_repr** for container types requires special recursion handling. In addition to protecting the stack, **tp_repr** also needs to track objects to prevent cycles. The following two functions facilitate this functionality. Effectively, these are the C equivalent to
reprlib.recursive_repr().

int **Py_ReprEnter**(PyObject *object)

Called at the beginning of the **tp_repr** implementation to detect cycles.

If the object has already been processed, the function returns a positive integer. In that case the **tp_repr** implementation should return a string object indicating a cycle. As examples, **dict** objects return `{...}` and **list** objects return `[[...]].`

The function will return a negative integer if the recursion limit is reached. In that case the **tp_repr** implementation should typically return **NULL**.

Otherwise, the function returns zero and the **tp_repr** implementation can continue normally.

void **Py_ReprLeave**(PyObject *object)

Ends a **Py_ReprEnter()**. Must be called once for each invocation of **Py_ReprEnter()** that returns zero.
Standard Exceptions

All standard Python exceptions are available as global variables whose names are `PyExc_` followed by the Python exception name. These have the type `PyObject*`; they are all class objects. For completeness, here are all the variables:

<table>
<thead>
<tr>
<th>C Name</th>
<th>Python Name</th>
</tr>

*New in version 3.3:* PyExc_BlockingIOError, PyExc_BrokenPipeError, PyExc_ChildProcessError, PyExc_ConnectionError, PyExc_ConnectionAbortedError, PyExc_ConnectionRefusedError, PyExc_ConnectionResetError, PyExc_FileExistsError, PyExc_FileNotFoundError, PyExc_InterruptedError, PyExc_IsADirectoryError, PyExc_NotADirectoryError, PyExc_PermissionError, PyExc_ProcessLookupError and PyExc_TimeoutError were introduced following [PEP 3151](https://www.python.org/dev/peps/pep-03151/).

*New in version 3.5:* PyExc_StopAsyncIteration and PyExc_RecursionError.

*New in version 3.6:* PyExc_ModuleNotFoundError.

These are compatibility aliases to PyExc_OSError:
PyExc_EnvironmentError
PyExc_IOError
PyExc_WindowsError (3)

*Changed in version 3.3:* These aliases used to be separate exception types.

Notes:

1. This is a base class for other standard exceptions.
2. This is the same as `weakref.ReferenceError`.
3. Only defined on Windows; protect code that uses this by testing that the preprocessor macro `MS_WINDOWS` is defined.
Standard Warning Categories

All standard Python warning categories are available as global variables whose names are `PyExc_` followed by the Python exception name. These have the type `PyObject*`; they are all class objects. For completeness, here are all the variables:

<table>
<thead>
<tr>
<th>C Name</th>
<th>Python Name</th>
</tr>
</thead>
<tbody>
<tr>
<td>PyExc_Warning</td>
<td>Warning</td>
</tr>
<tr>
<td>PyExc_BytesWarning</td>
<td>BytesWarning</td>
</tr>
<tr>
<td>PyExc_DeprecationWarning</td>
<td>DeprecationWarning</td>
</tr>
<tr>
<td>PyExc_FutureWarning</td>
<td>FutureWarning</td>
</tr>
<tr>
<td>PyExc.ImportWarning</td>
<td>ImportWarning</td>
</tr>
<tr>
<td>PyExc_PendingDeprecationWarning</td>
<td>PendingDeprecationWarning</td>
</tr>
<tr>
<td>PyExc_ResourceWarning</td>
<td>ResourceWarning</td>
</tr>
<tr>
<td>PyExc_RuntimeWarning</td>
<td>RuntimeWarning</td>
</tr>
<tr>
<td>PyExc_SyntaxWarning</td>
<td>SyntaxWarning</td>
</tr>
<tr>
<td>PyExc_UnicodeWarning</td>
<td>UnicodeWarning</td>
</tr>
<tr>
<td>PyExc_UserWarning</td>
<td>UserWarning</td>
</tr>
</tbody>
</table>

`New in version 3.2`: `PyExc_ResourceWarning`.

Notes:

1. This is a base class for other standard warning categories.

Utilities

The functions in this chapter perform various utility tasks, ranging from helping C code be more portable across platforms, using Python modules from C, and parsing function arguments and constructing Python values from C values.

- Operating System Utilities
- System Functions
- Process Control
- Importing Modules
- Data marshalling support
- Parsing arguments and building values
  - Parsing arguments
    - Strings and buffers
    - Numbers
    - Other objects
    - API Functions
  - Building values
- String conversion and formatting
- Reflection
- Codec registry and support functions
  - Codec lookup API
  - Registry API for Unicode encoding error handlers
Operating System Utilities

**PyObject** PyOS_FSPath(PyObject *path)

*Return value: New reference.*

Return the file system representation for *path*. If the object is a *str* or *bytes* object, then its reference count is incremented. If the object implements the *os.PathLike* interface, then `__fspath__()` is returned as long as it is a *str* or *bytes* object. Otherwise *TypeError* is raised and NULL is returned.

*New in version 3.6.*

**int** Py_FdIsInteractive(FILE *fp, const char *filename)

Return true (nonzero) if the standard I/O file *fp* with name *filename* is deemed interactive. This is the case for files for which `isatty(fileno(fp))` is true. If the global flag `Py_InteractiveFlag` is true, this function also returns true if the *filename* pointer is NULL or if the name is equal to one of the strings `'<stdin>'` or `'???'`.

**void** PyOS_AfterFork()

Function to update some internal state after a process fork; this should be called in the new process if the Python interpreter will continue to be used. If a new executable is loaded into the new process, this function does not need to be called.

**int** PyOS_CheckStack()

Return true when the interpreter runs out of stack space. This is a reliable check, but is only available when USE_STACKCHECK is defined (currently on Windows using the Microsoft Visual C++
compiler). USE_STACKCHECK will be defined automatically; you should never change the definition in your own code.

`PyOS_sighandler_t PyOS_getsig(int i)`

Return the current signal handler for signal `i`. This is a thin wrapper around either `sigaction()` or `signal()`. Do not call those functions directly! `PyOS_sighandler_t` is a typedef alias for `void (*)(int)`.

`PyOS_sighandler_t PyOS_setsig(int i, PyOS_sighandler_t h)`

Set the signal handler for signal `i` to be `h`; return the old signal handler. This is a thin wrapper around either `sigaction()` or `signal()`. Do not call those functions directly! `PyOS_sighandler_t` is a typedef alias for `void (*)(int)`.

`wchar_t* Py_DecodeLocale(const char* arg, size_t* size)`

Decode a byte string from the locale encoding with the surrogateescape error handler: undecodable bytes are decoded as characters in range U+DC80..U+DCFF. If a byte sequence can be decoded as a surrogate character, escape the bytes using the surrogateescape error handler instead of decoding them.

Return a pointer to a newly allocated wide character string, use `PyMem_RawFree()` to free the memory. If `size` is not `NULL`, write the number of wide characters excluding the null character into `*size`.

Return `NULL` on decoding error or memory allocation error. If `size` is not `NULL`, `*size` is set to `(size_t)-1` on memory error or set to `(size_t)-2` on decoding error.

Decoding errors should never happen, unless there is a bug in the
C library.

Use the `Py_EncodeLocale()` function to encode the character string back to a byte string.

**See also:** The `PyUnicode_DecodeFSDefaultAndSize()` and `PyUnicode_DecodeLocaleAndSize()` functions.

*New in version 3.5.*

cchar* `Py_EncodeLocale`(const wchar_t *text, size_t *error_pos)

Encode a wide character string to the locale encoding with the surrogateescape error handler: surrogate characters in the range U+DC80..U+DCFF are converted to bytes 0x80..0xFF.

Return a pointer to a newly allocated byte string, use `PyMem_Free()` to free the memory. Return `NULL` on encoding error or memory allocation error.

If `error_pos` is not `NULL`, `*error_pos` is set to the index of the invalid character on encoding error, or set to `(size_t)-1` otherwise.

Use the `Py_DecodeLocale()` function to decode the bytes string back to a wide character string.

**See also:** The `PyUnicode_EncodeFSDefault()` and `PyUnicode_EncodeLocale()` functions.

*New in version 3.5.*
System Functions

These are utility functions that make functionality from the `sys` module accessible to C code. They all work with the current interpreter thread's `sys` module's dict, which is contained in the internal thread state structure.

`PyObject *PySys_GetObject(const char *name)`

*Return value: Borrowed reference.*

Return the object `name` from the `sys` module or `NULL` if it does not exist, without setting an exception.

`int PySys_SetObject(const char *name, PyObject *v)`

Set `name` in the `sys` module to `v` unless `v` is `NULL`, in which case `name` is deleted from the `sys` module. Returns 0 on success, -1 on error.

`void PySys_ResetWarnOptions()`

Reset `sys.warnoptions` to an empty list.

`void PySys_AddWarnOption(wchar_t *s)`

Append `s` to `sys.warnoptions`.

`void PySys_AddWarnOptionUnicode(PyObject *unicode)`

Append `unicode` to `sys.warnoptions`.

`void PySys_SetPath(wchar_t *path)`

Set `sys.path` to a list object of paths found in `path` which should be a list of paths separated with the platform's search path delimiter (': on Unix, ; on Windows).
void PySys_WriteStdout(const char *format, ...)
  Write the output string described by format to sys.stdout. No
  exceptions are raised, even if truncation occurs (see below).

  format should limit the total size of the formatted output string to
  1000 bytes or less – after 1000 bytes, the output string is
  truncated. In particular, this means that no unrestricted “%s”
  formats should occur; these should be limited using “%.<N>s”
  where <N> is a decimal number calculated so that <N> plus the
  maximum size of other formatted text does not exceed 1000 bytes.
  Also watch out for “%f”, which can print hundreds of digits for very
  large numbers.

  If a problem occurs, or sys.stdout is unset, the formatted
  message is written to the real (C level) stdout.

void PySys_WriteStderr(const char *format, ...)
  As PySys_WriteStdout(), but write to sys.stderr or stderr
  instead.

void PySys_FormatStdout(const char *format, ...)
  Function similar to PySys_WriteStdout() but format the message
  using PyUnicode_FromFormatV() and don’t truncate the
  message to an arbitrary length.

  New in version 3.2.

void PySys_FormatStderr(const char *format, ...)
  As PySys_FormatStdout(), but write to sys.stderr or stderr
  instead.

  New in version 3.2.
void **PySys_AddXOption**(const wchar_t *s)

Parse s as a set of -X options and add them to the current options mapping as returned by **PySys_GetXOptions()**.

*New in version 3.2.*

**PyObject *PySys_GetXOptions()***

*Return value: Borrowed reference.*

Return the current dictionary of -X options, similarly to **sys._xoptions**. On error, **NULL** is returned and an exception is set.

*New in version 3.2.*
Process Control

void **Py_FatalError**(const char *message)

Print a fatal error message and kill the process. No cleanup is performed. This function should only be invoked when a condition is detected that would make it dangerous to continue using the Python interpreter; e.g., when the object administration appears to be corrupted. On Unix, the standard C library function abort() is called which will attempt to produce a core file.

void **Py_Exit**(int status)

Exit the current process. This calls **Py_FinalizeEx()** and then calls the standard C library function exit(status). If **Py_FinalizeEx()** indicates an error, the exit status is set to 120.

*Changed in version 3.6:* Errors from finalization no longer ignored.

int **Py_AtExit**(void (*func)())

Register a cleanup function to be called by **Py_FinalizeEx()**. The cleanup function will be called with no arguments and should return no value. At most 32 cleanup functions can be registered. When the registration is successful, **Py_AtExit()** returns 0; on failure, it returns -1. The cleanup function registered last is called first. Each cleanup function will be called at most once. Since Python’s internal finalization will have completed before the cleanup function, no Python APIs should be called by func.
Importing Modules

PyObject* PyImport_ImportModule(const char *name)

This is a simplified interface to PyImport_ImportModuleEx() below, leaving the globals and locals arguments set to NULL and level set to 0. When the name argument contains a dot (when it specifies a submodule of a package), the fromlist argument is set to the list ['*'] so that the return value is the named module rather than the top-level package containing it as would otherwise be the case. (Unfortunately, this has an additional side effect when name in fact specifies a subpackage instead of a submodule: the submodules specified in the package’s __all__ variable are loaded.) Return a new reference to the imported module, or NULL with an exception set on failure. A failing import of a module doesn’t leave the module in sys.modules.

This function always uses absolute imports.

PyObject* PyImport_ImportModuleNoBlock(const char *name)

This function is a deprecated alias of PyImport_ImportModule().

Changed in version 3.3: This function used to fail immediately when the import lock was held by another thread. In Python 3.3 though, the locking scheme switched to per-module locks for most purposes, so this function’s special behaviour isn’t needed anymore.

PyObject* PyImport_ImportModuleEx(const char *name,
PyObject *globals, PyObject *locals, PyObject *fromlist)

Import a module. This is best described by referring to the built-in Python function __import__().

The return value is a new reference to the imported module or top-level package, or NULL with an exception set on failure. Like for __import__(), the return value when a submodule of a package was requested is normally the top-level package, unless a non-empty fromlist was given.

Failing imports remove incomplete module objects, like with PyImport_ImportModule().

PyObject *
PyImport_ImportModuleLevelObject(PyObject *name,
PyObject *globals, PyObject *locals, PyObject *fromlist, int level)

Import a module. This is best described by referring to the built-in Python function __import__(), as the standard __import__() function calls this function directly.

The return value is a new reference to the imported module or top-level package, or NULL with an exception set on failure. Like for __import__(), the return value when a submodule of a package was requested is normally the top-level package, unless a non-empty fromlist was given.

New in version 3.3.

PyObject* PyImport_ImportModuleLevel(const char *name,
PyObject *globals, PyObject *locals, PyObject *fromlist, int level)

Similar to PyImport_ImportModuleLevelObject(), but the
name is a UTF-8 encoded string instead of a Unicode object.

*Changed in version 3.3:* Negative values for *level* are no longer accepted.

**PyObject** `PyImport_Import(PyObject *name)`

*R*eturn value: *New reference.*

This is a higher-level interface that calls the current “import hook function” (with an explicit *level* of 0, meaning absolute import). It invokes the `__import__() `function from the `__builtins__` of the current globals. This means that the import is done using whatever import hooks are installed in the current environment.

This function always uses absolute imports.

**PyObject** `PyImport_ReloadModule(PyObject *m)`

*R*eturn value: *New reference.*

Reload a module. Return a new reference to the reloaded module, or *NULL* with an exception set on failure (the module still exists in this case).

**PyObject** `PyImport_AddModuleObject(PyObject *name)`

Return the module object corresponding to a module name. The *name* argument may be of the form `package.module`. First check the modules dictionary if there's one there, and if not, create a new one and insert it in the modules dictionary. Return *NULL* with an exception set on failure.

**Note:** This function does not load or import the module; if the module wasn't already loaded, you will get an empty module object. Use `PyImport_ImportModule()` or one of its variants to import a module. Package structures implied by a dotted name for *name* are not created if not already present.
New in version 3.3.

**PyObject** PyImport_AddModule(const char *name)

*Return value: Borrowed reference.*

Similar to PyImport_AddModuleObject(), but the name is a UTF-8 encoded string instead of a Unicode object.

**PyObject** PyImport_ExecCodeModule(const char *name, PyObject *co)

*Return value: New reference.*

Given a module name (possibly of the form `package.module`) and a code object read from a Python bytecode file or obtained from the built-in function `compile()`, load the module. Return a new reference to the module object, or NULL with an exception set if an error occurred. *name* is removed from `sys.modules` in error cases, even if *name* was already in `sys.modules` on entry to `PyImport_ExecCodeModule()`. Leaving incompletely initialized modules in `sys.modules` is dangerous, as imports of such modules have no way to know that the module object is an unknown (and probably damaged with respect to the module author's intents) state.

The module's __spec__ and __loader__ will be set, if not set already, with the appropriate values. The spec's loader will be set to the module's __loader__ (if set) and to an instance of SourceFileLoader otherwise.

The module's __file__ attribute will be set to the code object's co_filename. If applicable, __cached__ will also be set.

This function will reload the module if it was already imported. See
PyImport_ReloadModule() for the intended way to reload a module.

If name points to a dotted name of the form package.module, any package structures not already created will still not be created.

See also PyImport_ExecCodeModuleEx() and PyImport_ExecCodeModuleWithPathnames().

PyObject* PyImport_ExecCodeModuleEx(const char *name, PyObject *co, const char *pathname)

Like PyImport_ExecCodeModule(), but the __file__ attribute of the module object is set to pathname if it is non-NULL.

See also PyImport_ExecCodeModuleWithPathnames().

PyObject* PyImport_ExecCodeModuleObject(PyObject *name, PyObject *co, PyObject *pathname, PyObject *cpathname)
Like PyImport_ExecCodeModuleEx(), but the __cached__ attribute of the module object is set to cpathname if it is non-NULL.
Of the three functions, this is the preferred one to use.

New in version 3.3.

PyObject* PyImport_ExecCodeModuleWithPathnames(const char *name, PyObject *co, const char *pathname, const char *cpathname)
Like PyImport_ExecCodeModuleObject(), but name, pathname and cpathname are UTF-8 encoded strings. Attempts are also made to figure out what the value for pathname should be
from cpathname if the former is set to NULL.

New in version 3.2.

Changed in version 3.3: Uses `imp.source_from_cache()` in calculating the source path if only the bytecode path is provided.

```c
long PyImport_GetMagicNumber()
```

Return the magic number for Python bytecode files (a.k.a. `.pyc` file). The magic number should be present in the first four bytes of the bytecode file, in little-endian byte order. Returns `-1` on error.

Changed in version 3.3: Return value of `-1` upon failure.

```c
const char * PyImport_GetMagicTag()
```

Return the magic tag string for PEP 3147 format Python bytecode file names. Keep in mind that the value at `sys.implementation.cache_tag` is authoritative and should be used instead of this function.

New in version 3.2.

```c
PyObject* PyImport_GetModuleDict()
```

Return value: Borrowed reference.

Return the dictionary used for the module administration (a.k.a. `sys.modules`). Note that this is a per-interpreter variable.

```c
PyObject* PyImport_GetImporter(PyObject *path)
```

Return a finder object for a `sys.path/pkg.__path__` item `path`, possibly by fetching it from the `sys.path_importer_cache` dict. If it wasn't yet cached, traverse `sys.path_hooks` until a hook is found that can handle the path item. Return `None` if no hook could; this tells our caller that the path based finder could not find a finder
for this path item. Cache the result in \texttt{sys.path_importer_cache}. Return a new reference to the finder object.

\begin{verbatim}
void \_PyImport\_Init()
    Initialize the import mechanism. For internal use only.
\end{verbatim}

\begin{verbatim}
void PyImport\_Cleanup()
    Empty the module table. For internal use only.
\end{verbatim}

\begin{verbatim}
void \_PyImport\_Fini()
    Finalize the import mechanism. For internal use only.
\end{verbatim}

\begin{verbatim}
PyObject* \_PyImport\_FindExtension(char *, char *)
    For internal use only.
\end{verbatim}

\begin{verbatim}
PyObject* PyImport\_ImportFrozenModuleObject(PyObject *name)
    Load a frozen module named \texttt{name}. Return 1 for success, 0 if the module is not found, and -1 with an exception set if the initialization failed. To access the imported module on a successful load, use \texttt{PyImport\_ImportModule()}. (Note the misnomer — this function would reload the module if it was already imported.)

    New in version 3.3.

    Changed in version 3.4: The \texttt{\_\_file\_\_} attribute is no longer set on the module.
\end{verbatim}

\begin{verbatim}
int PyImport\_ImportFrozenModule(const char *name)
    Similar to \texttt{PyImport\_ImportFrozenModuleObject()}, but the name is a UTF-8 encoded string instead of a Unicode object.
\end{verbatim}
struct _frozen

This is the structure type definition for frozen module descriptors, as generated by the freeze utility (see Tools/freeze/ in the Python source distribution). Its definition, found in Include/import.h, is:

```c
struct _frozen {
    char *name;
    unsigned char *code;
    int size;
};
```

cnst struct _frozen* PyImport_FrozenModules

This pointer is initialized to point to an array of struct _frozen records, terminated by one whose members are all NULL or zero. When a frozen module is imported, it is searched in this table. Third-party code could play tricks with this to provide a dynamically created collection of frozen modules.

int PyImport_AppendInittab(const char *name, PyObject* (*initfunc)(void))

Add a single module to the existing table of built-in modules. This is a convenience wrapper around PyImport_ExtendInittab(), returning -1 if the table could not be extended. The new module can be imported by the name name, and uses the function initfunc as the initialization function called on the first attempted import. This should be called before Py_Initialize().

struct _inittab

Structure describing a single entry in the list of built-in modules. Each of these structures gives the name and initialization function for a module built into the interpreter. The name is an ASCII
encoded string. Programs which embed Python may use an array of these structures in conjunction with `PyImport_ExtendInittab()` to provide additional built-in modules. The structure is defined in `include/import.h` as:

```
struct _inittab {
    char *name;     /* ASCII encoded 
    PyObject* (*initfunc)(void);
};
```

**`int PyImport_ExtendInittab(struct _inittab *newtab)`**

Add a collection of modules to the table of built-in modules. The `newtab` array must end with a sentinel entry which contains `NULL` for the name field; failure to provide the sentinel value can result in a memory fault. Returns 0 on success or -1 if insufficient memory could be allocated to extend the internal table. In the event of failure, no modules are added to the internal table. This should be called before `Py_Initialize()`.
Data marshalling support

These routines allow C code to work with serialized objects using the same data format as the marshal module. There are functions to write data into the serialization format, and additional functions that can be used to read the data back. Files used to store marshalled data must be opened in binary mode.

Numeric values are stored with the least significant byte first.

The module supports two versions of the data format: version 0 is the historical version, version 1 shares interned strings in the file, and upon unmarshalling. Version 2 uses a binary format for floating point numbers. Py_MARSHAL_VERSION indicates the current file format (currently 2).

void PyMarshal_WriteLongToFile(long value, FILE *file, int version)
    Marshal a long integer, value, to file. This will only write the least-significant 32 bits of value; regardless of the size of the native long type. version indicates the file format.

void PyMarshal_WriteObjectToFile(PyObject *value, FILE *file, int version)
    Marshal a Python object, value, to file. version indicates the file format.

PyObject* PyMarshal_WriteObjectToString(PyObject *value, int version)
    Return a bytes object containing the marshalled representation of
value. version indicates the file format.

The following functions allow marshalled values to be read back in.

XXX What about error detection? It appears that reading past the end of the file will always result in a negative numeric value (where that's relevant), but it's not clear that negative values won't be handled properly when there's no error. What's the right way to tell? Should only non-negative values be written using these routines?

long **PyMarshal_ReadLongFromFile** (FILE *file)

Return a C long from the data stream in a FILE* opened for reading. Only a 32-bit value can be read in using this function, regardless of the native size of long.

On error, raise an exception and return -1.

int **PyMarshal_ReadShortFromFile** (FILE *file)

Return a C short from the data stream in a FILE* opened for reading. Only a 16-bit value can be read in using this function, regardless of the native size of short.

On error, raise an exception and return -1.

PyObject* **PyMarshal_ReadObjectFromFile** (FILE *file)

*Return value: New reference.*

Return a Python object from the data stream in a FILE* opened for reading.

On error, sets the appropriate exception (EOFError or TypeError) and returns NULL.

PyObject*
PyMarshal_ReadLastObjectFromFile(FILE *file)

Return a Python object from the data stream in a FILE* opened for reading. Unlike PyMarshal_ReadObjectFromFile(), this function assumes that no further objects will be read from the file, allowing it to aggressively load file data into memory so that the deserialization can operate from data in memory rather than reading a byte at a time from the file. Only use these variant if you are certain that you won’t be reading anything else from the file.

On error, sets the appropriate exception (EOFError or TypeError) and returns NULL.

PyObject* PyMarshal_ReadObjectFromString(const char *data, Py_ssize_t len)

Return a Python object from the data stream in a byte buffer containing len bytes pointed to by data.

On error, sets the appropriate exception (EOFError or TypeError) and returns NULL.
Parsing arguments and building values

These functions are useful when creating your own extensions functions and methods. Additional information and examples are available in Extending and Embedding the Python Interpreter.

The first three of these functions described, `PyArg_ParseTuple()`, `PyArg_ParseTupleAndKeywords()`, and `PyArg_Parse()`, all use format strings which are used to tell the function about the expected arguments. The format strings use the same syntax for each of these functions.
Parsing arguments

A format string consists of zero or more “format units.” A format unit describes one Python object; it is usually a single character or a parenthesized sequence of format units. With a few exceptions, a format unit that is not a parenthesized sequence normally corresponds to a single address argument to these functions. In the following description, the quoted form is the format unit; the entry in (round) parentheses is the Python object type that matches the format unit; and the entry in [square] brackets is the type of the C variable(s) whose address should be passed.

Strings and buffers

These formats allow accessing an object as a contiguous chunk of memory. You don’t have to provide raw storage for the returned unicode or bytes area.

In general, when a format sets a pointer to a buffer, the buffer is managed by the corresponding Python object, and the buffer shares the lifetime of this object. You won’t have to release any memory yourself. The only exceptions are es, es#, et and et#.

However, when a Py_buffer structure gets filled, the underlying buffer is locked so that the caller can subsequently use the buffer even inside a Py_BEGIN_ALLOW_THREADS block without the risk of mutable data being resized or destroyed. As a result, you have to call PyBuffer_Release() after you have finished processing the data (or in any early abort case).

Unless otherwise stated, buffers are not NUL-terminated.
Some formats require a read-only bytes-like object, and set a pointer instead of a buffer structure. They work by checking that the object's PyBufferProcs.bf_releasebuffer field is NULL, which disallows mutable objects such as bytearray.

**Note:** For all # variants of formats (s#, y#, etc.), the type of the length argument (int or Py_ssize_t) is controlled by defining the macro PY_SSIZE_T_CLEAN before including Python.h. If the macro was defined, length is a Py_ssize_t rather than an int. This behavior will change in a future Python version to only support Py_ssize_t and drop int support. It is best to always define PY_SSIZE_T_CLEAN.

`s (str) [const char *]`

Convert a Unicode object to a C pointer to a character string. A pointer to an existing string is stored in the character pointer variable whose address you pass. The C string is NUL-terminated. The Python string must not contain embedded null code points; if it does, a ValueError exception is raised. Unicode objects are converted to C strings using 'utf-8' encoding. If this conversion fails, a UnicodeError is raised.

**Note:** This format does not accept bytes-like objects. If you want to accept filesystem paths and convert them to C character strings, it is preferable to use the 0& format with PyUnicode_FSConverter() as converter.

`s* (str or bytes-like object) [Py_buffer]`

Changed in version 3.5: Previously, TypeError was raised when embedded null code points were encountered in the Python string.
This format accepts Unicode objects as well as bytes-like objects. It fills a Py_buffer structure provided by the caller. In this case the resulting C string may contain embedded NUL bytes. Unicode objects are converted to C strings using 'utf-8' encoding.

s# (str, read-only bytes-like object) [const char *, int or Py_ssize_t]
Like s*, except that it doesn’t accept mutable objects. The result is stored into two C variables, the first one a pointer to a C string, the second one its length. The string may contain embedded null bytes. Unicode objects are converted to C strings using 'utf-8' encoding.

z (str or None) [const char *]
Like s, but the Python object may also be None, in which case the C pointer is set to NULL.

z* (str, bytes-like object or None) [Py_buffer]
Like s*, but the Python object may also be None, in which case the buf member of the Py_buffer structure is set to NULL.

z# (str, read-only bytes-like object or None) [const char *, int]
Like s#, but the Python object may also be None, in which case the C pointer is set to NULL.

y (read-only bytes-like object) [const char *]
This format converts a bytes-like object to a C pointer to a character string; it does not accept Unicode objects. The bytes buffer must not contain embedded null bytes; if it does, a ValueError exception is raised.

Changed in version 3.5: Previously, TypeError was raised when embedded null bytes were encountered in the bytes buffer.

y* (bytes-like object) [Py_buffer]
This variant on s* doesn’t accept Unicode objects, only bytes-like
objects. **This is the recommended way to accept binary data.**

**y#** (read-only *bytes-like object*) [const char *, int]
This variant on **s#** doesn’t accept Unicode objects, only bytes-like objects.

**S** (*bytes*) [PyBytesObject *]
Requires that the Python object is a *bytes* object, without attempting any conversion. Raises **TypeError** if the object is not a *bytes* object. The C variable may also be declared as **PyObject**.*.

**Y** (*bytearray*) [PyByteArrayObject *]
Requires that the Python object is a *bytearray* object, without attempting any conversion. Raises **TypeError** if the object is not a *bytearray* object. The C variable may also be declared as **PyObject**.*.

**u** (*str*) [Py_UNICODE *]
Convert a Python Unicode object to a C pointer to a NULL-terminated buffer of Unicode characters. You must pass the address of a *Py_UNICODE* pointer variable, which will be filled with the pointer to an existing Unicode buffer. Please note that the width of a *Py_UNICODE* character depends on compilation options (it is either 16 or 32 bits). The Python string must not contain embedded null code points; if it does, a **ValueError** exception is raised.

*Changed in version 3.5:* Previously, **TypeError** was raised when embedded null code points were encountered in the Python string.

**u#** (*str*) [Py_UNICODE *, int]
This variant on **u** stores into two C variables, the first one a pointer to a Unicode data buffer, the second one its length. This variant allows null code points.

**Z** (*str* or None) [Py_UNICODE *]
Like `u`, but the Python object may also be `None`, in which case the `Py_UNICODE` pointer is set to `NULL`.

**Z# (str or None) [Py_UNICODE *, int]**

Like `u#`, but the Python object may also be `None`, in which case the `Py_UNICODE` pointer is set to `NULL`.

**U (str) [PyObject *]**

Requires that the Python object is a Unicode object, without attempting any conversion. Raises `TypeError` if the object is not a Unicode object. The C variable may also be declared as `PyObject*`.

**w* (read-write bytes-like object) [Py_buffer]**

This format accepts any object which implements the read-write buffer interface. It fills a `Py_buffer` structure provided by the caller. The buffer may contain embedded null bytes. The caller have to call `PyBuffer_Release()` when it is done with the buffer.

**es (str) [const char *encoding, char **buffer]**

This variant on `s` is used for encoding Unicode into a character buffer. It only works for encoded data without embedded NUL bytes.

This format requires two arguments. The first is only used as input, and must be a `const char*` which points to the name of an encoding as a NUL-terminated string, or `NULL`, in which case 'utf-8' encoding is used. An exception is raised if the named encoding is not known to Python. The second argument must be a `char**`; the value of the pointer it references will be set to a buffer with the contents of the argument text. The text will be encoded in the encoding specified by the first argument.

`PyArg_ParseTuple()` will allocate a buffer of the needed size,
copy the encoded data into this buffer and adjust *buffer to reference the newly allocated storage. The caller is responsible for calling PyMem_Free() to free the allocated buffer after use.

et (str, bytes or bytearray) [const char *encoding, char **buffer]
Same as es except that byte string objects are passed through without recoding them. Instead, the implementation assumes that the byte string object uses the encoding passed in as parameter.

es# (str) [const char *encoding, char **buffer, int *buffer_length]
This variant on s# is used for encoding Unicode into a character buffer. Unlike the es format, this variant allows input data which contains NUL characters.

It requires three arguments. The first is only used as input, and must be a const char* which points to the name of an encoding as a NUL-terminated string, or NULL, in which case utf-8' encoding is used. An exception is raised if the named encoding is not known to Python. The second argument must be a char**; the value of the pointer it references will be set to a buffer with the contents of the argument text. The text will be encoded in the encoding specified by the first argument. The third argument must be a pointer to an integer; the referenced integer will be set to the number of bytes in the output buffer.

There are two modes of operation:

If *buffer points a NULL pointer, the function will allocate a buffer of the needed size, copy the encoded data into this buffer and set *buffer to reference the newly allocated storage. The caller is responsible for calling PyMem_Free() to free the allocated buffer after usage.
If *buffer points to a non-NULL pointer (an already allocated buffer), *PyArg_ParseTuple() will use this location as the buffer and interpret the initial value of *buffer_length as the buffer size. It will then copy the encoded data into the buffer and NUL-terminate it. If the buffer is not large enough, a ValueError will be set.

In both cases, *buffer_length is set to the length of the encoded data without the trailing NUL byte.

et# (str, bytes or bytearray) [const char *encoding, char **buffer, int *buffer_length]

Same as es# except that byte string objects are passed through without recoding them. Instead, the implementation assumes that the byte string object uses the encoding passed in as parameter.

Numbers

b (int) [unsigned char]

Convert a nonnegative Python integer to an unsigned tiny int, stored in a C unsigned char.

B (int) [unsigned char]

Convert a Python integer to a tiny int without overflow checking, stored in a C unsigned char.

h (int) [short int]

Convert a Python integer to a C short int.

H (int) [unsigned short int]

Convert a Python integer to a C unsigned short int, without overflow checking.

i (int) [int]

Convert a Python integer to a plain C int.

I (int) [unsigned int]
Convert a Python integer to a C unsigned int, without overflow checking.

\texttt{l (int) [long int]}

Convert a Python integer to a C long int.

\texttt{k (int) [unsigned long]}

Convert a Python integer to a C unsigned long without overflow checking.

\texttt{L (int) [long long]}

Convert a Python integer to a C long long.

\texttt{K (int) [unsigned long long]}

Convert a Python integer to a C unsigned long long without overflow checking.

\texttt{n (int) [Py_ssize_t]}

Convert a Python integer to a C Py_ssize_t.

\texttt{c (bytes or bytearray of length 1) [char]}

Convert a Python byte, represented as a bytes or bytearray object of length 1, to a C char.

\textit{Changed in version 3.3: Allow bytearray objects.}

\texttt{C (str of length 1) [int]}

Convert a Python character, represented as a str object of length 1, to a C int.

\texttt{f (float) [float]}

Convert a Python floating point number to a C float.

\texttt{d (float) [double]}

Convert a Python floating point number to a C double.

\texttt{D (complex) [Py_complex]}

Convert a Python complex number to a C Py_complex structure.
Other objects

0 (object) [PyObject *]
Store a Python object (without any conversion) in a C object pointer. The C program thus receives the actual object that was passed. The object’s reference count is not increased. The pointer stored is not NULL.

O! (object) [typeobject, PyObject *]
Store a Python object in a C object pointer. This is similar to 0, but takes two C arguments: the first is the address of a Python type object, the second is the address of the C variable (of type PyObject*) into which the object pointer is stored. If the Python object does not have the required type, TypeError is raised.

0& (object) [converter, anything]
Convert a Python object to a C variable through a converter function. This takes two arguments: the first is a function, the second is the address of a C variable (of arbitrary type), converted to void *. The converter function in turn is called as follows:

\[
status = \text{converter}(\text{object}, \text{address});
\]

where object is the Python object to be converted and address is the void* argument that was passed to the PyArg_Parse*() function. The returned status should be 1 for a successful conversion and 0 if the conversion has failed. When the conversion fails, the converter function should raise an exception and leave the content of address unmodified.

If the converter returns Py_CLEANUP_SUPPORTED, it may get called a second time if the argument parsing eventually fails, giving the converter a chance to release any memory that it had already
allocated. In this second call, the *object* parameter will be NULL; *address* will have the same value as in the original call.

*Changed in version 3.1:* `Py_CLEANUP_SUPPORTED` was added.

```c
p (bool) [int]
```
Tests the value passed in for truth (a boolean *predicate*) and converts the result to its equivalent C true/false integer value. Sets the int to 1 if the expression was true and 0 if it was false. This accepts any valid Python value. See *Truth Value Testing* for more information about how Python tests values for truth.

*New in version 3.3.*

```c
(items) (tuple) [matching-items]
```
The object must be a Python sequence whose length is the number of format units in *items*. The C arguments must correspond to the individual format units in *items*. Format units for sequences may be nested.

It is possible to pass “long” integers (integers whose value exceeds the platform’s LONG_MAX) however no proper range checking is done — the most significant bits are silently truncated when the receiving field is too small to receive the value (actually, the semantics are inherited from downcasts in C — your mileage may vary).

A few other characters have a meaning in a format string. These may not occur inside nested parentheses. They are:

```c
|
```
Indicates that the remaining arguments in the Python argument list are optional. The C variables corresponding to optional arguments should be initialized to their default value — when an optional argument is not specified, `PyArg_ParseTuple()` does not touch
the contents of the corresponding C variable(s).

$\textit{PyArg_ParseTupleAndKeywords()}$ only: Indicates that the remaining arguments in the Python argument list are keyword-only. Currently, all keyword-only arguments must also be optional arguments, so $|$ must always be specified before $|$ in the format string.

\textit{New in version 3.3.}\n
\textbf{;}

The list of format units ends here; the string after the colon is used as the function name in error messages (the “associated value” of the exception that $\textit{PyArg_ParseTuple()}$ raises).

\textbf{;}

The list of format units ends here; the string after the semicolon is used as the error message \textit{instead} of the default error message. $|$ and $|$ mutually exclude each other.

Note that any Python object references which are provided to the caller are \textit{borrowed} references; do not decrement their reference count!

Additional arguments passed to these functions must be addresses of variables whose type is determined by the format string; these are used to store values from the input tuple. There are a few cases, as described in the list of format units above, where these parameters are used as input values; they should match what is specified for the corresponding format unit in that case.

For the conversion to succeed, the \textit{arg} object must match the format and the format must be exhausted. On success, the $\textit{PyArg_Parse*()}$ functions return true, otherwise they return false and raise an
appropriate exception. When the `PyArg_Parse*()` functions fail due to conversion failure in one of the format units, the variables at the addresses corresponding to that and the following format units are left untouched.

### API Functions

**int PyArg_ParseTuple**(PyObject *args, const char *format, ...)  
Parse the parameters of a function that takes only positional parameters into local variables. Returns true on success; on failure, it returns false and raises the appropriate exception.

**int PyArg_VaParse**(PyObject *args, const char *format, va_list vargs)  
Identical to `PyArg_ParseTuple()`, except that it accepts a va_list rather than a variable number of arguments.

**int PyArg_ParseTupleAndKeywords**(PyObject *args, PyObject *kw, const char *format, char *keywords[], ...)  
Parse the parameters of a function that takes both positional and keyword parameters into local variables. The `keywords` argument is a NULL-terminated array of keyword parameter names. Empty names denote positional-only parameters. Returns true on success; on failure, it returns false and raises the appropriate exception.

*Changed in version 3.6*: Added support for positional-only parameters.

**int PyArg_VaParseTupleAndKeywords**(PyObject *args, PyObject *kw, const char *format, char *keywords[], va_list vargs)  
Identical to `PyArg_ParseTupleAndKeywords()`, except that it
accepts a va_list rather than a variable number of arguments.

```c
int PyArg_VALIDATEKeywordArguments(PyObject *)
```

Ensure that the keys in the keywords argument dictionary are strings. This is only needed if `PyArg_ParseTupleAndKeywords()` is not used, since the latter already does this check.

*New in version 3.2.*

```c
int PyArg_Parse(PyObject *args, const char *format, ...)
```

Function used to deconstruct the argument lists of “old-style” functions — these are functions which use the METH_OLDARGS parameter parsing method, which has been removed in Python 3. This is not recommended for use in parameter parsing in new code, and most code in the standard interpreter has been modified to no longer use this for that purpose. It does remain a convenient way to decompose other tuples, however, and may continue to be used for that purpose.

```c
int PyArg_UnpackTuple(PyObject *args, const char *name, Py_ssize_t min, Py_ssize_t max, ...)
```

A simpler form of parameter retrieval which does not use a format string to specify the types of the arguments. Functions which use this method to retrieve their parameters should be declared as METH_VARARGS in function or method tables. The tuple containing the actual parameters should be passed as `args`; it must actually be a tuple. The length of the tuple must be at least `min` and no more than `max`; `min` and `max` may be equal. Additional arguments must be passed to the function, each of which should be a pointer to a `PyObject*` variable; these will be filled in with the values from `args`; they will contain borrowed references. The variables
which correspond to optional parameters not given by *args will not be filled in; these should be initialized by the caller. This function returns true on success and false if *args is not a tuple or contains the wrong number of elements; an exception will be set if there was a failure.

This is an example of the use of this function, taken from the sources for the _weakref helper module for weak references:

```c
static PyObject *
weakref_ref(PyObject *self, PyObject *args)
{
    PyObject *object;
    PyObject *callback = NULL;
    PyObject *result = NULL;

    if (PyArg_UnpackTuple(args, "ref", 1, 2, &object, &callback)
        result = PyWeakref_NewRef(object, callback)
    }
    return result;
}
```

The call to `PyArg_UnpackTuple()` in this example is entirely equivalent to this call to `PyArg_ParseTuple()`:

```c
PyArg_ParseTuple(args, "O|O:ref", &object, &callback)
```
Building values

PyObject* Py_BuildValue(const char *format, ...)

*Return value: New reference.*
Create a new value based on a format string similar to those accepted by the PyArg_Parse*() family of functions and a sequence of values. Returns the value or NULL in the case of an error; an exception will be raised if NULL is returned.

Py_BuildValue() does not always build a tuple. It builds a tuple only if its format string contains two or more format units. If the format string is empty, it returns None; if it contains exactly one format unit, it returns whatever object is described by that format unit. To force it to return a tuple of size 0 or one, parenthesize the format string.

When memory buffers are passed as parameters to supply data to build objects, as for the s and s# formats, the required data is copied. Buffers provided by the caller are never referenced by the objects created by Py_BuildValue(). In other words, if your code invokes malloc() and passes the allocated memory to Py_BuildValue(), your code is responsible for calling free() for that memory once Py_BuildValue() returns.

In the following description, the quoted form is the format unit; the entry in (round) parentheses is the Python object type that the format unit will return; and the entry in [square] brackets is the type of the C value(s) to be passed.

The characters space, tab, colon and comma are ignored in format strings (but not within format units such as s#). This can be used
to make long format strings a tad more readable.

s (str or None) [char *]
    Convert a null-terminated C string to a Python str object using 'utf-8' encoding. If the C string pointer is NULL, None is used.

s# (str or None) [char *, int]
    Convert a C string and its length to a Python str object using 'utf-8' encoding. If the C string pointer is NULL, the length is ignored and None is returned.

y (bytes) [char *]
    This converts a C string to a Python bytes object. If the C string pointer is NULL, None is returned.

y# (bytes) [char *, int]
    This converts a C string and its lengths to a Python object. If the C string pointer is NULL, None is returned.

z (str or None) [char *]
    Same as s.

z# (str or None) [char *, int]
    Same as s#.

u (str) [Py_UNICODE *]
    Convert a null-terminated buffer of Unicode (UCS-2 or UCS-4) data to a Python Unicode object. If the Unicode buffer pointer is NULL, None is returned.

u# (str) [Py_UNICODE *, int]
    Convert a Unicode (UCS-2 or UCS-4) data buffer and its length to a Python Unicode object. If the Unicode buffer pointer is NULL, the length is ignored and None is returned.

U (str or None) [char *]
Same as s.

U# (str or None) [char *, int]
    Same as s#.

i (int) [int]
    Convert a plain C int to a Python integer object.

b (int) [char]
    Convert a plain C char to a Python integer object.

h (int) [short int]
    Convert a plain C short int to a Python integer object.

l (int) [long int]
    Convert a C long int to a Python integer object.

B (int) [unsigned char]
    Convert a C unsigned char to a Python integer object.

H (int) [unsigned short int]
    Convert a C unsigned short int to a Python integer object.

I (int) [unsigned int]
    Convert a C unsigned int to a Python integer object.

k (int) [unsigned long]
    Convert a C unsigned long to a Python integer object.

L (int) [long long]
    Convert a C long long to a Python integer object.

K (int) [unsigned long long]
    Convert a C unsigned long long to a Python integer object.

n (int) [Py_ssize_t]
Convert a C Py_ssize_t to a Python integer.

C (bytes of length 1) [char]
Convert a C int representing a byte to a Python bytes object of length 1.

C (str of length 1) [int]
Convert a C int representing a character to Python str object of length 1.

d (float) [double]
Convert a C double to a Python floating point number.

f (float) [float]
Convert a C float to a Python floating point number.

D (complex) [Py_complex *]
Convert a C Py_complex structure to a Python complex number.

O (object) [PyObject *]
Pass a Python object untouched (except for its reference count, which is incremented by one). If the object passed in is a NULL pointer, it is assumed that this was caused because the call producing the argument found an error and set an exception. Therefore, Py_BuildValue() will return NULL but won’t raise an exception. If no exception has been raised yet, SystemError is set.

S (object) [PyObject *]
Same as O.

N (object) [PyObject *]
Same as O, except it doesn’t increment the reference count on the object. Useful when the object is created by a call to an object constructor in the argument list.
0& (object) [converter, anything]

Convert anything to a Python object through a converter function. The function is called with anything (which should be compatible with void *) as its argument and should return a “new” Python object, or NULL if an error occurred.

(items) (tuple) [matching-items]

Convert a sequence of C values to a Python tuple with the same number of items.

[items] (list) [matching-items]

Convert a sequence of C values to a Python list with the same number of items.

{items} (dict) [matching-items]

Convert a sequence of C values to a Python dictionary. Each pair of consecutive C values adds one item to the dictionary, serving as key and value, respectively.

If there is an error in the format string, the SystemError exception is set and NULL returned.

PyObject* Py_VaBuildValue(const char *format, va_list vargs)

Identical to Py_BuildValue(), except that it accepts a va_list rather than a variable number of arguments.
String conversion and formatting

Functions for number conversion and formatted string output.

```c
int PyOS_snprintf(char *str, size_t size, const char *format, ...)
```

Output not more than `size` bytes to `str` according to the format string `format` and the extra arguments. See the Unix man page `snprintf(2)`.

```c
int PyOS_vsnprintf(char *str, size_t size, const char *format, va_list va)
```

Output not more than `size` bytes to `str` according to the format string `format` and the variable argument list `va`. Unix man page `vsnprintf(2)`.

`PyOS_snprintf()` and `PyOS_vsnprintf()` wrap the Standard C library functions `snprintf()` and `vsnprintf()`. Their purpose is to guarantee consistent behavior in corner cases, which the Standard C functions do not.

The wrappers ensure that `str[\star size-1]` is always `\0` upon return. They never write more than `size` bytes (including the trailing `\0`) into `str`. Both functions require that `str != NULL`, `size > 0` and `format != NULL`.

If the platform doesn’t have `vsnprintf()` and the buffer size needed to avoid truncation exceeds `size` by more than 512 bytes, Python aborts with a `Py_FatalError`.

The return value (`rv`) for these functions should be interpreted as follows:
• When \( 0 \leq rv < size \), the output conversion was successful and \( rv \) characters were written to \( str \) (excluding the trailing '0' byte at \( str[rv] \)).

• When \( rv \geq size \), the output conversion was truncated and a buffer with \( rv + 1 \) bytes would have been needed to succeed. \( str[size-1] \) is '0' in this case.

• When \( rv < 0 \), “something bad happened.” \( str[size-1] \) is '0' in this case too, but the rest of \( str \) is undefined. The exact cause of the error depends on the underlying platform.

The following functions provide locale-independent string to number conversions.

```c
double PyOS_string_to_double(const char *s, char **endptr, PyObject *overflow_exception)
```

Convert a string \( s \) to a double, raising a Python exception on failure. The set of accepted strings corresponds to the set of strings accepted by Python’s \texttt{float()}\ constructor, except that \( s \) must not have leading or trailing whitespace. The conversion is independent of the current locale.

If \( endptr \) is \texttt{NULL}, convert the whole string. Raise \texttt{ValueError} and return \texttt{-1.0} if the string is not a valid representation of a floating-point number.

If \( endptr \) is not \texttt{NULL}, convert as much of the string as possible and set \*\texttt{endptr} to point to the first unconverted character. If no initial segment of the string is the valid representation of a floating-point number, set \*\texttt{endptr} to point to the beginning of the string, raise \texttt{ValueError}, and return \texttt{-1.0}.

If \( s \) represents a value that is too large to store in a float (for
example, \texttt{"1e500"} is such a string on many platforms) then if \texttt{overflow_exception} is NULL return \texttt{Py\_HUGE\_VAL} (with an appropriate sign) and don’t set any exception. Otherwise, \texttt{overflow_exception} must point to a Python exception object; raise that exception and return \texttt{-1.0}. In both cases, set \texttt{*endptr} to point to the first character after the converted value.

If any other error occurs during the conversion (for example an out-of-memory error), set the appropriate Python exception and return \texttt{-1.0}.

\textit{New in version 3.1.}

\begin{verbatim}
char* PyOS_double_to_string(double val, char format_code, int precision, int flags, int *ptype)
    Convert a double val to a string using supplied format_code, precision, and flags.

    format_code must be one of \texttt{\'e\'}, \texttt{\'E\'}, \texttt{\'f\'}, \texttt{\'F\'}, \texttt{\'g\'}, \texttt{\'G\'} or \texttt{\'r\'}. For \texttt{\'r\'}, the supplied precision must be 0 and is ignored. The \texttt{\'r\'} format code specifies the standard \texttt{repr()} format.

    flags can be zero or more of the values \texttt{Py\_DTSF\_SIGN}, \texttt{Py\_DTSF\_ADD\_DOT\_0}, or \texttt{Py\_DTSF\_ALT}, or-ed together:

    \begin{itemize}
    \item \texttt{Py\_DTSF\_SIGN} means to always precede the returned string with a sign character, even if \texttt{val} is non-negative.
    \item \texttt{Py\_DTSF\_ADD\_DOT\_0} means to ensure that the returned string will not look like an integer.
    \item \texttt{Py\_DTSF\_ALT} means to apply “alternate” formatting rules. See the documentation for the \texttt{PyOS\_snprintf()} \texttt{\'#\'} specifier for details.
    \end{itemize}

    If \texttt{ptype} is non-NULL, then the value it points to will be set to one of
\end{verbatim}
Py_DTST_FINITE, Py_DTST_INFINITE, or Py_DTST_NAN, signifying that val is a finite number, an infinite number, or not a number, respectively.

The return value is a pointer to buffer with the converted string or NULL if the conversion failed. The caller is responsible for freeing the returned string by calling PyMem_Free().

New in version 3.1.

int PyOS_stricmp(const char *s1, const char *s2)

Case insensitive comparison of strings. The function works almost identically to strcmp() except that it ignores the case.

int PyOS_strnicmp(const char *s1, const char *s2, Py_ssize_t size)

Case insensitive comparison of strings. The function works almost identically to strncmp() except that it ignores the case.
Reflection

PyObject* **PyEval_GetBuiltins()**

*Return value: Borrowed reference.*
Return a dictionary of the builtins in the current execution frame, or the interpreter of the thread state if no frame is currently executing.

PyObject* **PyEval_GetLocals()**

*Return value: Borrowed reference.*
Return a dictionary of the local variables in the current execution frame, or *NULL* if no frame is currently executing.

PyObject* **PyEval_GetGlobals()**

*Return value: Borrowed reference.*
Return a dictionary of the global variables in the current execution frame, or *NULL* if no frame is currently executing.

PyFrameObject* **PyEval_GetFrame()**

*Return value: Borrowed reference.*
Return the current thread state's frame, which is *NULL* if no frame is currently executing.

int **PyFrame_GetLineNumber**(PyFrameObject *frame)

Return the line number that frame is currently executing.

const char* **PyEval_GetFuncName**(PyObject *func)

Return the name of *func* if it is a function, class or instance object, else the name of *func's* type.

const char* **PyEval_GetFuncDesc**(PyObject *func)

Return a description string, depending on the type of *func*. Return
values include “()” for functions and methods, ” constructor”, ” instance”, and ” object”. Concatenated with the result of `PyEval_GetFuncName()`, the result will be a description of `func`. 
Codec registry and support functions

int PyCodec_Register(PyObject *search_function)
   Register a new codec search function.

   As side effect, this tries to load the encodings package, if not yet done, to make sure that it is always first in the list of search functions.

int PyCodec_KnownEncoding(const char *encoding)
   Return 1 or 0 depending on whether there is a registered codec for the given encoding.

PyObject* PyCodec_Encode(PyObject *object, const char *encoding, const char *errors)
   Generic codec based encoding API.

   object is passed through the encoder function found for the given encoding using the error handling method defined by errors. errors may be NULL to use the default method defined for the codec. Raises a LookupError if no encoder can be found.

PyObject* PyCodec_Decode(PyObject *object, const char *encoding, const char *errors)
   Generic codec based decoding API.

   object is passed through the decoder function found for the given encoding using the error handling method defined by errors. errors may be NULL to use the default method defined for the codec. Raises a LookupError if no encoder can be found.
Codec lookup API

In the following functions, the *encoding* string is looked up converted to all lower-case characters, which makes encodings looked up through this mechanism effectively case-insensitive. If no codec is found, a **KeyError** is set and **NULL** returned.

**PyObject** * **PyCodec_Encoder** (const char *encoding)
  Get an encoder function for the given *encoding*.

**PyObject** * **PyCodec_Decoder** (const char *encoding)
  Get a decoder function for the given *encoding*.

**PyObject** * **PyCodec_IncrementalEncoder** (const char *encoding, const char *errors)
  Get an IncrementalEncoder object for the given *encoding*.

**PyObject** * **PyCodec_IncrementalDecoder** (const char *encoding, const char *errors)
  Get an IncrementalDecoder object for the given *encoding*.

**PyObject** * **PyCodec_StreamReader** (const char *encoding, PyObject *stream, const char *errors)
  Get a StreamReader factory function for the given *encoding*.

**PyObject** * **PyCodec_StreamWriter** (const char *encoding, PyObject *stream, const char *errors)
  Get a StreamWriter factory function for the given *encoding*. 
Registry API for Unicode encoding error handlers

```c
int PyCodec_RegisterError(const char *name, PyObject *error)
```

Register the error handling callback function `error` under the given `name`. This callback function will be called by a codec when it encounters unencodable characters/undecodable bytes and `name` is specified as the error parameter in the call to the encode/decode function.

The callback gets a single argument, an instance of `UnicodeEncodeError`, `UnicodeDecodeError` or `UnicodeTranslateError` that holds information about the problematic sequence of characters or bytes and their offset in the original string (see Unicode Exception Objects for functions to extract this information). The callback must either raise the given exception, or return a two-item tuple containing the replacement for the problematic sequence, and an integer giving the offset in the original string at which encoding/decoding should be resumed.

Return 0 on success, -1 on error.

```c
PyObject* PyCodec_LookupError(const char *name)
```

Lookup the error handling callback function registered under `name`. As a special case `NULL` can be passed, in which case the error handling callback for “strict” will be returned.

```c
PyObject* PyCodec_StrictErrors(PyObject *exc)
```

Raise `exc` as an exception.
PyObject* PyCodec_IgnoreErrors(PyObject *exc)
    Ignore the unicode error, skipping the faulty input.

PyObject* PyCodec_ReplaceErrors(PyObject *exc)
    Replace the unicode encode error with ? or U+FFFD.

PyObject* PyCodec_XMLCharRefReplaceErrors(PyObject *exc)
    Replace the unicode encode error with XML character references.

PyObject* PyCodec_BackslashReplaceErrors(PyObject *exc)
    Replace the unicode encode error with backslash escapes (\x, \u
    and \U).

PyObject* PyCodec_NameReplaceErrors(PyObject *exc)
    Replace the unicode encode error with \N{...} escapes.

*New in version 3.5.*
Abstract Objects Layer

The functions in this chapter interact with Python objects regardless of their type, or with wide classes of object types (e.g. all numerical types, or all sequence types). When used on object types for which they do not apply, they will raise a Python exception.

It is not possible to use these functions on objects that are not properly initialized, such as a list object that has been created by `PyList_New()`, but whose items have not been set to some non-`NULL` value yet.

- Object Protocol
- Number Protocol
- Sequence Protocol
- Mapping Protocol
- Iterator Protocol
- Buffer Protocol
  - Buffer structure
  - Buffer request types
    - request-independent fields
    - readonly, format
    - shape, strides, suboffsets
    - contiguity requests
    - compound requests
  - Complex arrays
    - NumPy-style: shape and strides
    - PIL-style: shape, strides and suboffsets
  - Buffer-related functions
- Old Buffer Protocol
Object Protocol

Carthy* Py_NotImplemented

The NotImplemented singleton, used to signal that an operation is not implemented for the given type combination.

Py_RETURN_NOTIMPLEMENTED

Properly handle returning Py_NotImplemented from within a C function (that is, increment the reference count of NotImplemented and return it).

int PyObject_Print(PyObject *o, FILE *fp, int flags)

Print an object o, on file fp. Returns -1 on error. The flags argument is used to enable certain printing options. The only option currently supported is Py_PRINT_RAW; if given, the str() of the object is written instead of the repr().

int PyObject_HasAttr(PyObject *o, PyObject *attr_name)

Returns 1 if o has the attribute attr_name, and 0 otherwise. This is equivalent to the Python expression hasattr(o, attr_name). This function always succeeds.

int PyObject_HasAttrString(PyObject *o, const char *attr_name)

Returns 1 if o has the attribute attr_name, and 0 otherwise. This is equivalent to the Python expression hasattr(o, attr_name). This function always succeeds.

PyObject* PyObject_GetAttr(PyObject *o, PyObject *attr_name)

Retrieve an attribute named `attr_name` from object `o`. Returns the attribute value on success, or `NULL` on failure. This is the equivalent of the Python expression `o.attr_name`.

```
PyObject* PyObject_GetAttrString(PyObject *o, const char *attr_name)
```

*Return value: New reference.*
Retrieve an attribute named `attr_name` from object `o`. Returns the attribute value on success, or `NULL` on failure. This is the equivalent of the Python expression `o.attr_name`.

```
PyObject* PyObject_GenericGetAttr(PyObject *o, PyObject *name)
```

Generic attribute getter function that is meant to be put into a type object's `tp_getattro` slot. It looks for a descriptor in the dictionary of classes in the object's MRO as well as an attribute in the object's `__dict__` (if present). As outlined in Implementing Descriptors, data descriptors take preference over instance attributes, while non-data descriptors don't. Otherwise, an AttributeError is raised.

```
int PyObject_SetAttr(PyObject *o, PyObject *attr_name, PyObject *v)
```

Set the value of the attribute named `attr_name`, for object `o`, to the value `v`. Raise an exception and return `-1` on failure; return `0` on success. This is the equivalent of the Python statement `o.attr_name = v`.

If `v` is `NULL`, the attribute is deleted, however this feature is deprecated in favour of using `PyObject_DelAttr()`.

```
int PyObject_SetAttrString(PyObject *o, const
```
char *attr_name, PyObject *v)
    Set the value of the attribute named attr_name, for object o, to the value v. Raise an exception and return -1 on failure; return 0 on success. This is the equivalent of the Python statement o.attr_name = v.

    If v is NULL, the attribute is deleted, however this feature is deprecated in favour of using PyObject_DelAttrString().

int PyObject_GenericSetAttr(PyObject *o, PyObject *name, PyObject *value)
    Generic attribute setter and deleter function that is meant to be put into a type object’s tp_setattro slot. It looks for a data descriptor in the dictionary of classes in the object’s MRO, and if found it takes preference over setting or deleting the attribute in the instance dictionary. Otherwise, the attribute is set or deleted in the object’s __dict__ (if present). On success, 0 is returned, otherwise an AttributeError is raised and -1 is returned.

int PyObject_DelAttr(PyObject *o, PyObject *attr_name)
    Delete attribute named attr_name, for object o. Returns -1 on failure. This is the equivalent of the Python statement del o.attr_name.

int PyObject_DelAttrString(PyObject *o, const char *attr_name)
    Delete attribute named attr_name, for object o. Returns -1 on failure. This is the equivalent of the Python statement del o.attr_name.

PyObject* PyObject_GenericGetDict(PyObject *o, void *context)
A generic implementation for the getter of a __dict__ descriptor. It creates the dictionary if necessary.

*New in version 3.3.*

```c
int PyObject_GenericSetDict(PyObject *o, void *context)
```

A generic implementation for the setter of a __dict__ descriptor. This implementation does not allow the dictionary to be deleted.

*New in version 3.3.*

```c
PyObject* PyObject_RichCompare(PyObject *o1, PyObject *o2, int opid)
```

*Return value: New reference.*

Compare the values of `o1` and `o2` using the operation specified by `opid`, which must be one of `Py_LT`, `Py_LE`, `Py_EQ`, `Py_NE`, `Py_GT`, or `Py_GE`, corresponding to `<`, `<=`, `==`, `!=`, `>`, or `>=` respectively. This is the equivalent of the Python expression `o1 op o2`, where `op` is the operator corresponding to `opid`. Returns the value of the comparison on success, or `NULL` on failure.

```c
int PyObject_RichCompareBool(PyObject *o1, PyObject *o2, int opid)
```

Compare the values of `o1` and `o2` using the operation specified by `opid`, which must be one of `Py_LT`, `Py_LE`, `Py_EQ`, `Py_NE`, `Py_GT`, or `Py_GE`, corresponding to `<`, `<=`, `==`, `!=`, `>`, or `>=` respectively. Returns `-1` on error, `0` if the result is false, `1` otherwise. This is the equivalent of the Python expression `o1 op o2`, where `op` is the operator corresponding to `opid`.

**Note:** If `o1` and `o2` are the same object, `PyObject_RichCompareBool()` will always return `1` for `Py_EQ`.
and 0 for Py_NE.

PyObject* **PyObject_Repr**(PyObject *o)

*Return value: New reference.*

Compute a string representation of object *o*. Returns the string representation on success, *NULL* on failure. This is the equivalent of the Python expression `repr(o)`. Called by the `repr()` built-in function.

*Changed in version 3.4:* This function now includes a debug assertion to help ensure that it does not silently discard an active exception.

PyObject* **PyObject_ASCII**(PyObject *o)

As **PyObject_Repr()**, compute a string representation of object *o*, but escape the non-ASCII characters in the string returned by **PyObject_Repr()** with \x, \u or \U escapes. This generates a string similar to that returned by **PyObject_Repr()** in Python 2. Called by the `ascii()` built-in function.

PyObject* **PyObject_Str**(PyObject *o)

*Return value: New reference.*

Compute a string representation of object *o*. Returns the string representation on success, *NULL* on failure. This is the equivalent of the Python expression `str(o)`. Called by the `str()` built-in function and, therefore, by the `print()` function.

*Changed in version 3.4:* This function now includes a debug assertion to help ensure that it does not silently discard an active exception.

PyObject* **PyObject_Bytes**(PyObject *o)
Compute a bytes representation of object o. NULL is returned on failure and a bytes object on success. This is equivalent to the Python expression bytes(o), when o is not an integer. Unlike bytes(o), a TypeError is raised when o is an integer instead of a zero-initialized bytes object.

```c
int PyObject_IsSubclass(PyObject *derived, PyObject *cls)
```

Return 1 if the class derived is identical to or derived from the class cls, otherwise return 0. In case of an error, return -1.

If cls is a tuple, the check will be done against every entry in cls. The result will be 1 when at least one of the checks returns 1, otherwise it will be 0.

If cls has a __subclasscheck__() method, it will be called to determine the subclass status as described in PEP 3119. Otherwise, derived is a subclass of cls if it is a direct or indirect subclass, i.e. contained in cls.__mro__.

Normally only class objects, i.e. instances of type or a derived class, are considered classes. However, objects can override this by having a __bases__ attribute (which must be a tuple of base classes).

```c
int PyObject_IsInstance(PyObject *inst, PyObject *cls)
```

Return 1 if inst is an instance of the class cls or a subclass of cls, or 0 if not. On error, returns -1 and sets an exception.

If cls is a tuple, the check will be done against every entry in cls. The result will be 1 when at least one of the checks returns 1, otherwise it will be 0.
If `cls` has a `__instancecheck__()` method, it will be called to determine the subclass status as described in PEP 3119. Otherwise, `inst` is an instance of `cls` if its class is a subclass of `cls`.

An instance `inst` can override what is considered its class by having a `__class__` attribute.

An object `cls` can override if it is considered a class, and what its base classes are, by having a `__bases__` attribute (which must be a tuple of base classes).

```c
int PyCallable_Check(PyObject *o)
```

Determine if the object `o` is callable. Return 1 if the object is callable and 0 otherwise. This function always succeeds.

```c
PyObject* PyObject_Call(PyObject *callable_object, PyObject *args, PyObject *kw)
```

*Return value: New reference.*

Call a callable Python object `callable_object`, with arguments given by the tuple `args`, and named arguments given by the dictionary `kw`. If no named arguments are needed, `kw` may be `NULL`. `args` must not be `NULL`, use an empty tuple if no arguments are needed. Returns the result of the call on success, or `NULL` on failure. This is the equivalent of the Python expression `callable_object(*args, **kw)`.

```c
PyObject* PyObject_CallObject(PyObject *callable_object, PyObject *args)
```

*Return value: New reference.*

Call a callable Python object `callable_object`, with arguments given by the tuple `args`. If no arguments are needed, then `args` may be `NULL`. Returns the result of the call on success, or `NULL` on failure.
This is the equivalent of the Python expression `callable_object(*args)`.

`PyObject* PyObject_CallFunction(PyObject *callable, const char *format, ...)`

*Return value: New reference.*
Call a callable Python object `callable`, with a variable number of C arguments. The C arguments are described using a `Py_BuildValue()` style format string. The format may be `NULL`, indicating that no arguments are provided. Returns the result of the call on success, or `NULL` on failure. This is the equivalent of the Python expression `callable(*args)`. Note that if you only pass `PyObject * args, PyObject_CallFunctionObjArgs()` is a faster alternative.

*Changed in version 3.4:* The type of `format` was changed from `char *`.

`PyObject* PyObject_CallMethod(PyObject *o, const char *method, const char *format, ...)`

*Return value: New reference.*
Call the method named `method` of object `o` with a variable number of C arguments. The C arguments are described by a `Py_BuildValue()` format string that should produce a tuple. The format may be `NULL`, indicating that no arguments are provided. Returns the result of the call on success, or `NULL` on failure. This is the equivalent of the Python expression `o.method(args)`. Note that if you only pass `PyObject * args, PyObject_CallMethodObjArgs()` is a faster alternative.

*Changed in version 3.4:* The types of `method` and `format` were changed from `char *`. 
PyObject*
PyObject_CallFunctionObjArgs(PyObject *callable, ..., NULL)

Call a callable Python object callable, with a variable number of PyObject* arguments. The arguments are provided as a variable number of parameters followed by NULL. Returns the result of the call on success, or NULL on failure.

PyObject* PyObject_CallMethodObjArgs(PyObject *o, PyObject *name, ..., NULL)

Calls a method of the object o, where the name of the method is given as a Python string object in name. It is called with a variable number of PyObject* arguments. The arguments are provided as a variable number of parameters followed by NULL. Returns the result of the call on success, or NULL on failure.

Py_hash_t PyObject_Hash(PyObject *o)
Compute and return the hash value of an object o. On failure, return -1. This is the equivalent of the Python expression hash(o).

Changed in version 3.2: The return type is now Py_hash_t. This is a signed integer the same size as Py_ssize_t.

Py_hash_t PyObject_HashNotImplemented(PyObject *o)
Set a TypeError indicating that type(o) is not hashable and return -1. This function receives special treatment when stored in a tp_hash slot, allowing a type to explicitly indicate to the interpreter that it is not hashable.
int **PyObject_IsTrue(PyObject *o)**

Returns 1 if the object o is considered to be true, and 0 otherwise. This is equivalent to the Python expression not not o. On failure, return -1.

int **PyObject_Not(PyObject *o)**

Returns 0 if the object o is considered to be true, and 1 otherwise. This is equivalent to the Python expression not o. On failure, return -1.

PyObject* **PyObject_Type(PyObject *o)**

*Return value: New reference.*

When o is non-NULL, returns a type object corresponding to the object type of object o. On failure, raises SystemError and returns NULL. This is equivalent to the Python expression type(o). This function increments the reference count of the return value. There's really no reason to use this function instead of the common expression o->ob_type, which returns a pointer of type PyTypeObject*, except when the incremented reference count is needed.

int **PyObject_TypeCheck(PyObject *o, PyTypeObject *type)**

Return true if the object o is of type type or a subtype of type. Both parameters must be non-NULL.

Py_ssize_t **PyObject_Length(PyObject *o)**

Py_ssize_t **PyObject_Size(PyObject *o)**

Return the length of object o. If the object o provides either the sequence and mapping protocols, the sequence length is returned. On error, -1 is returned. This is the equivalent to the Python expression len(o).
Py_ssize_t PyObject_LengthHint(PyObject *o, Py_ssize_t default)

Return an estimated length for the object o. First try to return its actual length, then an estimate using \_length\_hint\_(), and finally return the default value. On error return -1. This is the equivalent to the Python expression `operator.length_hint(o, default)`. New in version 3.4.

PyObject* PyObject_GetItem(PyObject *o, PyObject *key)

Return element of o corresponding to the object key or NULL on failure. This is the equivalent of the Python expression o[key].

int PyObject_SetItem(PyObject *o, PyObject *key, PyObject *v)

Map the object key to the value v. Raise an exception and return -1 on failure; return 0 on success. This is the equivalent of the Python statement o[key] = v.

int PyObject_DelItem(PyObject *o, PyObject *key)

Delete the mapping for key from o. Returns -1 on failure. This is the equivalent of the Python statement del o[key].

PyObject* PyObject_Dir(PyObject *o)

This is equivalent to the Python expression dir(o), returning a (possibly empty) list of strings appropriate for the object argument, or NULL if there was an error. If the argument is NULL, this is like the Python dir(), returning the names of the current locals; in this case, if no execution frame is active then NULL is returned but PyErr_Occurred() will return false.
PyObject* **PyObject_GetIter** (PyObject *o)

*Return value: New reference.*

This is equivalent to the Python expression `iter(o)`. It returns a new iterator for the object argument, or the object itself if the object is already an iterator. Raises `TypeError` and returns `NULL` if the object cannot be iterated.
Number Protocol

int `PyNumber_Check`(*PyObject* `*o`)
   Returns 1 if the object `o` provides numeric protocols, and false otherwise. This function always succeeds.

PyObject* `PyNumber_Add`(*PyObject* `*o1`, *PyObject* `*o2`)
   Returns the result of adding `o1` and `o2`, or `NULL` on failure. This is the equivalent of the Python expression `o1 + o2`.

PyObject* `PyNumber_Subtract`(*PyObject* `*o1`, *PyObject* `*o2`)
   Returns the result of subtracting `o2` from `o1`, or `NULL` on failure. This is the equivalent of the Python expression `o1 - o2`.

PyObject* `PyNumber_Multiply`(*PyObject* `*o1`, *PyObject* `*o2`)
   Returns the result of multiplying `o1` and `o2`, or `NULL` on failure. This is the equivalent of the Python expression `o1 * o2`.

PyObject* `PyNumber_MatrixMultiply`(*PyObject* `*o1`, *PyObject* `*o2`)
   Returns the result of matrix multiplication on `o1` and `o2`, or `NULL` on failure. This is the equivalent of the Python expression `o1 @ o2`.

   `New in version 3.5.`

PyObject* `PyNumber_FloorDivide`(*PyObject* `*o1`, *PyObject* `*o2`)

Return the floor of \( o1 \) divided by \( o2 \), or NULL on failure. This is equivalent to the “classic” division of integers.

PyObject* PyNumber_TrueDivide(PyObject *o1, PyObject *o2)

Return a reasonable approximation for the mathematical value of \( o1 \) divided by \( o2 \), or NULL on failure. The return value is “approximate” because binary floating point numbers are approximate; it is not possible to represent all real numbers in base two. This function can return a floating point value when passed two integers.

PyObject* PyNumber_Remainder(PyObject *o1, PyObject *o2)

Returns the remainder of dividing \( o1 \) by \( o2 \), or NULL on failure. This is the equivalent of the Python expression \( o1 \% o2 \).

PyObject* PyNumber_Divmod(PyObject *o1, PyObject *o2)

See the built-in function \texttt{divmod()}\texttt{.} Returns NULL on failure. This is the equivalent of the Python expression \texttt{divmod(o1, o2)}.

PyObject* PyNumber_Power(PyObject *o1, PyObject *o2, PyObject *o3)

See the built-in function \texttt{pow()}\texttt{.} Returns NULL on failure. This is the equivalent of the Python expression \texttt{pow(o1, o2, o3)}, where \( o3 \) is optional. If \( o3 \) is to be ignored, pass \texttt{Py_None} in its place (passing NULL for \( o3 \) would cause an illegal memory access).
PyObject* PyNumber_Negative(PyObject *o)

Returns the negation of o on success, or NULL on failure. This is the equivalent of the Python expression -o.

PyObject* PyNumber_Positve(PyObject *o)

Returns o on success, or NULL on failure. This is the equivalent of the Python expression +o.

PyObject* PyNumber_Absolute(PyObject *o)

Returns the absolute value of o, or NULL on failure. This is the equivalent of the Python expression abs(o).

PyObject* PyNumber_Invert(PyObject *o)

Returns the bitwise negation of o on success, or NULL on failure. This is the equivalent of the Python expression ~o.

PyObject* PyNumber_Lshift(PyObject *o1, PyObject *o2)

Returns the result of left shifting o1 by o2 on success, or NULL on failure. This is the equivalent of the Python expression o1 << o2.

PyObject* PyNumber_Rshift(PyObject *o1, PyObject *o2)

Returns the result of right shifting o1 by o2 on success, or NULL on failure. This is the equivalent of the Python expression o1 >> o2.

PyObject* PyNumber_And(PyObject *o1, PyObject *o2)

Returns the “bitwise and” of $o1$ and $o2$ on success and NULL on failure. This is the equivalent of the Python expression $o1 \& o2$.

**PyObject* PyNumber_Xor**(PyObject *$o1$, PyObject *$o2$)

*Return value: New reference.*

Returns the “bitwise exclusive or” of $o1$ by $o2$ on success, or NULL on failure. This is the equivalent of the Python expression $o1 \oplus o2$.

**PyObject* PyNumber_or**(PyObject *$o1$, PyObject *$o2$)

*Return value: New reference.*

Returns the “bitwise or” of $o1$ and $o2$ on success, or NULL on failure. This is the equivalent of the Python expression $o1 \mid o2$.

**PyObject* PyNumber_InPlaceAdd**(PyObject *$o1$, PyObject *$o2$)

*Return value: New reference.*

Returns the result of adding $o1$ and $o2$, or NULL on failure. The operation is done *in-place* when $o1$ supports it. This is the equivalent of the Python statement $o1 += o2$.

**PyObject* PyNumber_InPlaceSubtract**(PyObject *$o1$, PyObject *$o2$)

*Return value: New reference.*

Returns the result of subtracting $o2$ from $o1$, or NULL on failure. The operation is done *in-place* when $o1$ supports it. This is the equivalent of the Python statement $o1 -= o2$.

**PyObject* PyNumber_InPlaceMultiply**(PyObject *$o1$, PyObject *$o2$)

*Return value: New reference.*

Returns the result of multiplying $o1$ and $o2$, or NULL on failure. The operation is done *in-place* when $o1$ supports it. This is the
equivalent of the Python statement \( o1 *= o2 \).

**PyObject**

**PyNumber_InPlaceMatrixMultiply**(*PyObject* *o1, *PyObject* *o2*)

Returns the result of matrix multiplication on \( o1 \) and \( o2 \), or NULL on failure. The operation is done in-place when \( o1 \) supports it. This is the equivalent of the Python statement \( o1 @= o2 \).

*New in version 3.5.*

**PyObject**

**PyNumber_InPlaceFloorDivide**(*PyObject* *o1, *PyObject* *o2*)

*Return value: New reference.*

Returns the mathematical floor of dividing \( o1 \) by \( o2 \), or NULL on failure. The operation is done in-place when \( o1 \) supports it. This is the equivalent of the Python statement \( o1 //= o2 \).

**PyObject**

**PyNumber_InPlaceTrueDivide**(*PyObject* *o1, *PyObject* *o2*)

*Return value: New reference.*

Return a reasonable approximation for the mathematical value of \( o1 \) divided by \( o2 \), or NULL on failure. The return value is “approximate” because binary floating point numbers are approximate; it is not possible to represent all real numbers in base two. This function can return a floating point value when passed two integers. The operation is done in-place when \( o1 \) supports it.

**PyObject**

**PyNumber_InPlaceRemainder**(*PyObject* *o1, *PyObject* *o2*)

*Return value: New reference.*

Returns the remainder of dividing \( o1 \) by \( o2 \), or NULL on failure. The operation is done in-place when \( o1 \) supports it. This is the
equivalent of the Python statement \( o1 \%=} o2.\)

**PyObject**\* **PyNumber\_InPlacePower** (PyObject \*o1, PyObject \*o2, PyObject \*o3)

*Return value: New reference.*

See the built-in function `pow()`). Returns `NULL` on failure. The operation is done *in-place* when \( o1 \) supports it. This is the equivalent of the Python statement \( o1 \%=} o2 \) when \( o3 \) is *Py\_None*, or an in-place variant of `pow(o1, o2, o3)` otherwise. If \( o3 \) is to be ignored, pass *Py\_None* in its place (passing *NULL* for \( o3 \) would cause an illegal memory access).

**PyObject**\* **PyNumber\_InPlaceLshift** (PyObject \*o1, PyObject \*o2)

*Return value: New reference.*

Returns the result of left shifting \( o1 \) by \( o2 \) on success, or *NULL* on failure. The operation is done *in-place* when \( o1 \) supports it. This is the equivalent of the Python statement \( o1 \ll=} o2.\)

**PyObject**\* **PyNumber\_InPlaceRshift** (PyObject \*o1, PyObject \*o2)

*Return value: New reference.*

Returns the result of right shifting \( o1 \) by \( o2 \) on success, or *NULL* on failure. The operation is done *in-place* when \( o1 \) supports it. This is the equivalent of the Python statement \( o1 \gg=} o2.\)

**PyObject**\* **PyNumber\_InPlaceAnd** (PyObject \*o1, PyObject \*o2)

*Return value: New reference.*

Returns the “bitwise and” of \( o1 \) and \( o2 \) on success and *NULL* on failure. The operation is done *in-place* when \( o1 \) supports it. This is the equivalent of the Python statement \( o1 \&=} o2.\)
PyObject* PyNumber_InPlaceXor(PyObject *o1, PyObject *o2)

*Return value: New reference.*
Returns the “bitwise exclusive or” of `o1` by `o2` on success, or `NULL` on failure. The operation is done *in-place* when `o1` supports it. This is the equivalent of the Python statement `o1 ^= o2`.

PyObject* PyNumber_InPlaceOr(PyObject *o1, PyObject *o2)

*Return value: New reference.*
Returns the “bitwise or” of `o1` and `o2` on success, or `NULL` on failure. The operation is done *in-place* when `o1` supports it. This is the equivalent of the Python statement `o1 |= o2`.

PyObject* PyNumber_Long(PyObject *o)

*Return value: New reference.*
Returns the `o` converted to an integer object on success, or `NULL` on failure. This is the equivalent of the Python expression `int(o)`.

PyObject* PyNumber_Float(PyObject *o)

*Return value: New reference.*
Returns the `o` converted to a float object on success, or `NULL` on failure. This is the equivalent of the Python expression `float(o)`.

PyObject* PyNumber_Index(PyObject *o)

Returns the `o` converted to a Python int on success or `NULL` with a `TypeError` exception raised on failure.

PyObject* PyNumber_ToBase(PyObject *n, int base)

Returns the integer `n` converted to base `base` as a string. The `base` argument must be one of 2, 8, 10, or 16. For base 2, 8, or 16, the returned string is prefixed with a base marker of ‘`0b`’, ‘`0o`’, or ‘`0x`’, respectively. If `n` is not a Python int, it is converted with `PyNumber_Index()` first.
Py_ssize_t PyNumber_AsSsize_t(PyObject *o, PyObject *exc)

Returns `o` converted to a Py_ssize_t value if `o` can be interpreted as an integer. If the call fails, an exception is raised and `-1` is returned.

If `o` can be converted to a Python int but the attempt to convert to a Py_ssize_t value would raise an `OverflowError`, then the `exc` argument is the type of exception that will be raised (usually `IndexError` or `OverflowError`). If `exc` is `NULL`, then the exception is cleared and the value is clipped to `PY_SSIZE_T_MIN` for a negative integer or `PY_SSIZE_T_MAX` for a positive integer.

int PyIndex_Check(PyObject *o)

Returns `1` if `o` is an index integer (has the `nb_index` slot of the `tp_as_number` structure filled in), and `0` otherwise.
Sequence Protocol

int **sequence_check**(PyObject *o)

Return 1 if the object provides sequence protocol, and 0 otherwise. This function always succeeds.

Py_ssize_t **sequence_size**(PyObject *o)

Py_ssize_t **sequence_length**(PyObject *o)

Returns the number of objects in sequence o on success, and -1 on failure. For objects that do not provide sequence protocol, this is equivalent to the Python expression `len(o)`.

PyObject* **sequence_concat**(PyObject *o1, PyObject *o2)

*Return value: New reference.*

Return the concatenation of o1 and o2 on success, and NULL on failure. This is the equivalent of the Python expression `o1 + o2`.

PyObject* **sequence_repeat**(PyObject *o, Py_ssize_t count)

*Return value: New reference.*

Return the result of repeating sequence object o count times, or NULL on failure. This is the equivalent of the Python expression `o * count`.

PyObject* **sequence_inplace_concat**(PyObject *o1, PyObject *o2)

*Return value: New reference.*

Return the concatenation of o1 and o2 on success, and NULL on failure. The operation is done in-place when o1 supports it. This is the equivalent of the Python expression `o1 += o2`.

PyObject* **sequence_inplace_repeat**(PyObject *o,
Py_ssize_t count)
    Return the result of repeating sequence object o count times, or NULL on failure. The operation is done in-place when o supports it. This is the equivalent of the Python expression o *= count.

PyObject* PySequence_GetItem(PyObject *o, Py_ssize_t i)
    Return the i\textsuperscript{th} element of o, or NULL on failure. This is the equivalent of the Python expression o[i].

PyObject* PySequence_GetSlice(PyObject *o, Py_ssize_t i1, Py_ssize_t i2)
    Return the slice of sequence object o between i1 and i2, or NULL on failure. This is the equivalent of the Python expression o[i1:i2].

int PySequence_SetItem(PyObject *o, Py_ssize_t i, PyObject *v)
    Assign object v to the i\textsuperscript{th} element of o. Raise an exception and return -1 on failure; return 0 on success. This is the equivalent of the Python statement o[i] = v. This function does not steal a reference to v.

    If v is NULL, the element is deleted, however this feature is deprecated in favour of using PySequence_DelItem().

int PySequence_DelItem(PyObject *o, Py_ssize_t i)
    Delete the i\textsuperscript{th} element of object o. Returns -1 on failure. This is the equivalent of the Python statement del o[i].
int **PySequence_SetSlice**(*PyObject* *o*, *Py_ssize_t i1, Py_ssize_t i2, *PyObject* *v*)

Assign the sequence object *v* to the slice in sequence object *o* from *i1* to *i2*. This is the equivalent of the Python statement *o*[i1:i2] = *v*.

int **PySequence_DelSlice**(*PyObject* *o*, *Py_ssize_t i1, *Py_ssize_t i2*)

Delete the slice in sequence object *o* from *i1* to *i2*. Returns -1 on failure. This is the equivalent of the Python statement del *o*[i1:i2].

Py_ssize_t **PySequence_Count**(*PyObject* *o*, *PyObject* *value*)

Return the number of occurrences of *value* in *o*, that is, return the number of keys for which *o*[key] == *value*. On failure, return -1. This is equivalent to the Python expression *o*.count(*value*).

int **PySequence_Contains**(*PyObject* *o*, *PyObject* *value*)

Determine if *o* contains *value*. If an item in *o* is equal to *value*, return 1, otherwise return 0. On error, return -1. This is equivalent to the Python expression *value* in *o*.

Py_ssize_t **PySequence_Index**(*PyObject* *o*, *PyObject* *value*)

Return the first index *i* for which *o*[*i*] == *value*. On error, return -1. This is equivalent to the Python expression *o*.index(*value*).

PyObject* **PySequence_List**(*PyObject* *o*)

*Return value: New reference.*

Return a list object with the same contents as the sequence or
iterable o, or NULL on failure. The returned list is guaranteed to be new. This is equivalent to the Python expression `list(o)`.

**PyObject** PySequence_Tuple (**PyObject** o)**

*Return value: New reference.*

Return a tuple object with the same contents as the arbitrary sequence o or NULL on failure. If o is a tuple, a new reference will be returned, otherwise a tuple will be constructed with the appropriate contents. This is equivalent to the Python expression `tuple(o)`.

**PyObject** PySequence_Fast (**PyObject** o, const char *m)**

*Return value: New reference.*

Return the sequence o as a list, unless it is already a tuple or list, in which case o is returned. Use PySequence_Fast_GET_ITEM() to access the members of the result. Returns NULL on failure. If the object is not a sequence, raises TypeError with m as the message text.

**PyObject** PySequence_Fast_GET_ITEM (**PyObject** o, Py_ssize_t i)**

*Return value: Borrowed reference.*

Return the i-th element of o, assuming that o was returned by PySequence_Fast(), o is not NULL, and that i is within bounds.

**PyObject** PySequence_Fast_ITEMS (**PyObject** o)**

Return the underlying array of PyObject pointers. Assumes that o was returned by PySequence_Fast() and o is not NULL.

Note, if a list gets resized, the reallocation may relocate the items array. So, only use the underlying array pointer in contexts where the sequence cannot change.
PyObject* `PySequence_ITEM(PyObject *o, Py_ssize_t i)`

*Return value: New reference.*

Return the *i*th element of *o* or *NULL* on failure. Macro form of `PySequence_GetItem()` but without checking that `PySequence_Check()` on *o* is true and without adjustment for negative indices.

Py_ssize_t `PySequence_Fast_GET_SIZE(PyObject *o)`

Returns the length of *o*, assuming that *o* was returned by `PySequence_Fast()` and that *o* is not *NULL*. The size can also be gotten by calling `PySequence_Size()` on *o*, but `PySequence_Fast_GET_SIZE()` is faster because it can assume *o* is a list or tuple.
Mapping Protocol

int **PyMapping__Check**(PyObject *o)
  Return 1 if the object provides mapping protocol, and 0 otherwise.
  This function always succeeds.

Py_ssize_t **PyMapping__Size**(PyObject *o)
Py_ssize_t **PyMapping__Length**(PyObject *o)
  Returns the number of keys in object o on success, and -1 on failure. For objects that do not provide mapping protocol, this is equivalent to the Python expression `len(o)`.

int **PyMapping__DelItemString**(PyObject *o, const char *key)
  Remove the mapping for object key from the object o. Return -1 on failure. This is equivalent to the Python statement `del o[key]`.

int **PyMapping__DelItem**(PyObject *o, PyObject *key)
  Remove the mapping for object key from the object o. Return -1 on failure. This is equivalent to the Python statement `del o[key]`.

int **PyMapping__HasKeyString**(PyObject *o, const char *key)
  On success, return 1 if the mapping object has the key key and 0 otherwise. This is equivalent to the Python expression `key in o`. This function always succeeds.

int **PyMapping__HasKey**(PyObject *o, PyObject *key)
  Return 1 if the mapping object has the key key and 0 otherwise. This is equivalent to the Python expression `key in o`. This
function always succeeds.

PyObject* **PyMapping** _**Keys***(PyObject *o)

_Return value: New reference._
On success, return a list or tuple of the keys in object o. On failure, return NULL.

PyObject* **PyMapping** _**Values***(PyObject *o)

_Return value: New reference._
On success, return a list or tuple of the values in object o. On failure, return NULL.

PyObject* **PyMapping** _**Items***(PyObject *o)

_Return value: New reference._
On success, return a list or tuple of the items in object o, where each item is a tuple containing a key-value pair. On failure, return NULL.

PyObject* **PyMapping** _**GetItemString***(PyObject *o, const char *key)

_Return value: New reference._
Return element of o corresponding to the object key or NULL on failure. This is the equivalent of the Python expression o[key].

int **PyMapping** _**SetItemString***(PyObject *o, const char *key, PyObject *v)

Map the object key to the value v in object o. Returns -1 on failure. This is the equivalent of the Python statement o[key] = v.
Iterator Protocol

There are two functions specifically for working with iterators.

```c
int PyIter_Check(PyObject *o)

    Return true if the object o supports the iterator protocol.
```

```c
PyObject* PyIter_Next(PyObject *o)

    Return the next value from the iteration o. The object must be an iterator (it is up to the caller to check this). If there are no remaining values, returns NULL with no exception set. If an error occurs while retrieving the item, returns NULL and passes along the exception.
```

To write a loop which iterates over an iterator, the C code should look something like this:

```c
PyObject  *iterator = PyObject_GetIter(obj);
PyObject  *item;

if (iterator == NULL) {
    /* propagate error */
}

while (item = PyIter_Next(iterator)) {
    /* do something with item */
    ...
    /* release reference when done */
    Py_XDECREF(item);
}

Py_XDECREF(iterator);

if (PyErr_Occurred()) {
```
/* propagate error */
}
else {
    /* continue doing useful work */
}
Buffer Protocol

Certain objects available in Python wrap access to an underlying memory array or buffer. Such objects include the built-in bytes and bytearray, and some extension types like array.array. Third-party libraries may define their own types for special purposes, such as image processing or numeric analysis.

While each of these types have their own semantics, they share the common characteristic of being backed by a possibly large memory buffer. It is then desirable, in some situations, to access that buffer directly and without intermediate copying.

Python provides such a facility at the C level in the form of the buffer protocol. This protocol has two sides:

- on the producer side, a type can export a “buffer interface” which allows objects of that type to expose information about their underlying buffer. This interface is described in the section Buffer Object Structures;
- on the consumer side, several means are available to obtain a pointer to the raw underlying data of an object (for example a method parameter).

Simple objects such as bytes and bytearray expose their underlying buffer in byte-oriented form. Other forms are possible; for example, the elements exposed by an array.array can be multi-byte values.

An example consumer of the buffer interface is the write() method of file objects: any object that can export a series of bytes through the buffer interface can be written to a file. While write() only needs
read-only access to the internal contents of the object passed to it, other methods such as `readinto()` need write access to the contents of their argument. The buffer interface allows objects to selectively allow or reject exporting of read-write and read-only buffers.

There are two ways for a consumer of the buffer interface to acquire a buffer over a target object:

- call `PyObject_GetBuffer()` with the right parameters;
- call `PyArg_ParseTuple()` (or one of its siblings) with one of the `y*`, `w*` or `s*` format codes.

In both cases, `PyBuffer_Release()` must be called when the buffer isn’t needed anymore. Failure to do so could lead to various issues such as resource leaks.
Buffer structure

Buffer structures (or simply “buffers”) are useful as a way to expose the binary data from another object to the Python programmer. They can also be used as a zero-copy slicing mechanism. Using their ability to reference a block of memory, it is possible to expose any data to the Python programmer quite easily. The memory could be a large, constant array in a C extension, it could be a raw block of memory for manipulation before passing to an operating system library, or it could be used to pass around structured data in its native, in-memory format.

Contrary to most data types exposed by the Python interpreter, buffers are not PyObject pointers but rather simple C structures. This allows them to be created and copied very simply. When a generic wrapper around a buffer is needed, a memoryview object can be created.

For short instructions how to write an exporting object, see Buffer Object Structures. For obtaining a buffer, see PyObject_GetBuffer().

Py_buffer

void *buf

A pointer to the start of the logical structure described by the buffer fields. This can be any location within the underlying physical memory block of the exporter. For example, with negative strides the value may point to the end of the memory block.

For contiguous arrays, the value points to the beginning of the memory block.
void *obj
A new reference to the exporting object. The reference is owned by the consumer and automatically decremented and set to NULL by PyBuffer_Release(). The field is the equivalent of the return value of any standard C-API function.

As a special case, for temporary buffers that are wrapped by PyMemoryView_FromBuffer() or PyBuffer_FillInfo() this field is NULL. In general, exporting objects MUST NOT use this scheme.

Py_ssize_t len
product(shape) * itemsize. For contiguous arrays, this is the length of the underlying memory block. For non-contiguous arrays, it is the length that the logical structure would have if it were copied to a contiguous representation.

Accessing ((char *)buf)[0] up to ((char *)buf)[len-1] is only valid if the buffer has been obtained by a request that guarantees contiguity. In most cases such a request will be PyBUF_SIMPLE or PyBUF_WRITABLE.

int readonly
An indicator of whether the buffer is read-only. This field is controlled by the PyBUF_WRITABLE flag.

Py_ssize_t itemsize
Item size in bytes of a single element. Same as the value of struct.calcsize() called on non-NULL format values.

Important exception: If a consumer requests a buffer without the PyBUF_FORMAT flag, format will be set to NULL, but
itemsize still has the value for the original format.

If shape is present, the equality \( \text{product(shape)} \times \text{itemsize} == \text{len} \) still holds and the consumer can use itemsize to navigate the buffer.

If shape is NULL as a result of a PyBUF_SIMPLE or a PyBUF_WRITABLE request, the consumer must disregard itemsize and assume \( \text{itemsize} == 1 \).

const char *format
A NULL terminated string in struct module style syntax describing the contents of a single item. If this is NULL, "B" (unsigned bytes) is assumed.

This field is controlled by the PyBUF_FORMAT flag.

int ndim
The number of dimensions the memory represents as an n-dimensional array. If it is 0, buf points to a single item representing a scalar. In this case, shape, strides and suboffsets MUST be NULL.

The macro PyBUF_MAX_NDIM limits the maximum number of dimensions to 64. Exporters MUST respect this limit, consumers of multi-dimensional buffers SHOULD be able to handle up to PyBUF_MAX_NDIM dimensions.

Py_ssize_t *shape
An array of Py_ssize_t of length ndim indicating the shape of the memory as an n-dimensional array. Note that \( \text{shape[0]} \times \ldots \times \text{shape[ndim-1]} \times \text{itemsize} \) MUST be equal to
Shape values are restricted to `shape[n] >= 0`. The case `shape[n] == 0` requires special attention. See complex arrays for further information.

The shape array is read-only for the consumer.

**Py_ssize_t** *strides*

An array of `Py_ssize_t` of length `ndim` giving the number of bytes to skip to get to a new element in each dimension.

Stride values can be any integer. For regular arrays, strides are usually positive, but a consumer MUST be able to handle the case `strides[n] <= 0`. See complex arrays for further information.

The strides array is read-only for the consumer.

**Py_ssize_t** *suboffsets*

An array of `Py_ssize_t` of length `ndim`. If `suboffsets[n] >= 0`, the values stored along the nth dimension are pointers and the suboffset value dictates how many bytes to add to each pointer after de-referencing. A suboffset value that is negative indicates that no de-referencing should occur (striding in a contiguous memory block).

If all suboffsets are negative (i.e. no de-referencing is needed, then this field must be NULL (the default value).

This type of array representation is used by the Python Imaging Library (PIL). See complex arrays for further information how to access elements of such an array.
The suboffsets array is read-only for the consumer.

void *internal

This is for use internally by the exporting object. For example, this might be re-cast as an integer by the exporter and used to store flags about whether or not the shape, strides, and suboffsets arrays must be freed when the buffer is released. The consumer MUST NOT alter this value.
Buffer request types

Buffers are usually obtained by sending a buffer request to an exporting object via `PyObject_GetBuffer()`. Since the complexity of the logical structure of the memory can vary drastically, the consumer uses the `flags` argument to specify the exact buffer type it can handle.

All `Py_buffer` fields are unambiguously defined by the request type.

request-independent fields

The following fields are not influenced by `flags` and must always be filled in with the correct values: `obj, buf, len, itemsize, ndim`.

readonly, format

**PyBUF_WRITABLE**
Controls the `readonly` field. If set, the exporter MUST provide a writable buffer or else report failure. Otherwise, the exporter MAY provide either a read-only or writable buffer, but the choice MUST be consistent for all consumers.

**PyBUF_FORMAT**
Controls the `format` field. If set, this field MUST be filled in correctly. Otherwise, this field MUST be `NULL`.

`PyBUF_WRITABLE` can be |'d to any of the flags in the next section. Since `PyBUF_SIMPLE` is defined as 0, `PyBUF_WRITABLE` can be used as a stand-alone flag to request a simple writable buffer.
**PyBUF_FORMAT** can be |'d to any of the flags except **PyBUF_SIMPLE**. The latter already implies format $B$ (unsigned bytes).

**shape, strides, suboffsets**

The flags that control the logical structure of the memory are listed in decreasing order of complexity. Note that each flag contains all bits of the flags below it.

<table>
<thead>
<tr>
<th>Request</th>
<th>shape</th>
<th>strides</th>
<th>suboffsets</th>
</tr>
</thead>
<tbody>
<tr>
<td>PyBUF_INDIRECT</td>
<td>yes</td>
<td>yes</td>
<td>if needed</td>
</tr>
<tr>
<td>PyBUF_STRIDES</td>

<td>yes</td>
<td>NULL</td>
</tr>
<tr>
<td>PyBUF_ND</td>
<td>yes</td>
<td>NULL</td>
<td>NULL</td>
</tr>
<tr>
<td>PyBUF_SIMPLE</td>
<td>NULL</td>
<td>NULL</td>
<td>NULL</td>
</tr>
</tbody>
</table>

**contiguity requests**

C or Fortran contiguity can be explicitly requested, with and without stride information. Without stride information, the buffer must be C-contiguous.

<table>
<thead>
<tr>
<th>Request</th>
<th>shape</th>
<th>strides</th>
<th>suboffsets</th>
<th>contig</th>
</tr>
</thead>
<tbody>
<tr>
<td>PyBUF_C_CONTIGUOUS</td>
<td>yes</td>
<td>yes</td>
<td>NULL</td>
<td>C</td>
</tr>
<tr>
<td>PyBUF_F_CONTIGUOUS</td>
<td>yes</td>
<td>yes</td>
<td>NULL</td>
<td>F</td>
</tr>
<tr>
<td>PyBUF_ANY_CONTIGUOUS</td>
<td>yes</td>
<td>yes</td>
<td>NULL</td>
<td>C</td>
</tr>
</tbody>
</table>
compound requests

All possible requests are fully defined by some combination of the flags in the previous section. For convenience, the buffer protocol provides frequently used combinations as single flags.

In the following table $U$ stands for undefined contiguity. The consumer would have to call `PyBuffer_IsContiguous()` to determine contiguity.

<table>
<thead>
<tr>
<th>Request</th>
<th>shape</th>
<th>strides</th>

</tr>
</tbody>
</table>
Complex arrays

NumPy-style: shape and strides

The logical structure of NumPy-style arrays is defined by `itemsize`, `ndim`, `shape` and `strides`.

If `ndim == 0`, the memory location pointed to by `buf` is interpreted as a scalar of size `itemsize`. In that case, both `shape` and `strides` are `NULL`.

If `strides` is `NULL`, the array is interpreted as a standard n-dimensional C-array. Otherwise, the consumer must access an n-dimensional array as follows:

```
ptr = (char *)buf + indices[0] * strides[0] + ... + indices[n-1] * strides[n-1]
item = *((typeof(item) *)ptr);
```

As noted above, `buf` can point to any location within the actual memory block. An exporter can check the validity of a buffer with this function:

```python
def verify_structure(memlen, itemsize, ndim, shape, buf):
    """Verify that the parameters represent a valid array within the bounds of the allocated memory:
    char *mem: start of the physical memory block
    memlen: length of the physical memory block
    offset: (char *)buf - mem
    ""
    if offset % itemsize:
        return False
    if offset < 0 or offset+itemsize > memlen:
        return False
```
if any(v % itemsize for v in strides):
    return False

if ndim <= 0:
    return ndim == 0 and not shape and not strides
if 0 in shape:
    return True

imin = sum(strides[j]*(shape[j]-1) for j in range(len(strides)) if strides[j] <= 0)
imax = sum(strides[j]*(shape[j]-1) for j in range(len(strides)) if strides[j] > 0)

return 0 <= offset+imin and offset+imax+itemsize

PIL-style: shape, strides and suboffsets

In addition to the regular items, PIL-style arrays can contain pointers that must be followed in order to get to the next element in a dimension. For example, the regular three-dimensional C-array `char v[2][2][3]` can also be viewed as an array of 2 pointers to 2 two-dimensional arrays: `char (*v[2])[2][3]`. In suboffsets representation, those two pointers can be embedded at the start of `buf`, pointing to two `char x[2][3]` arrays that can be located anywhere in memory.

Here is a function that returns a pointer to the element in an N-D array pointed to by an N-dimensional index when there are both non-NULL strides and suboffsets:

```c
void *get_item_pointer(int ndim, void *buf, Py_ssize_t *suboffsets, Py_ssize_t itemsize, Py_ssize_t *shape, Py_ssize_t *strides)
    char *pointer = (char*)buf;
```
int i;

for (i = 0; i < ndim; i++) {
    pointer += strides[i] * indices[i];
    if (suboffsets[i] >= 0) {
        pointer = *((char**)pointer) + suboffsets[i];
    }
}

return (void*)pointer;
Buffer-related functions

```c
int PyObject_CheckBuffer(PyObject *obj)
```

Return 1 if `obj` supports the buffer interface otherwise 0. When 1 is returned, it doesn’t guarantee that `PyObject_GetBuffer()` will succeed.

```c
int PyObject_GetBuffer(PyObject *exporter, Py_buffer *view, int flags)
```

Send a request to `exporter` to fill in `view` as specified by `flags`. If the exporter cannot provide a buffer of the exact type, it MUST raise `PyExc_BufferError`, set `view->obj` to `NULL` and return -1.

On success, fill in `view`, set `view->obj` to a new reference to `exporter` and return 0. In the case of chained buffer providers that redirect requests to a single object, `view->obj` MAY refer to this object instead of `exporter` (See Buffer Object Structures).

Successful calls to `PyObject_GetBuffer()` must be paired with calls to `PyBuffer_Release()`, similar to `malloc()` and `free()`. Thus, after the consumer is done with the buffer, `PyBuffer_Release()` must be called exactly once.

```c
void PyBuffer_Release(Py_buffer *view)
```

Release the buffer `view` and decrement the reference count for `view->obj`. This function MUST be called when the buffer is no longer being used, otherwise reference leaks may occur.

It is an error to call this function on a buffer that was not obtained via `PyObject_GetBuffer()`.
Py_ssize_t PyBuffer_SizeFromFormat(const char *)
   Return the implied itemsize from format. This function is not yet implemented.

int PyBuffer_IsContiguous(Py_buffer *view, char order)
   Return 1 if the memory defined by the view is C-style (order is 'C') or Fortran-style (order is 'F') contiguous or either one (order is 'A'). Return 0 otherwise.

void PyBuffer_FillContiguousStrides(int ndim,
Py_ssize_t *shape, Py_ssize_t *strides, Py_ssize_t itemsize, char order)
   Fill the strides array with byte-strides of a contiguous (C-style if order is 'C' or Fortran-style if order is 'F') array of the given shape with the given number of bytes per element.

int PyBuffer_FillInfo(Py_buffer *view, PyObject *exporter,
void *buf, Py_ssize_t len, int readonly, int flags)
   Handle buffer requests for an exporter that wants to expose buf of size len with writability set according to readonly. buf is interpreted as a sequence of unsigned bytes.

   The flags argument indicates the request type. This function always fills in view as specified by flags, unless buf has been designated as read-only and PyBUF_WRITABLE is set in flags.

   On success, set view->obj to a new reference to exporter and return 0. Otherwise, raise PyExc_BufferError, set view->obj to NULL and return -1;

   If this function is used as part of a getbufferproc, exporter MUST be set to the exporting object and flags must be passed unmodified.
Otherwise, *exporter* MUST be NULL.
Old Buffer Protocol

*Deprecated since version 3.0.*

These functions were part of the “old buffer protocol” API in Python 2. In Python 3, this protocol doesn’t exist anymore but the functions are still exposed to ease porting 2.x code. They act as a compatibility wrapper around the new buffer protocol, but they don’t give you control over the lifetime of the resources acquired when a buffer is exported.

Therefore, it is recommended that you call `PyObject_GetBuffer()` (or the `y` or `w` format codes with the `PyArg_ParseTuple()` family of functions) to get a buffer view over an object, and `PyBuffer_Release()` when the buffer view can be released.

```c
int PyObject_AsCharBuffer(PyObject *obj, const char **buffer, Py_ssize_t *buffer_len)
```

Returns a pointer to a read-only memory location usable as character-based input. The `obj` argument must support the single-segment character buffer interface. On success, returns 0, sets `buffer` to the memory location and `buffer_len` to the buffer length. Returns -1 and sets a `TypeError` on error.

```c
int PyObject_AsReadBuffer(PyObject *obj, const void **buffer, Py_ssize_t *buffer_len)
```

Returns a pointer to a read-only memory location containing arbitrary data. The `obj` argument must support the single-segment readable buffer interface. On success, returns 0, sets `buffer` to the memory location and `buffer_len` to the buffer length. Returns -1 and sets a `TypeError` on error.
int `PyObject_CheckReadBuffer(PyObject *o)`

Returns 1 if `o` supports the single-segment readable buffer interface. Otherwise returns 0.

int `PyObject_AsWriteBuffer(PyObject *obj, void **buffer, Py_ssize_t *buffer_len)`

Returns a pointer to a writable memory location. The `obj` argument must support the single-segment, character buffer interface. On success, returns 0, sets `buffer` to the memory location and `buffer_len` to the buffer length. Returns -1 and sets a `TypeError` on error.
Concrete Objects Layer

The functions in this chapter are specific to certain Python object types. Passing them an object of the wrong type is not a good idea; if you receive an object from a Python program and you are not sure that it has the right type, you must perform a type check first; for example, to check that an object is a dictionary, use \texttt{PyDict\_Check()}. The chapter is structured like the “family tree” of Python object types.

\textbf{Warning:} While the functions described in this chapter carefully check the type of the objects which are passed in, many of them do not check for \texttt{NULL} being passed instead of a valid object. Allowing \texttt{NULL} to be passed in can cause memory access violations and immediate termination of the interpreter.
Fundamental Objects

This section describes Python type objects and the singleton object None.

- Type Objects
- The None Object
Numeric Objects

- Integer Objects

Type Objects

**PyTypeObject**

The C structure of the objects used to describe built-in types.

**PyObject**\* **PyType_Type**

This is the type object for type objects; it is the same object as `type` in the Python layer.

`int PyType_Check(PyObject *o)`

Return true if the object `o` is a type object, including instances of types derived from the standard type object. Return false in all other cases.

`int PyType_CheckExact(PyObject *o)`

Return true if the object `o` is a type object, but not a subtype of the standard type object. Return false in all other cases.

`unsigned int PyType_ClearCache()`

Clear the internal lookup cache. Return the current version tag.

`long PyType_GetFlags(PyTypeObject *type)`

Return the `tp_flags` member of `type`. This function is primarily meant for use with `Py_LIMITED_API`; the individual flag bits are guaranteed to be stable across Python releases, but access to `tp_flags` itself is not part of the limited API.

*New in version 3.2.*

`void PyType_Modified(PyTypeObject *type)`

Invalidate the internal lookup cache for the type and all of its
subtypes. This function must be called after any manual modification of the attributes or base classes of the type.

```c
int PyType_HasFeature(PyTypeObject *o, int feature)
```
Return true if the type object `o` sets the feature `feature`. Type features are denoted by single bit flags.

```c
int PyType_IS_GC(PyTypeObject *o)
```
Return true if the type object includes support for the cycle detector; this tests the type flag `Py_TPFLAGS_HAVE_GC`.

```c
int PyType_IsSubtype(PyTypeObject *a, PyTypeObject *b)
```
Return true if `a` is a subtype of `b`.

This function only checks for actual subtypes, which means that `__subclasscheck__()` is not called on `b`. Call `PyObject_IsSubclass()` to do the same check that `issubclass()` would do.

```c
PyObject* PyType_GenericAlloc(PyTypeObject *type, Py_ssize_t nitems)
```
**Return value: New reference.**
Generic handler for the `tp_alloc` slot of a type object. Use Python’s default memory allocation mechanism to allocate a new instance and initialize all its contents to `NULL`.

```c
PyObject* PyType_GenericNew(PyTypeObject *type, PyObject *args, PyObject *kwds)
```
**Return value: New reference.**
Generic handler for the `tp_new` slot of a type object. Create a new instance using the type’s `tp_alloc` slot.

```c
int PyType_Ready(PyTypeObject *type)
```
Finalize a type object. This should be called on all type objects to finish their initialization. This function is responsible for adding inherited slots from a type's base class. Return 0 on success, or return -1 and sets an exception on error.

PyObject* PyType_FromSpec(PyType_Spec *spec)

Creates and returns a heap type object from the spec passed to the function.

PyObject* PyType_FromSpecWithBases(PyType_Spec *spec, PyObject *bases)

Creates and returns a heap type object from the spec. In addition to that, the created heap type contains all types contained by the bases tuple as base types. This allows the caller to reference other heap types as base types.

*New in version 3.3.*

void* PyType_GetSlot(PyTypeObject *type, int slot)

Return the function pointer stored in the given slot. If the result is NULL, this indicates that either the slot is NULL, or that the function was called with invalid parameters. Callers will typically cast the result pointer into the appropriate function type.

*New in version 3.4.*
The None Object

Note that the PyTypeObject for None is not directly exposed in the Python/C API. Since None is a singleton, testing for object identity (using == in C) is sufficient. There is no PyNone_Check() function for the same reason.

PyObject* Py_None

The Python None object, denoting lack of value. This object has no methods. It needs to be treated just like any other object with respect to reference counts.

Py_RETURN_NONE

Properly handle returning Py_None from within a C function (that is, increment the reference count of None and return it.)
Integer Objects

All integers are implemented as “long” integer objects of arbitrary size.

**PyLongObject**
This subtype of **PyObject** represents a Python integer object.

**PyTypeObject** **PyLong_Type**
This instance of **PyTypeObject** represents the Python integer type. This is the same object as **int** in the Python layer.

int **PyLong_Check**(PyObject *p)
Return true if its argument is a **PyLongObject** or a subtype of **PyLongObject**.

int **PyLong_CheckExact**(PyObject *p)
Return true if its argument is a **PyLongObject**, but not a subtype of **PyLongObject**.

PyObject* **PyLong_FromLong**(long v)
Return a new **PyLongObject** object from v, or **NULL** on failure.

The current implementation keeps an array of integer objects for all integers between -5 and 256, when you create an int in that range you actually just get back a reference to the existing object. So it should be possible to change the value of 1. I suspect the behaviour of Python in this case is undefined. :-)

PyObject* **PyLong_FromUnsignedLong**(unsigned long v)
Return a new `PyLongObject` object from a C unsigned long, or `NULL` on failure.

```c
PyObject* PyLong_FromSsize_t(Py_ssize_t v)
```
Return a new `PyLongObject` object from a C `Py_ssize_t`, or `NULL` on failure.

```c
PyObject* PyLong_FromSize_t(size_t v)
```
Return a new `PyLongObject` object from a C `size_t`, or `NULL` on failure.

```c
PyObject* PyLong_FromLongLong(long long v)
```
*Return value: New reference.*
Return a new `PyLongObject` object from a C `long long`, or `NULL` on failure.

```c
PyObject* PyLong_FromUnsignedLongLong(unsigned long long v)
```
*Return value: New reference.*
Return a new `PyLongObject` object from a C unsigned long long, or `NULL` on failure.

```c
PyObject* PyLong_FromDouble(double v)
```
*Return value: New reference.*
Return a new `PyLongObject` object from the integer part of `v`, or `NULL` on failure.

```c
PyObject* PyLong_FromString(const char *str, char **pend, int base)
```
*Return value: New reference.*
Return a new `PyLongObject` based on the string value in `str`, which is interpreted according to the radix in `base`. If `pend` is non-
"NULL, *pend will point to the first character in str which follows the representation of the number. If base is 0, str is interpreted using the Integer literals definition; in this case, leading zeros in a non-zero decimal number raises a ValueError. If base is not 0, it must be between 2 and 36, inclusive. Leading spaces and single underscores after a base specifier and between digits are ignored. If there are no digits, ValueError will be raised.

PyObject* PyLong_FromUnicode(Py_UNICODE *u, Py_ssize_t length, int base)

Convert a sequence of Unicode digits to a Python integer value. The Unicode string is first encoded to a byte string using PyUnicode_EncodeDecimal() and then converted using PyLong_FromString().

Deprecated since version 3.3, will be removed in version 4.0: Part of the old-style Py_UNICODE API; please migrate to using PyLong_FromUnicodeObject().

PyObject* PyLong_FromUnicodeObject(PyObject *u, int base)

Convert a sequence of Unicode digits in the string u to a Python integer value. The Unicode string is first encoded to a byte string using PyUnicode_EncodeDecimal() and then converted using PyLong_FromString().

New in version 3.3.

PyObject* PyLong_FromVoidPtr(void *p)

Create a Python integer from the pointer p. The pointer value can
be retrieved from the resulting value using PyLong_AsVoidPtr().

long **PyLong_AsLong** *(PyObject *obj)\n*  
Return a C long representation of *obj*. If *obj* is not an instance of PyLongObject, first call its **__int__()** method (if present) to convert it to a PyLongObject.

Raise *OverflowError* if the value of *obj* is out of range for a long.

long **PyLong_AsLongAndOverflow** *(PyObject *obj, int *overflow)\n*  
Return a C long representation of *obj*. If *obj* is not an instance of PyLongObject, first call its **__int__()** method (if present) to convert it to a PyLongObject.

If the value of *obj* is greater than LONG_MAX or less than LONG_MIN, set *overflow* to 1 or -1, respectively, and return -1; otherwise, set *overflow* to 0. If any other exception occurs set *overflow* to 0 and return -1 as usual.

long long **PyLong_AsLongLong** *(PyObject *obj)\n*  
Return a C long long representation of *obj*. If *obj* is not an instance of PyLongObject, first call its **__int__()** method (if present) to convert it to a PyLongObject.

Raise *OverflowError* if the value of *obj* is out of range for a long.

long long **PyLong_AsLongLongAndOverflow** *(PyObject *obj, int *overflow)\n*
Return a C long long representation of obj. If obj is not an instance of `PyLongObject`, first call its `__int__()` method (if present) to convert it to a `PyLongObject`.

If the value of obj is greater than `PY_LLONG_MAX` or less than `PY_LLONG_MIN`, set *overflow to 1 or -1, respectively, and return -1; otherwise, set *overflow to 0. If any other exception occurs set *overflow to 0 and return -1 as usual.

*New in version 3.2.*

**Py_ssize_t** `PyLong_AsSsize_t(PyObject *pylong)`

Return a C Py_ssize_t representation of pylong. pylong must be an instance of `PyLongObject`.

Raise `OverflowError` if the value of pylong is out of range for a Py_ssize_t.

**unsigned long** `PyLong_AsUnsignedLong(PyObject *pylong)`

Return a C unsigned long representation of pylong. pylong must be an instance of `PyLongObject`.

Raise `OverflowError` if the value of pylong is out of range for a unsigned long.

**size_t** `PyLong_AsSize_t(PyObject *pylong)`

Return a C size_t representation of pylong. pylong must be an instance of `PyLongObject`.

Raise `OverflowError` if the value of pylong is out of range for a size_t.

unsigned long long
PyLong_AsUnsignedLongLong (PyObject *pylong)
Return a C unsigned long long representation of pylong. pylong must be an instance of PyLongObject.

Raise OverflowError if the value of pylong is out of range for an unsigned long long.

Changed in version 3.1: A negative pylong now raises OverflowError, not TypeError.

unsigned long PyLong_AsUnsignedLongMask (PyObject *obj)
Return a C unsigned long representation of obj. If obj is not an instance of PyLongObject, first call its __int__() method (if present) to convert it to a PyLongObject.

If the value of obj is out of range for an unsigned long, return the reduction of that value modulo ULONG_MAX + 1.

unsigned long long PyLong_AsUnsignedLongLongMask (PyObject *obj)
Return a C unsigned long long representation of obj. If obj is not an instance of PyLongObject, first call its __int__() method (if present) to convert it to a PyLongObject.

If the value of obj is out of range for an unsigned long long, return the reduction of that value modulo PY_ULLONG_MAX + 1.

double PyLong_AsDouble (PyObject *pylong)
Return a C double representation of pylong. pylong must be an instance of PyLongObject.

Raise OverflowError if the value of pylong is out of range for a
void* PyLong_AsVoidPtr(PyObject *pylong)

Convert a Python integer pylong to a C void pointer. If pylong cannot be converted, an OverflowError will be raised. This is only assured to produce a usable void pointer for values created with PyLong_FromVoidPtr().
Boolean Objects

Booleans in Python are implemented as a subclass of integers. There are only two booleans, Py_False and Py_True. As such, the normal creation and deletion functions don’t apply to booleans. The following macros are available, however.

```c
int PyBool_Check(PyObject *o)
    Return true if o is of type PyBool_Type.

PyObject* Py_False
    The Python False object. This object has no methods. It needs to be treated just like any other object with respect to reference counts.

PyObject* Py_True
    The Python True object. This object has no methods. It needs to be treated just like any other object with respect to reference counts.

Py_RETURN_FALSE
    Return Py_False from a function, properly incrementing its reference count.

Py_RETURN_TRUE
    Return Py_True from a function, properly incrementing its reference count.

PyObject* PyBool_FromLong(long v)
    Return a new reference to Py_TRUE or Py_FALSE depending on
the truth value of \( v \).
Floating Point Objects

**PyFloatObject**
This subtype of `PyObject` represents a Python floating point object.

**PyTypeObject** `PyFloat_Type`
This instance of `PyTypeObject` represents the Python floating point type. This is the same object as `float` in the Python layer.

```
int PyFloat_Check(PyObject *p)
```
Return true if its argument is a `PyFloatObject` or a subtype of `PyFloatObject`.

```
int PyFloat_CheckExact(PyObject *p)
```
Return true if its argument is a `PyFloatObject`, but not a subtype of `PyFloatObject`.

```
PyObject* PyFloat_FromString(PyObject *str)
```
*Return value: New reference.*
Create a `PyFloatObject` object based on the string value in `str`, or `NULL` on failure.

```
PyObject* PyFloat_FromDouble(double v)
```
*Return value: New reference.*
Create a `PyFloatObject` object from `v`, or `NULL` on failure.

```
double PyFloat_AsDouble(PyObject *pyfloat)
```
Return a C double representation of the contents of `pyfloat`. If `pyfloat` is not a Python floating point object but has a `__float__()` method, this method will first be called to convert
`pyfloat` into a float. This method returns `-1.0` upon failure, so one should call `PyErr_Occurred()` to check for errors.

```c
double PyFloat_AS_DOUBLE(PyObject *pyfloat)
```

Return a C double representation of the contents of `pyfloat`, but without error checking.

```c
PyObject* PyFloat_GetInfo(void)
```

Return a `structseq` instance which contains information about the precision, minimum and maximum values of a float. It's a thin wrapper around the header file `float.h`.

```c
double PyFloat_GetMax()
```

Return the maximum representable finite float `DBL_MAX` as C double.

```c
double PyFloat_GetMin()
```

Return the minimum normalized positive float `DBL_MIN` as C double.

```c
int PyFloat_ClearFreeList()
```

Clear the float free list. Return the number of items that could not be freed.
Complex Number Objects

Python’s complex number objects are implemented as two distinct types when viewed from the C API: one is the Python object exposed to Python programs, and the other is a C structure which represents the actual complex number value. The API provides functions for working with both.
Complex Numbers as C Structures

Note that the functions which accept these structures as parameters and return them as results do so by value rather than dereferencing them through pointers. This is consistent throughout the API.

**Py_complex**

The C structure which corresponds to the value portion of a Python complex number object. Most of the functions for dealing with complex number objects use structures of this type as input or output values, as appropriate. It is defined as:

```c
typedef struct {
    double real;
    double imag;
} Py_complex;
```

**Py_complex **__Py_c_sum**(Py_complex left, Py_complex right)**

Return the sum of two complex numbers, using the C Py_complex representation.

**Py_complex **__Py_c_diff**(Py_complex left, Py_complex right)**

Return the difference between two complex numbers, using the C Py_complex representation.

**Py_complex **__Py_c_neg**(Py_complex complex)**

Return the negation of the complex number complex, using the C Py_complex representation.

**Py_complex **__Py_c_prod**(Py_complex left, Py_complex right)**

Return the product of two complex numbers, using the C Py_complex representation.
Py_complex _Py_c_quot(Py_complex dividend, Py_complex divisor)
    Return the quotient of two complex numbers, using the C Py_complex representation.

    If divisor is null, this method returns zero and sets errno to EDOM.

Py_complex _Py_c_pow(Py_complex num, Py_complex exp)
    Return the exponentiation of num by exp, using the C Py_complex representation.

    If num is null and exp is not a positive real number, this method returns zero and sets errno to EDOM.
Complex Numbers as Python Objects

**PyComplexObject**
This subtype of *PyObject* represents a Python complex number object.

**PyTypeObject** *PyComplex_Type*
This instance of *PyTypeObject* represents the Python complex number type. It is the same object as *complex* in the Python layer.

**int PyComplex_Check(PyObject *p)**
Return true if its argument is a *PyComplexObject* or a subtype of *PyComplexObject*.

**int PyComplex_CheckExact(PyObject *p)**
Return true if its argument is a *PyComplexObject*, but not a subtype of *PyComplexObject*.

**PyObject* PyComplex_FromCComplex(Py_complex v)**
*Return value: New reference.*
Create a new Python complex number object from a C *Py_complex* value.

**PyObject* PyComplex_FromDoubles(double real, double imag)**
*Return value: New reference.*
Return a new *PyComplexObject* object from *real* and *imag*.

**double PyComplex_RealAsDouble(PyObject *op)**
Return the real part of *op* as a C double.

**double PyComplex_ImagAsDouble(PyObject *op)**
Return the imaginary part of \( op \) as a C double.

\texttt{Py_complex PyComplex_AsCComplex(PyObject *op)}

Return the \texttt{Py_complex} value of the complex number \( op \).

If \( op \) is not a Python complex number object but has a \texttt{__complex__()} method, this method will first be called to convert \( op \) to a Python complex number object. Upon failure, this method returns \(-1.0\) as a real value.
Bytes Objects

These functions raise \texttt{TypeError} when expecting a bytes parameter and are called with a non-bytes parameter.

\textbf{PyBytesObject}

This subtype of \texttt{PyObject} represents a Python bytes object.

\textbf{PyTypeObject} \texttt{PyBytes\_Type}

This instance of \texttt{PyTypeObject} represents the Python bytes type; it is the same object as \texttt{bytes} in the Python layer.

\textbf{int} \texttt{PyBytes\_Check} (\texttt{PyObject} *\textit{o})

Return true if the object \textit{o} is a bytes object or an instance of a subtype of the bytes type.

\textbf{int} \texttt{PyBytes\_CheckExact} (\texttt{PyObject} *\textit{o})

Return true if the object \textit{o} is a bytes object, but not an instance of a subtype of the bytes type.

\textbf{PyObject\*} \texttt{PyBytes\_FromString} (\texttt{const char} *\textit{v})

Return a new bytes object with a copy of the string \textit{v} as value on success, and \texttt{NULL} on failure. The parameter \textit{v} must not be \texttt{NULL}; it will not be checked.

\textbf{PyObject\*} \texttt{PyBytes\_FromStringAndSize} (\texttt{const char} *\textit{v}, \texttt{Py\_ssize\_t} \textit{len})

Return a new bytes object with a copy of the string \textit{v} as value and length \textit{len} on success, and \texttt{NULL} on failure. If \textit{v} is \texttt{NULL}, the contents of the bytes object are uninitialized.
```c
PyObject* PyBytes_FromFormat(const char *format, ...)  
Take a C printf()-style `format` string and a variable number of arguments, calculate the size of the resulting Python bytes object and return a bytes object with the values formatted into it. The variable arguments must be C types and must correspond exactly to the format characters in the `format` string. The following format characters are allowed:

<table>
<thead>
<tr>
<th>Format Characters</th>
<th>Type</th>
<th>Comment</th>
</tr>
</thead>
<tbody>
<tr>
<td>%**</td>
<td>n/a</td>
<td>The literal % character.</td>
</tr>
<tr>
<td>%c</td>
<td>int</td>
<td>A single byte, represented as a C int.</td>
</tr>
<tr>
<td>%d</td>
<td>int</td>
<td>Exactly equivalent to printf(&quot;%d&quot;).</td>
</tr>
<tr>
<td>%u</td>
<td>unsigned int</td>
<td>Exactly equivalent to printf(&quot;%u&quot;).</td>
</tr>
<tr>
<td>%ld</td>
<td>long</td>
<td>Exactly equivalent to printf(&quot;%ld&quot;).</td>
</tr>
<tr>
<td>%lu</td>
<td>unsigned long</td>
<td>Exactly equivalent to printf(&quot;%lu&quot;).</td>
</tr>
<tr>
<td>%zd</td>
<td>Py_ssize_t</td>
<td>Exactly equivalent to printf(&quot;%zd&quot;).</td>
</tr>
<tr>
<td>%zu</td>
<td>size_t</td>
<td>Exactly equivalent to printf(&quot;%zu&quot;).</td>
</tr>
<tr>
<td>%i</td>
<td>int</td>
<td>Exactly equivalent to printf(&quot;%i&quot;).</td>
</tr>
<tr>
<td>%x</td>
<td>int</td>
<td>Exactly equivalent to printf(&quot;%x&quot;).</td>
</tr>
<tr>
<td>%s</td>
<td>char*</td>
<td>A null-terminated C character</td>
</tr>
</tbody>
</table>
```
array.

| %p      | void*       | The hex representation of a C pointer. Mostly equivalent to `printf("%p")` except that it is guaranteed to start with the literal 0x regardless of what the platform's `printf` yields. |

An unrecognized format character causes all the rest of the format string to be copied as-is to the result object, and any extra arguments discarded.

**PyObject** `PyBytes_FromFormatV` (const char *format, va_list vargs)

Identical to `PyBytes_FromFormat()` except that it takes exactly two arguments.

**PyObject** `PyBytes_FromObject` (PyObject *o)

Return the bytes representation of object o that implements the buffer protocol.

**Py_ssize_t** `PyBytes_Size` (PyObject *o)

Return the length of the bytes in bytes object o.

**Py_ssize_t** `PyBytes_GET_SIZE` (PyObject *o)

Macro form of `PyBytes_Size()` but without error checking.

**char** `PyBytes_AsString` (PyObject *o)

Return a pointer to the contents of o. The pointer refers to the internal buffer of o, which consists of len(o) + 1 bytes. The last byte in the buffer is always null, regardless of whether there are any other null bytes. The data must not be modified in any way,
unless the object was just created using PyBytes_FromStringAndSize(NULL, size). It must not be deallocated. If o is not a bytes object at all, PyBytes_AsString() returns NULL and raises TypeError.

char* **PyBytes_AS_STRING(PyObject *string)
Macro form of PyBytes_AsString() but without error checking.

int PyBytes_AsStringAndSize(PyObject *obj, char **buffer, Py_ssize_t *length)
Return the null-terminated contents of the object obj through the output variables buffer and length.

If length is NULL, the bytes object may not contain embedded null bytes; if it does, the function returns -1 and a ValueError is raised.

The buffer refers to an internal buffer of obj, which includes an additional null byte at the end (not counted in length). The data must not be modified in any way, unless the object was just created using PyBytes_FromStringAndSize(NULL, size). It must not be deallocated. If obj is not a bytes object at all, PyBytes_AsStringAndSize() returns -1 and raises TypeError.

Changed in version 3.5: Previously, TypeError was raised when embedded null bytes were encountered in the bytes object.

void **PyBytes_Concat(PyObject **bytes, PyObject *newpart)
Create a new bytes object in *bytes containing the contents of newpart appended to bytes; the caller will own the new reference. The reference to the old value of bytes will be stolen. If the new
object cannot be created, the old reference to bytes will still be discarded and the value of *bytes will be set to NULL; the appropriate exception will be set.

```c
void PyBytes_ConcatAndDel(PyObject **bytes, PyObject *newpart)

Create a new bytes object in *bytes containing the contents of newpart appended to bytes. This version decrements the reference count of newpart.
```

```c
int _PyBytes_Resize(PyObject **bytes, Py_ssize_t newsize)

A way to resize a bytes object even though it is “immutable”. Only use this to build up a brand new bytes object; don’t use this if the bytes may already be known in other parts of the code. It is an error to call this function if the refcount on the input bytes object is not one. Pass the address of an existing bytes object as an lvalue (it may be written into), and the new size desired. On success, *bytes holds the resized bytes object and 0 is returned; the address in *bytes may differ from its input value. If the reallocation fails, the original bytes object at *bytes is deallocated, *bytes is set to NULL, MemoryError is set, and -1 is returned.
```
Byte Array Objects

**PyByteArrayObject**
This subtype of `PyObject` represents a Python bytearray object.

**PyTypeObject `PyByteArray_Type`**
This instance of `PyTypeObject` represents the Python bytearray type; it is the same object as `bytearray` in the Python layer.
Type check macros

int **PyByteArray_Check**(*PyObject *o*)

Return true if the object o is a bytearray object or an instance of a subtype of the bytearray type.

int **PyByteArray_CheckExact**(*PyObject *o*)

Return true if the object o is a bytearray object, but not an instance of a subtype of the bytearray type.
Direct API functions

PyObject* **PyByteArray_FromObject**(PyObject *o)

    Return a new bytearray object from any object, o, that implements the buffer protocol.

PyObject* **PyByteArray_FromStringAndSize**(const char *string, Py_ssize_t len)

    Create a new bytearray object from string and its length, len. On failure, NULL is returned.

PyObject* **PyByteArray_Concat**(PyObject *a, PyObject *b)

    Concat bytearrays a and b and return a new bytearray with the result.

Py_ssize_t **PyByteArray_Size**(PyObject *bytearray)

    Return the size of bytearray after checking for a NULL pointer.

cchar* **PyByteArray_AsString**(PyObject *bytearray)

    Return the contents of bytearray as a char array after checking for a NULL pointer. The returned array always has an extra null byte appended.

int **PyByteArray_Resize**(PyObject *bytearray, Py_ssize_t len)

    Resize the internal buffer of bytearray to len.
Macros

These macros trade safety for speed and they don’t check pointers.

```c
char* PyByteArray_AS_STRING(PyObject *bytearray)
Macro version of PyByteArray_AsString().
```

```c
Py_ssize_t PyByteArray_GET_SIZE(PyObject *bytearray)
Macro version of PyByteArray_Size().
```
Unicode Objects and Codecs
Unicode Objects

Since the implementation of PEP 393 in Python 3.3, Unicode objects internally use a variety of representations, in order to allow handling the complete range of Unicode characters while staying memory efficient. There are special cases for strings where all code points are below 128, 256, or 65536; otherwise, code points must be below 1114112 (which is the full Unicode range).

Py_UNICODE* and UTF-8 representations are created on demand and cached in the Unicode object. The Py_UNICODE* representation is deprecated and inefficient; it should be avoided in performance- or memory-sensitive situations.

Due to the transition between the old APIs and the new APIs, unicode objects can internally be in two states depending on how they were created:

- “canonical” unicode objects are all objects created by a non-deprecated unicode API. They use the most efficient representation allowed by the implementation.
- “legacy” unicode objects have been created through one of the deprecated APIs (typically PyUnicode_FromUnicode()) and only bear the Py_UNICODE* representation; you will have to call PyUnicode_READY() on them before calling any other API.

Unicode Type

These are the basic Unicode object types used for the Unicode implementation in Python:

Py_UCS4
**Py_UCS2**
**Py_UCS1**

These types are typedefs for unsigned integer types wide enough to contain characters of 32 bits, 16 bits and 8 bits, respectively. When dealing with single Unicode characters, use **Py_UCS4**.

*New in version 3.3.*

**Py_UNICODE**

This is a typedef of wchar_t, which is a 16-bit type or 32-bit type depending on the platform.

*Changed in version 3.3:* In previous versions, this was a 16-bit type or a 32-bit type depending on whether you selected a “narrow” or “wide” Unicode version of Python at build time.

**PyASCIIObject**
**PyCompactUnicodeObject**
**PyUnicodeObject**

These subtypes of **PyObject** represent a Python Unicode object. In almost all cases, they shouldn’t be used directly, since all API functions that deal with Unicode objects take and return **PyObject** pointers.

*New in version 3.3.*

**PyTypeObject** **PyUnicode_Type**

This instance of **PyTypeObject** represents the Python Unicode type. It is exposed to Python code as **str**.

The following APIs are really C macros and can be used to do fast checks and to access internal read-only data of Unicode objects:
int PyUnicode_Check(PyObject *o)
Return true if the object o is a Unicode object or an instance of a Unicode subtype.

int PyUnicode_CheckExact(PyObject *o)
Return true if the object o is a Unicode object, but not an instance of a subtype.

int PyUnicode_READY(PyObject *o)
Ensure the string object o is in the “canonical” representation. This is required before using any of the access macros described below.

Returns 0 on success and -1 with an exception set on failure, which in particular happens if memory allocation fails.

New in version 3.3.

Py_ssize_t PyUnicode_GET_LENGTH(PyObject *o)
Return the length of the Unicode string, in code points. o has to be a Unicode object in the “canonical” representation (not checked).

New in version 3.3.

Py_UCS1* PyUnicode_1BYTE_DATA(PyObject *o)
Py_UCS2* PyUnicode_2BYTE_DATA(PyObject *o)
Py_UCS4* PyUnicode_4BYTE_DATA(PyObject *o)
Return a pointer to the canonical representation cast to UCS1, UCS2 or UCS4 integer types for direct character access. No checks are performed if the canonical representation has the correct character size; use PyUnicode_KIND() to select the right macro. Make sure PyUnicode_READY() has been called before accessing this.
New in version 3.3.

PyUnicode_WCHAR_KIND
PyUnicode_1BYTE_KIND
PyUnicode_2BYTE_KIND
PyUnicode_4BYTE_KIND

Return values of the PyUnicode_KIND() macro.

New in version 3.3.

int PyUnicode_KIND(PyObject *o)

Return one of the PyUnicode kind constants (see above) that indicate how many bytes per character this Unicode object uses to store its data. o has to be a Unicode object in the “canonical” representation (not checked).

New in version 3.3.

void* PyUnicode_DATA(PyObject *o)

Return a void pointer to the raw unicode buffer. o has to be a Unicode object in the “canonical” representation (not checked).

New in version 3.3.

void PyUnicode_WRITE(int kind, void *data, Py_ssize_t index, Py_UCS4 value)

Write into a canonical representation data (as obtained with PyUnicode_DATA()). This macro does not do any sanity checks and is intended for usage in loops. The caller should cache the kind value and data pointer as obtained from other macro calls. index is the index in the string (starts at 0) and value is the new code point value which should be written to that location.
New in version 3.3.

**Py_UCS4 PyUnicode_READ(int kind, void *data, Py_ssize_t index)**

Read a code point from a canonical representation *data* (as obtained with `PyUnicode_DATA()`). No checks or ready calls are performed.

New in version 3.3.

**Py_UCS4 PyUnicode_READ_CHAR(PyObject *o, Py_ssize_t index)**

Read a character from a Unicode object *o*, which must be in the “canonical” representation. This is less efficient than `PyUnicode_READ()` if you do multiple consecutive reads.

New in version 3.3.

**PyUnicode_MAX_CHAR_VALUE(PyObject *o)**

Return the maximum code point that is suitable for creating another string based on *o*, which must be in the “canonical” representation. This is always an approximation but more efficient than iterating over the string.

New in version 3.3.

**int PyUnicode_ClearFreeList()**

Clear the free list. Return the total number of freed items.

**Py_ssize_t PyUnicode_GET_SIZE(PyObject *o)**

Return the size of the deprecated `Py_UNICODE` representation, in code units (this includes surrogate pairs as 2 units). *o* has to be a Unicode object (not checked).
Deprecated since version 3.3, will be removed in version 4.0: Part of the old-style Unicode API, please migrate to using PyUnicode_GET_LENGTH().

Py_ssize_t PyUnicode_GET_DATA_SIZE(PyObject *o)
Return the size of the deprecated Py_UNICODE representation in bytes. o has to be a Unicode object (not checked).

Deprecated since version 3.3, will be removed in version 4.0: Part of the old-style Unicode API, please migrate to using PyUnicode_GET_LENGTH().

Py_UNICODE* PyUnicode_AS_UNICODE(PyObject *o)
const char* PyUnicode_AS_DATA(PyObject *o)
Return a pointer to a Py_UNICODE representation of the object. The returned buffer is always terminated with an extra null code point. It may also contain embedded null code points, which would cause the string to be truncated when used in most C functions. The AS_DATA form casts the pointer to const char *. The o argument has to be a Unicode object (not checked).

Changed in version 3.3: This macro is now inefficient – because in many cases the Py_UNICODE representation does not exist and needs to be created – and can fail (return NULL with an exception set). Try to port the code to use the new PyUnicode_nBYTE_DATA() macros or use PyUnicode_WRITE() or PyUnicode_READ().

Deprecated since version 3.3, will be removed in version 4.0: Part of the old-style Unicode API, please migrate to using the PyUnicode_nBYTE_DATA() family of macros.
Unicode Character Properties

Unicode provides many different character properties. The most often needed ones are available through these macros which are mapped to C functions depending on the Python configuration.

```c
int Py_UNICODE_ISSPACE(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a whitespace character.
```

```c
int Py_UNICODE_ISLOWER(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a lowercase character.
```

```c
int Py_UNICODE_ISUPPER(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is an uppercase character.
```

```c
int Py_UNICODE_ISTITLE(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a titlecase character.
```

```c
int Py_UNICODE_ISLINEBREAK(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a linebreak character.
```

```c
int Py_UNICODE_ISDECIMAL(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a decimal character.
```

```c
int Py_UNICODE_ISDIGIT(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a digit character.
```

```c
int Py_UNICODE_ISNUMERIC(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is a numeric character.
```

```c
int Py_UNICODE_ISALPHA(Py_UNICODE ch)
    Return 1 or 0 depending on whether ch is an alphabetic character.
```
int Py_UNICODE_ISALNUM(Py_UNICODE ch)
Return 1 or 0 depending on whether ch is an alphanumeric character.

int Py_UNICODE_ISPRINTABLE(Py_UNICODE ch)
Return 1 or 0 depending on whether ch is a printable character. Nonprintable characters are those characters defined in the Unicode character database as “Other” or “Separator”, excepting the ASCII space (0x20) which is considered printable. (Note that printable characters in this context are those which should not be escaped when repr() is invoked on a string. It has no bearing on the handling of strings written to sys.stdout or sys.stderr.)

These APIs can be used for fast direct character conversions:

Py_UNICODE Py_UNICODE_TOLOWER(Py_UNICODE ch)
Return the character ch converted to lower case.

Deprecate since version 3.3: This function uses simple case mappings.

Py_UNICODE Py_UNICODE_TOUPPER(Py_UNICODE ch)
Return the character ch converted to upper case.

Deprecate since version 3.3: This function uses simple case mappings.

Py_UNICODE Py_UNICODE_TOTITLE(Py_UNICODE ch)
Return the character ch converted to title case.

Deprecate since version 3.3: This function uses simple case mappings.
int \textbf{Py\_UNICODE\_TODECIMAL}(Py\_UNICODE \textit{ch})

Return the character \textit{ch} converted to a decimal positive integer. Return -1 if this is not possible. This macro does not raise exceptions.

int \textbf{Py\_UNICODE\_TODIGIT}(Py\_UNICODE \textit{ch})

Return the character \textit{ch} converted to a single digit integer. Return -1 if this is not possible. This macro does not raise exceptions.

double \textbf{Py\_UNICODE\_TONUMERIC}(Py\_UNICODE \textit{ch})

Return the character \textit{ch} converted to a double. Return -1.0 if this is not possible. This macro does not raise exceptions.

These APIs can be used to work with surrogates:

\textbf{Py\_UNICODE\_IS\_SURROGATE}(\textit{ch})

Check if \textit{ch} is a surrogate (0xD800 \leq \textit{ch} \leq 0xDFFF).

\textbf{Py\_UNICODE\_IS\_HIGH\_SURROGATE}(\textit{ch})

Check if \textit{ch} is a high surrogate (0xD800 \leq \textit{ch} \leq 0xDBFF).

\textbf{Py\_UNICODE\_IS\_LOW\_SURROGATE}(\textit{ch})

Check if \textit{ch} is a low surrogate (0xDC00 \leq \textit{ch} \leq 0xDFFF).

\textbf{Py\_UNICODE\_JOIN\_SURROGATES}(\textit{high}, \textit{low})

Join two surrogate characters and return a single Py\_UCS4 value. \textit{high} and \textit{low} are respectively the leading and trailing surrogates in a surrogate pair.

Creating and accessing Unicode strings

To create Unicode objects and access their basic sequence properties,
use these APIs:

**PyObject* PyUnicode_New**(Py_ssize_t size, Py_UCS4 maxchar)

Create a new Unicode object. `maxchar` should be the true maximum code point to be placed in the string. As an approximation, it can be rounded up to the nearest value in the sequence 127, 255, 65535, 1114111.

This is the recommended way to allocate a new Unicode object. Objects created using this function are not resizable.

*New in version 3.3.*

**PyObject* PyUnicode_FromKindAndData**(int kind, const void *buffer, Py_ssize_t size)

Create a new Unicode object with the given `kind` (possible values are `PyUnicode_1BYTE_KIND` etc., as returned by `PyUnicode_KIND()`). The `buffer` must point to an array of `size` units of 1, 2 or 4 bytes per character, as given by the kind.

*New in version 3.3.*

**PyObject* PyUnicode_FromStringAndSize**(const char *u, Py_ssize_t size)

Create a Unicode object from the char buffer `u`. The bytes will be interpreted as being UTF-8 encoded. The buffer is copied into the new object. If the buffer is not `NULL`, the return value might be a shared object, i.e. modification of the data is not allowed.

If `u` is `NULL`, this function behaves like `PyUnicode_FromUnicode()` with the buffer set to `NULL`. This usage is deprecated in favor of `PyUnicode_New()`.
PyObject *PyUnicode_FromString(const char *u)
Create a Unicode object from a UTF-8 encoded null-terminated char buffer u.

PyObject* PyUnicode_FromFormat(const char *format, ...)
Take a C printf()-style format string and a variable number of arguments, calculate the size of the resulting Python unicode string and return a string with the values formatted into it. The variable arguments must be C types and must correspond exactly to the format characters in the format ASCII-encoded string. The following format characters are allowed:

<table>
<thead>
<tr>
<th>Format Characters</th>
<th>Type</th>
<th>Comment</th>
</tr>
</thead>
<tbody>
<tr>
<td>%</td>
<td>n/a</td>
<td>The literal % character.</td>
</tr>
<tr>
<td>%c</td>
<td>int</td>
<td>A single character, represented as a C int.</td>
</tr>
<tr>
<td>%d</td>
<td>int</td>
<td>Exactly equivalent to printf(&quot;%d&quot;).</td>
</tr>
<tr>
<td>%u</td>
<td>unsigned int</td>
<td>Exactly equivalent to printf(&quot;%u&quot;).</td>
</tr>
<tr>
<td>%ld</td>
<td>long</td>
<td>Exactly equivalent to printf(&quot;%ld&quot;).</td>
</tr>
<tr>
<td>%li</td>
<td>long</td>
<td>Exactly equivalent to printf(&quot;%li&quot;).</td>
</tr>
<tr>
<td>%lu</td>
<td>unsigned long</td>
<td>Exactly equivalent to printf(&quot;%lu&quot;).</td>
</tr>
<tr>
<td>%lld</td>
<td>long long</td>
<td>Exactly equivalent to printf(&quot;%lld&quot;).</td>

<td>Exactly equivalent to printf(&quot;%x&quot;).</td>
</tr>
<tr>
<td>%s</td>
<td>char*</td>
<td>A null-terminated C character array.</td>
</tr>
<tr>
<td>%p</td>
<td>void*</td>
<td>The hex representation of a C pointer. Mostly equivalent to printf(&quot;%p&quot;) except that it is guaranteed to start with the literal 0x regardless of what the platform’s printf yields.</td>
</tr>
<tr>
<td>%A</td>
<td>PyObject*</td>
<td>The result of calling ascii().</td>
</tr>
<tr>
<td>%U</td>
<td>PyObject*</td>
<td>A unicode object.</td>
</tr>
<tr>
<td>%V</td>
<td>PyObject*, char*</td>
<td>A unicode object (which may be NULL) and a null-terminated C character array as a second parameter (which will be used, if the first parameter is NULL).</td>
</tr>
<tr>
<td>Format</td>
<td>Type</td>
<td>Description</td>
</tr>
<tr>
<td>--------</td>
<td>--------------</td>
<td>---------------------------------------</td>
</tr>
<tr>
<td>%S</td>
<td>PyObject*</td>
<td>The result of calling <code>PyObject_Str()</code></td>
</tr>
<tr>
<td>%R</td>
<td>PyObject*</td>
<td>The result of calling <code>PyObject_Repr()</code></td>
</tr>
</tbody>
</table>

An unrecognized format character causes all the rest of the format string to be copied as-is to the result string, and any extra arguments discarded.

**Note:** The width formatter unit is number of characters rather than bytes. The precision formatter unit is number of bytes for "%s" and "%V" (if the PyObject* argument is NULL), and a number of characters for "%A", "%U", "%S", "%R" and "%V" (if the PyObject* argument is not NULL).

*Changed in version 3.2:* Support for "%lld" and "%llu" added.

*Changed in version 3.3:* Support for "%li", "%lli" and "%zi" added.

*Changed in version 3.4:* Support width and precision formatter for "%s", "%A", "%U", "%V", "%S", "%R" added.

**PyObject** `PyUnicode_FromFormatV` (const char *format, va_list vargs)

Identical to `PyUnicode_FromFormat()` except that it takes exactly two arguments.

**PyObject** `PyUnicode_FromEncodedObject` (PyObject *obj, const char *encoding, const char *errors)

*Return value: New reference.*

Decode an encoded object `obj` to a Unicode object.
bytes, bytearray and other bytes-like objects are decoded according to the given encoding and using the error handling defined by errors. Both can be NULL to have the interface use the default values (see Built-in Codecs for details).

All other objects, including Unicode objects, cause a TypeError to be set.

The API returns NULL if there was an error. The caller is responsible for decref'ing the returned objects.

Py_ssize_t PyUnicode_GetLength(PyObject *unicode)
Return the length of the Unicode object, in code points.

New in version 3.3.

Py_ssize_t PyUnicode_CopyCharacters(PyObject *to, Py_ssize_t to_start, PyObject *from, Py_ssize_t from_start, Py_ssize_t how_many)
Copy characters from one Unicode object into another. This function performs character conversion when necessary and falls back to memcpy() if possible. Returns -1 and sets an exception on error, otherwise returns the number of copied characters.

New in version 3.3.

Py_ssize_t PyUnicode_Fill(PyObject *unicode, Py_ssize_t start, Py_ssize_t length, Py_UCS4 fill_char)
Fill a string with a character: write fill_char into unicode[start:start+length].

Fail if fill_char is bigger than the string maximum character, or if the string has more than 1 reference.
Return the number of written character, or return -1 and raise an exception on error.

*New in version 3.3.*

```c
int PyUnicode_WriteChar(PyObject *unicode,
                        Py_ssize_t index, Py_UCS4 character)
    Write a character to a string. The string must have been created through
    `PyUnicode_New()`. Since Unicode strings are supposed to be immutable, the
    string must not be shared, or have been hashed yet.

    This function checks that `unicode` is a Unicode object, that the
    index is not out of bounds, and that the object can be modified safely (i.e.
    that it its reference count is one).

    *New in version 3.3.*

Py_UCS4 PyUnicode_ReadChar(PyObject *unicode,
                           Py_ssize_t index)
    Read a character from a string. This function checks that `unicode`
    is a Unicode object and the index is not out of bounds, in contrast
    to the macro version `PyUnicode_READ_CHAR()`.

    *New in version 3.3.*

PyObject* PyUnicode_Substring(PyObject *str,
                             Py_ssize_t start, Py_ssize_t end)
    Return a substring of `str`, from character index `start` (included) to
    character index `end` (excluded). Negative indices are not supported.

    *New in version 3.3.*
**Py_UCS4** * PyUnicode_AsUCS4(*PyObject* *u, Py_UCS4 *buffer, Py_ssize_t buflen, int copy_null)

Copy the string *u* into a UCS4 buffer, including a null character, if *copy_null* is set. Returns *NULL* and sets an exception on error (in particular, a *SystemError* if *buflen* is smaller than the length of *u*). *buffer* is returned on success.

New in version 3.3.

**Py_UCS4** * PyUnicode_AsUCS4Copy(*PyObject* *u)

Copy the string *u* into a new UCS4 buffer that is allocated using *PyMem_Malloc()* . If this fails, *NULL* is returned with a *MemoryError* set. The returned buffer always has an extra null code point appended.

New in version 3.3.

**Deprecated Py_UNICODE APIs**

*Deprecated since version 3.3, will be removed in version 4.0.*

These API functions are deprecated with the implementation of PEP 393. Extension modules can continue using them, as they will not be removed in Python 3.x, but need to be aware that their use can now cause performance and memory hits.

**PyObject** * PyUnicode_FromUnicode(const Py_UNICODE *u, Py_ssize_t size)

*Return value: New reference.*

Create a Unicode object from the Py_UNICODE buffer *u* of the given size. *u* may be *NULL* which causes the contents to be undefined. It is the user’s responsibility to fill in the needed data.
The buffer is copied into the new object.

If the buffer is not NULL, the return value might be a shared object. Therefore, modification of the resulting Unicode object is only allowed when u is NULL.

If the buffer is NULL, PyUnicode_READY() must be called once the string content has been filled before using any of the access macros such as PyUnicode_KIND().

Please migrate to using PyUnicode_FromKindAndData(), PyUnicode_FromWideChar() or PyUnicode_New().

\textbf{Py_UNICODE* PyUnicode\_AsUnicode}(PyObject *unicode)

Return a read-only pointer to the Unicode object's internal Py_UNICODE buffer, or NULL on error. This will create the Py_UNICODE* representation of the object if it is not yet available. The buffer is always terminated with an extra null code point. Note that the resulting Py_UNICODE string may also contain embedded null code points, which would cause the string to be truncated when used in most C functions.

Please migrate to using PyUnicode\_AsUCS4(), PyUnicode\_AsWideChar(), PyUnicode\_ReadChar() or similar new APIs.

\textbf{PyObject*}

\textbf{PyUnicode\_TransformDecimalToASCII}(Py_UNICODE *s, Py\_ssize_t size)

Create a Unicode object by replacing all decimal digits in Py_UNICODE buffer of the given size by ASCII digits 0–9 according to their decimal value. Return NULL if an exception occurs.
Py_UNICODE*

PyUnicode_AsUnicodeAndSize(PyObject *unicode, Py_ssize_t *size)
Like PyUnicode_AsUnicode(), but also saves the Py_UNICODE() array length (excluding the extra null terminator) in size. Note that the resulting Py_UNICODE* string may contain embedded null code points, which would cause the string to be truncated when used in most C functions.

New in version 3.3.

Py_UNICODE*

PyUnicode_AsUnicodeCopy(PyObject *unicode)
Create a copy of a Unicode string ending with a null code point. Return NULL and raise a MemoryError exception on memory allocation failure, otherwise return a new allocated buffer (use PyMem_Free() to free the buffer). Note that the resulting Py_UNICODE* string may contain embedded null code points, which would cause the string to be truncated when used in most C functions.

New in version 3.2.

Please migrate to using PyUnicode_AsUCS4Copy() or similar new APIs.

Py_ssize_t PyUnicode_GetSize(PyObject *unicode)
Return the size of the deprecated Py_UNICODE representation, in code units (this includes surrogate pairs as 2 units).

Please migrate to using PyUnicode_GetLength().

PyObject* PyUnicode_FromObject(PyObject *obj)
Copy an instance of a Unicode subtype to a new true Unicode object if necessary. If obj is already a true Unicode object (not a subtype), return the reference with incremented refcount.

Objects other than Unicode or its subtypes will cause a TypeError.

Locale Encoding

The current locale encoding can be used to decode text from the operating system.

PyObject* PyUnicode_DecodeLocaleAndSize(const char *str, Py_ssize_t len, const char *errors)

Decode a string from the current locale encoding. The supported error handlers are "strict" and "surrogatescape" (PEP 383). The decoder uses "strict" error handler if errors is NULL. str must end with a null character but cannot contain embedded null characters.

Use PyUnicode_DecodeFSDefaultAndSize() to decode a string from Py_FileSystemDefaultEncoding (the locale encoding read at Python startup).

See also: The Py_DecodeLocale() function.

New in version 3.3.

PyObject* PyUnicode_DecodeLocale(const char *str, const char *errors)

Similar to PyUnicode_DecodeLocaleAndSize(), but compute
the string length using strlen().

*New in version 3.3.*

**PyObject**\* **PyUnicode_EncodeLocale**(**PyObject \*unicode, const char \*errors**)

Encode a Unicode object to the current locale encoding. The supported error handlers are "strict" and "surrogateescape" (PEP 383). The encoder uses "strict" error handler if errors is NULL. Return a bytes object. unicode cannot contain embedded null characters.

Use **PyUnicode_EncodeFSDefault()** to encode a string to Py_FileSystemDefaultEncoding (the locale encoding read at Python startup).

**See also:** The **Py_EncodeLocale()** function.

*New in version 3.3.*

**File System Encoding**

To encode and decode file names and other environment strings, Py_FileSystemDefaultEncoding should be used as the encoding, and Py_FileSystemDefaultEncodeErrors should be used as the error handler (PEP 383 and PEP 529). To encode file names to bytes during argument parsing, the "O&" converter should be used, passing **PyUnicode_FSConverter()** as the conversion function:

```c
int PyUnicode_FSConverter(PyObject* obj, void* result)
```

ParseTuple converter: encode str objects – obtained directly or
through the `os.PathLike` interface – to `bytes` using `PyUnicode_EncodeFSDefault()`. `bytes` objects are output as-is. `result` must be a `PyBytesObject*` which must be released when it is no longer used.

*New in version 3.1.*

*Changed in version 3.6:* Accepts a path-like object.

To decode file names to `str` during argument parsing, the "O&" converter should be used, passing `PyUnicode_FSDecoder()` as the conversion function:

```python
int PyUnicode_FSDecoder(PyObject* obj, void* result)
```

`ParseTuple` converter: decode `bytes` objects – obtained either directly or indirectly through the `os.PathLike` interface – to `str` using `PyUnicode_DecodeFSDefaultAndSize()`. `str` objects are output as-is. `result` must be a `PyUnicodeObject*` which must be released when it is no longer used.

*New in version 3.2.*

*Changed in version 3.6:* Accepts a path-like object.

```python
PyObject* PyUnicode_DecodeFSDefaultAndSize(const char *s, Py_ssize_t size)
```

Decode a string using `Py_FileSystemDefaultEncoding` and the `Py_FileSystemDefaultEncodeErrors` error handler.

If `Py_FileSystemDefaultEncoding` is not set, fall back to the locale encoding.

`Py_FileSystemDefaultEncoding` is initialized at startup from
the locale encoding and cannot be modified later. If you need to decode a string from the current locale encoding, use `PyUnicode_DecodeLocaleAndSize()`.

**See also:** The `Py_DecodeLocale()` function.

*Changed in version 3.6:* Use `Py_FileSystemDefaultEncodeErrors` error handler.

```c
PyObject* PyUnicode_DecodeFSDefault(const char *s)
```

If `Py_FileSystemDefaultEncoding` is not set, fall back to the locale encoding.

Use `PyUnicode_DecodeFSDefaultAndSize()` if you know the string length.

*Changed in version 3.6:* Use `Py_FileSystemDefaultEncodeErrors` error handler.

```c
PyObject* PyUnicode_EncodeFSDefault(PyObject *unicode)
```

Encode a Unicode object to `Py_FileSystemDefaultEncoding` with the `Py_FileSystemDefaultEncodeErrors` error handler, and return `bytes`. Note that the resulting `bytes` object may contain null bytes.

If `Py_FileSystemDefaultEncoding` is not set, fall back to the locale encoding.

`Py_FileSystemDefaultEncoding` is initialized at startup from
the locale encoding and cannot be modified later. If you need to encode a string to the current locale encoding, use `PyUnicode_EncodeLocale()`.

**See also:** The `Py_EncodeLocale()` function.

*New in version 3.2.*

*Changed in version 3.6:* Use `Py_FileSystemDefaultEncodeErrors` error handler.

**wchar_t Support**

`wchar_t` support for platforms which support it:

```c
PyObject* PyUnicode_FromWideChar(const wchar_t *w, Py_ssize_t size)
```

*Return value: New reference.*

Create a Unicode object from the `wchar_t` buffer `w` of the given `size`. Passing `-1` as the `size` indicates that the function must itself compute the length, using `wcslen`. Return `NULL` on failure.

```c
Py_ssize_t
PyUnicode_AsWideChar(PyUnicodeObject *unicode, wchar_t *w, Py_ssize_t size)
```

Copy the Unicode object contents into the `wchar_t` buffer `w`. At most `size` `wchar_t` characters are copied (excluding a possibly trailing null termination character). Return the number of `wchar_t` characters copied or `-1` in case of an error. Note that the resulting `wchar_t*` string may or may not be null-terminated. It is the responsibility of the caller to make sure that the `wchar_t*` string is null-terminated in case this is required by the application. Also,
note that the wchar_t* string might contain null characters, which would cause the string to be truncated when used with most C functions.

**wchar_t* PyUnicode_AsWideCharString(PyObject *unicode, Py_ssize_t *size)**

Convert the Unicode object to a wide character string. The output string always ends with a null character. If size is not NULL, write the number of wide characters (excluding the trailing null termination character) into *size.

Returns a buffer allocated by PyMem_Alloc() (use PyMem_Free() to free it) on success. On error, returns NULL, *size is undefined and raises a MemoryError. Note that the resulting wchar_t string might contain null characters, which would cause the string to be truncated when used with most C functions.

*New in version 3.2.*
Built-in Codecs

Python provides a set of built-in codecs which are written in C for speed. All of these codecs are directly usable via the following functions.

Many of the following APIs take two arguments encoding and errors, and they have the same semantics as the ones of the built-in \texttt{str()} string object constructor.

Setting encoding to \texttt{NULL} causes the default encoding to be used which is ASCII. The file system calls should use \texttt{PyUnicode_FSCConverter()} for encoding file names. This uses the variable \texttt{Py\_FileSystemDefaultEncoding} internally. This variable should be treated as read-only: on some systems, it will be a pointer to a static string, on others, it will change at run-time (such as when the application invokes setlocale).

Error handling is set by errors which may also be set to \texttt{NULL} meaning to use the default handling defined for the codec. Default error handling for all built-in codecs is “strict” (\texttt{ValueError} is raised).

The codecs all use a similar interface. Only deviation from the following generic ones are documented for simplicity.

Generic Codecs

These are the generic codec APIs:

\begin{verbatim}
PyObject* PyUnicode_Decode(const char *s, Py_ssize_t size, const char *encoding, const char *errors)
\end{verbatim}

\textit{Return value: New reference.}
Create a Unicode object by decoding size bytes of the encoded string s. \textit{encoding} and \textit{errors} have the same meaning as the parameters of the same name in the \texttt{str()} built-in function. The codec to be used is looked up using the Python codec registry. Return \texttt{NULL} if an exception was raised by the codec.

\texttt{PyObject* PyUnicode\_AsEncodedString(PyObject \texttt{*unicode}, \texttt{const char *encoding, const char *errors})}

\textit{Return value: New reference.}

Encode a Unicode object and return the result as Python bytes object. \textit{encoding} and \textit{errors} have the same meaning as the parameters of the same name in the Unicode \texttt{encode()} method. The codec to be used is looked up using the Python codec registry. Return \texttt{NULL} if an exception was raised by the codec.

\texttt{PyObject* PyUnicode\_Encode(const Py\_UNICODE *s, Py\_ssize\_t size, \texttt{const char *encoding, const char *errors})}

\textit{Return value: New reference.}

Encode the Py\_UNICODE buffer \texttt{s} of the given \texttt{size} and return a Python bytes object. \textit{encoding} and \textit{errors} have the same meaning as the parameters of the same name in the Unicode \texttt{encode()} method. The codec to be used is looked up using the Python codec registry. Return \texttt{NULL} if an exception was raised by the codec.

\textit{Deprecated since version 3.3, will be removed in version 4.0: Part of the old-style Py\_UNICODE API; please migrate to using PyUnicode\_AsEncodedString().}

\textbf{UTF-8 Codecs}

These are the UTF-8 codec APIs:
PyObject* PyUnicode_DecodeUTF8(const char *s, Py_ssize_t size, const char *errors)

    Create a Unicode object by decoding size bytes of the UTF-8 encoded string s. Return NULL if an exception was raised by the codec.

PyObject* PyUnicode_DecodeUTF8Stateful(const char *s, Py_ssize_t size, const char *errors, Py_ssize_t *consumed)

    If consumed is NULL, behave like PyUnicode_DecodeUTF8(). If consumed is not NULL, trailing incomplete UTF-8 byte sequences will not be treated as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in consumed.

PyObject* PyUnicode_AsUTF8String(PyObject *unicode)

    Encode a Unicode object using UTF-8 and return the result as Python bytes object. Error handling is “strict”. Return NULL if an exception was raised by the codec.

char* PyUnicode_AsUTF8AndSize(PyObject *unicode, Py_ssize_t *size)

    Return a pointer to the UTF-8 encoding of the Unicode object, and store the size of the encoded representation (in bytes) in size. The size argument can be NULL; in this case no size will be stored. The returned buffer always has an extra null byte appended (not included in size), regardless of whether there are any other null code points.

    In the case of an error, NULL is returned with an exception set and
no size is stored.

This caches the UTF-8 representation of the string in the Unicode object, and subsequent calls will return a pointer to the same buffer. The caller is not responsible for deallocating the buffer.

*New in version 3.3.*

```c
char* PyUnicode_AsUTF8(PyObject *unicode)
```

As `PyUnicode_AsUTF8AndSize()`, but does not store the size.

*New in version 3.3.*

```c
PyObject* PyUnicode_EncodeUTF8(const Py_UNICODE *s, Py_ssize_t size, const char *errors)
```

Encode the `Py_UNICODE` buffer `s` of the given `size` using UTF-8 and return a Python bytes object. Return `NULL` if an exception was raised by the codec.

*Deprecated since version 3.3, will be removed in version 4.0:* Part of the old-style `Py_UNICODE` API; please migrate to using `PyUnicode_AsUTF8String()`, `PyUnicode_AsUTF8AndSize()` or `PyUnicode_AsEncodedString()`.

**UTF-32 Codecs**

These are the UTF-32 codec APIs:

```c
PyObject* PyUnicode_DecodeUTF32(const char *s, Py_ssize_t size, const char *errors, int *byteorder)
```

Decode `size` bytes from a UTF-32 encoded buffer string and return
the corresponding Unicode object. *errors* (if non-NULL) defines the error handling. It defaults to “strict”.

If *byteorder* is non-NULL, the decoder starts decoding using the given byte order:

*byteorder == -1: little endian
*byteorder == 0: native order
*byteorder == 1: big endian

If *byteorder* is zero, and the first four bytes of the input data are a byte order mark (BOM), the decoder switches to this byte order and the BOM is not copied into the resulting Unicode string. If *byteorder* is -1 or 1, any byte order mark is copied to the output.

After completion, *byteorder* is set to the current byte order at the end of input data.

If *byteorder* is NULL, the codec starts in native order mode.

Return *NULL* if an exception was raised by the codec.

**PyObject** PyUnicode_DecodeUTF32Stateful(const char *s, Py_ssize_t size, const char *errors, int *byteorder, Py_ssize_t *consumed)

If consumed is NULL, behave like PyUnicode_DecodeUTF32(). If consumed is not NULL, PyUnicode_DecodeUTF32Stateful() will not treat trailing incomplete UTF-32 byte sequences (such as a number of bytes not divisible by four) as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in consumed.
PyObject* PyUnicode_AsUTF32String(PyObject *unicode)
Return a Python byte string using the UTF-32 encoding in native byte order. The string always starts with a BOM mark. Error handling is “strict”. Return NULL if an exception was raised by the codec.

PyObject* PyUnicode_EncodeUTF32(const Py_UNICODE *s, Py_ssize_t size, const char *errors, int byteorder)
Return a Python bytes object holding the UTF-32 encoded value of the Unicode data in s. Output is written according to the following byte order:

```plaintext
byteorder == -1: little endian
byteorder == 0: native byte order (writes a BOM mark)
byteorder == 1: big endian
```

If byteorder is 0, the output string will always start with the Unicode BOM mark (U+FEFF). In the other two modes, no BOM mark is prepended.

If Py_UNICODE_WIDE is not defined, surrogate pairs will be output as a single code point.

Return NULL if an exception was raised by the codec.

*Deprecated since version 3.3, will be removed in version 4.0:* Part of the old-style Py_UNICODE API; please migrate to using PyUnicode_AsUTF32String() or PyUnicode_AsEncodedString().

UTF-16 Codecs
These are the UTF-16 codec APIs:

**PyObject**\* **PyUnicode_DecodeUTF16** (const char *s, Py_ssize_t size, const char *errors, int *byteorder)

*Return value: New reference.*
Decode size bytes from a UTF-16 encoded buffer string and return the corresponding Unicode object. *errors* (if non-NULL) defines the error handling. It defaults to “strict”.

If *byteorder* is non-NULL, the decoder starts decoding using the given byte order:

- *byteorder == -1*: little endian
- *byteorder == 0*: native order
- *byteorder == 1*: big endian

If *byteorder* is zero, and the first two bytes of the input data are a byte order mark (BOM), the decoder switches to this byte order and the BOM is not copied into the resulting Unicode string. If *byteorder* is -1 or 1, any byte order mark is copied to the output (where it will result in either a \ufeff or a \ufffe character).

After completion, *byteorder* is set to the current byte order at the end of input data.

If *byteorder* is NULL, the codec starts in native order mode.

Return NULL if an exception was raised by the codec.

**PyObject**\* **PyUnicode_DecodeUTF16Stateful** (const char *s, Py_ssize_t size, const char *errors, int *byteorder, Py_ssize_t *consumed)

*Return value: New reference.*
If \textit{consumed} is \texttt{NULL}, behave like \texttt{PyUnicode.DecodeUTF16()}. If \textit{consumed} is not \texttt{NULL}, \texttt{PyUnicode.DecodeUTF16Stateful()} will not treat trailing incomplete UTF-16 byte sequences (such as an odd number of bytes or a split surrogate pair) as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in \textit{consumed}.

\textbf{PyObject* PyUnicode.AsUTF16String(PyObject *unicode)}

\textit{Return value: New reference.}

Return a Python byte string using the UTF-16 encoding in native byte order. The string always starts with a BOM mark. Error handling is “strict”. Return \texttt{NULL} if an exception was raised by the codec.

\textbf{PyObject* PyUnicode.EncodeUTF16(const Py_UNICODE *s, Py_ssize_t size, const char *errors, int byteorder)}

\textit{Return value: New reference.}

Return a Python bytes object holding the UTF-16 encoded value of the Unicode data in \texttt{s}. Output is written according to the following byte order:

\begin{verbatim}
byteorder == -1: little endian
byteorder == 0: native byte order (writes a BOM mark)
byteorder == 1: big endian
\end{verbatim}

If byteorder is 0, the output string will always start with the Unicode BOM mark (U+FEFF). In the other two modes, no BOM mark is prepended.

If \texttt{Py_UNICODE_WIDE} is defined, a single \texttt{Py_UNICODE} value may get represented as a surrogate pair. If it is not defined, each
Py_UNICODE values is interpreted as a UCS-2 character.

Return NULL if an exception was raised by the codec.

Deprecated since version 3.3, will be removed in version 4.0: Part of the old-style Py_UNICODE API; please migrate to using PyUnicode_AsUTF16String() or PyUnicode_AsEncodedString().

UTF-7 Codecs

These are the UTF-7 codec APIs:

PyObject* PyUnicode_DecodeUTF7(const char *s, Py_ssize_t size, const char *errors)
Create a Unicode object by decoding size bytes of the UTF-7 encoded string s. Return NULL if an exception was raised by the codec.

PyObject* PyUnicode_DecodeUTF7Stateful(const char *s, Py_ssize_t size, const char *errors, Py_ssize_t *consumed)
If consumed is NULL, behave like PyUnicode_DecodeUTF7(). If consumed is not NULL, trailing incomplete UTF-7 base-64 sections will not be treated as an error. Those bytes will not be decoded and the number of bytes that have been decoded will be stored in consumed.

PyObject* PyUnicode_EncodeUTF7(const Py_UNICODE *s, Py_ssize_t size, int base64SetO, int base64WhiteSpace, const char *errors)
Encode the Py_UNICODE buffer of the given size using UTF-7 and return a Python bytes object. Return NULL if an exception was
raised by the codec.

If `base64SetO` is nonzero, “Set O” (punctuation that has no otherwise special meaning) will be encoded in base-64. If `base64WhiteSpace` is nonzero, whitespace will be encoded in base-64. Both are set to zero for the Python “utf-7” codec.

*Deprecated since version 3.3, will be removed in version 4.0:* Part of the old-style `Py_UNICODE` API; please migrate to using `PyUnicode_AsEncodedString()`.

### Unicode-Escape Codecs

These are the “Unicode Escape” codec APIs:

**`PyObject* PyUnicode_DecodeUnicodeEscape`**

*Return value: New reference.*

Create a Unicode object by decoding `size` bytes of the Unicode-Escape encoded string `s`. Return `NULL` if an exception was raised by the codec.

**`PyObject* PyUnicode_AsUnicodeEscapeString`**

*Return value: New reference.*

Encode a Unicode object using Unicode-Escape and return the result as a bytes object. Error handling is “strict”. Return `NULL` if an exception was raised by the codec.

**`PyObject* PyUnicode_EncodeUnicodeEscape`**

*Return value: New reference.*

Encode the `Py_UNICODE` buffer of the given `size` using Unicode-
Escape and return a bytes object. Return NULL if an exception was raised by the codec.

Depreciated since version 3.3, will be removed in version 4.0: Part of the old-style Py_UNICODE API; please migrate to using PyUnicode_AsUnicodeEscapeString().

Raw-Unicode-Escape Codecs

These are the “Raw Unicode Escape” codec APIs:

PyObject* PyUnicode_DecodeRawUnicodeEscape(const char *s, Py_ssize_t size, const char *errors)

Create a Unicode object by decoding size bytes of the Raw-Unicode-Escape encoded string s. Return NULL if an exception was raised by the codec.

PyObject* PyUnicode_AsRawUnicodeEscapeString(PyObject *unicode)

Encode a Unicode object using Raw-Unicode-Escape and return the result as a bytes object. Error handling is “strict”. Return NULL if an exception was raised by the codec.

PyObject* PyUnicode_EncodeRawUnicodeEscape(const Py_UNICODE *s, Py_ssize_t size, const char *errors)

Encode the Py_UNICODE buffer of the given size using Raw-Unicode-Escape and return a bytes object. Return NULL if an exception was raised by the codec.

Depreciated since version 3.3, will be removed in version 4.0: Part
of the old-style `Py_UNICODE` API; please migrate to using
`PyUnicode_AsRawUnicodeEscapeString()` or
`PyUnicode_AsEncodedString()`.

**Latin-1 Codecs**

These are the Latin-1 codec APIs: Latin-1 corresponds to the first 256
Unicode ordinals and only these are accepted by the codecs during
encoding.

```c
PyObject* PyUnicode_DecodeLatin1(const char *s,
Py_ssize_t size, const char *errors)

Create a Unicode object by decoding size bytes of the Latin-1
encoded string s. Return NULL if an exception was raised by the
codec.
```

```c
PyObject* PyUnicode_AsLatin1String(PyObject *unicode)

Encode a Unicode object using Latin-1 and return the result as
Python bytes object. Error handling is “strict”. Return NULL if an
exception was raised by the codec.
```

```c
PyObject* PyUnicode_EncodeLatin1(const Py_UNICODE *s,
Py_ssize_t size, const char *errors)

Encode the Py_UNICODE buffer of the given size using Latin-1 and
return a Python bytes object. Return NULL if an exception was
raised by the codec.
```

*Deprecated since version 3.3, will be removed in version 4.0:* Part
of the old-style `Py_UNICODE` API; please migrate to using
PyUnicode_AsLatin1String() or PyUnicode_AsEncodedString().

ASCII Codecs

These are the ASCII codec APIs. Only 7-bit ASCII data is accepted. All other codes generate errors.

**PyObject** PyUnicode_DecodeASCII(const char *s, Py_ssize_t size, const char *errors)

*Return value: New reference.*

Create a Unicode object by decoding size bytes of the ASCII encoded string s. Return NULL if an exception was raised by the codec.

**PyObject** PyUnicode_AsASCIIString(PyObject *unicode)

*Return value: New reference.*

Encode a Unicode object using ASCII and return the result as Python bytes object. Error handling is “strict”. Return NULL if an exception was raised by the codec.

**PyObject** PyUnicode_EncodeASCII(const Py_UNICODE *s, Py_ssize_t size, const char *errors)

*Return value: New reference.*

Encode the Py_UNICODE buffer of the given size using ASCII and return a Python bytes object. Return NULL if an exception was raised by the codec.

*Deprecated since version 3.3, will be removed in version 4.0:* Part of the old-style Py_UNICODE API; please migrate to using PyUnicode_AsASCIIString() or PyUnicode_AsEncodedString().
Character Map Codecs

This codec is special in that it can be used to implement many different codecs (and this is in fact what was done to obtain most of the standard codecs included in the encodings package). The codec uses mapping to encode and decode characters. The mapping objects provided must support the `__getitem__()` mapping interface; dictionaries and sequences work well.

These are the mapping codec APIs:

```c
PyObject* PyUnicode_DecodeCharmap(const char *data, Py_ssize_t size, PyObject *mapping, const char *errors)

Create a Unicode object by decoding size bytes of the encoded string s using the given mapping object. Return NULL if an exception was raised by the codec.

If mapping is NULL, Latin-1 decoding will be applied. Else mapping must map bytes ordinals (integers in the range from 0 to 255) to Unicode strings, integers (which are then interpreted as Unicode ordinals) or None. Unmapped data bytes – ones which cause a LookupError, as well as ones which get mapped to None, 0xFFFE or '\ufffe', are treated as undefined mappings and cause an error.

PyObject* PyUnicode_AsCharmapString(PyObject *unicode, PyObject *mapping)

Encode a Unicode object using the given mapping object and return the result as a bytes object. Error handling is “strict”. Return NULL if an exception was raised by the codec.
```
The *mapping* object must map Unicode ordinal integers to bytes objects, integers in the range from 0 to 255 or None. Unmapped character ordinals (ones which cause a *LookupError*) as well as mapped to None are treated as “undefined mapping” and cause an error.

**PyObject** *PyUnicode_EncodeCharmap*(const 
Py_UNICODE *s, Py_ssize_t size, PyObject *mapping, const char *errors)

*Return value: New reference.*
Encode the Py_UNICODE buffer of the given size using the given mapping object and return the result as a bytes object. Return NULL if an exception was raised by the codec.

*Deprecated since version 3.3, will be removed in version 4.0:* Part of the old-style Py_UNICODE API; please migrate to using PyUnicode_AsCharmapString() or PyUnicode_AsEncodedString().

The following codec API is special in that maps Unicode to Unicode.

**PyObject** *PyUnicode_Translate*(PyObject *unicode, 
PyObject *mapping, const char *errors)

*Return value: New reference.*
Translate a Unicode object using the given mapping object and return the resulting Unicode object. Return NULL if an exception was raised by the codec.

The *mapping* object must map Unicode ordinal integers to Unicode strings, integers (which are then interpreted as Unicode ordinals) or None (causing deletion of the character). Unmapped character ordinals (ones which cause a *LookupError*) are left untouched and are copied as-is.
PyObject* **PyUnicode_TranslateCharmap**(**const Py_UNICODE *s**, **Py_ssize_t size**, **PyObject *mapping**, **const char *errors**)  

*Return value: New reference.*  
Translate a **Py_UNICODE** buffer of the given size by applying a character *mapping* table to it and return the resulting Unicode object. Return *NULL* when an exception was raised by the codec.

*Deprecated since version 3.3, will be removed in version 4.0:* Part of the old-style **Py_UNICODE** API; please migrate to using **PyUnicode_Translate()** or generic codec based API.

**MBCS codecs for Windows**

These are the MBCS codec APIs. They are currently only available on Windows and use the Win32 MBCS converters to implement the conversions. Note that MBCS (or DBCS) is a class of encodings, not just one. The target encoding is defined by the user settings on the machine running the codec.

PyObject* **PyUnicode_DecodeMBCS**(**const char *s**, **Py_ssize_t size**, **const char *errors**)  

*Return value: New reference.*  
Create a Unicode object by decoding size bytes of the MBCS encoded string s. Return *NULL* if an exception was raised by the codec.

PyObject* **PyUnicode_DecodeMBCSStateful**(**const char *s**, **int size**, **const char *errors**, **int *consumed**)  

If *consumed* is *NULL*, behave like **PyUnicode_DecodeMBCS()**. If *consumed* is not *NULL*, **PyUnicode_DecodeMBCSStateful()** will not decode trailing lead byte and the number of bytes that have
been decoded will be stored in consumed.

PyObject* PyUnicode_AsMBCSString(PyObject *unicode)

*Return value: New reference.*
Encode a Unicode object using MBCS and return the result as Python bytes object. Error handling is “strict”. Return NULL if an exception was raised by the codec.

PyObject* PyUnicode_EncodeCodePage(int code_page, PyObject *unicode, const char *errors)

Encode the Unicode object using the specified code page and return a Python bytes object. Return NULL if an exception was raised by the codec. Use CP_ACP code page to get the MBCS encoder.

*New in version 3.3.*

PyObject* PyUnicode_EncodeMBCS(const Py_UNICODE *s, Py_ssize_t size, const char *errors)

*Return value: New reference.*
Encode the Py_UNICODE buffer of the given size using MBCS and return a Python bytes object. Return NULL if an exception was raised by the codec.

*Deprecated since version 3.3, will be removed in version 4.0:* Part of the old-style Py_UNICODE API; please migrate to using PyUnicode_AsMBCSString(), PyUnicode_EncodeCodePage() or PyUnicode_AsEncodedString().

Methods & Slots
Methods and Slot Functions

The following APIs are capable of handling Unicode objects and strings on input (we refer to them as strings in the descriptions) and return Unicode objects or integers as appropriate.

They all return \textit{NULL} or \textbf{-1} if an exception occurs.

\textbf{PyObject* \texttt{PyUnicode\_Concat}(PyObject \texttt{*left}, PyObject \texttt{*right})}
\begin{itemize}
\item \textit{Return value: New reference.}
\item Concat two strings giving a new Unicode string.
\end{itemize}

\textbf{PyObject* \texttt{PyUnicode\_Split}(PyObject \texttt{*s}, PyObject \texttt{*sep}, Py\_ssize\_t \texttt{maxsplit})}
\begin{itemize}
\item \textit{Return value: New reference.}
\item Split a string giving a list of Unicode strings. If \texttt{sep} is \texttt{NULL}, splitting will be done at all whitespace substrings. Otherwise, splits occur at the given separator. At most \texttt{maxsplit} splits will be done. If negative, no limit is set. Separators are not included in the resulting list.
\end{itemize}

\textbf{PyObject* \texttt{PyUnicode\_Splitlines}(PyObject \texttt{*s}, int \texttt{keepend})}
\begin{itemize}
\item \textit{Return value: New reference.}
\item Split a Unicode string at line breaks, returning a list of Unicode strings. CRLF is considered to be one line break. If \texttt{keepend} is 0, the Line break characters are not included in the resulting strings.
\end{itemize}

\textbf{PyObject* \texttt{PyUnicode\_Translate}(PyObject \texttt{*str}, PyObject \texttt{*table}, const char \texttt{*errors})}
\begin{itemize}
\item Translate a string by applying a character mapping table to it and return the resulting Unicode object.
\end{itemize}
The mapping table must map Unicode ordinal integers to Unicode ordinal integers or None (causing deletion of the character).

Mapping tables need only provide the `__getitem__()` interface; dictionaries and sequences work well. Unmapped character ordinals (ones which cause a `LookupError`) are left untouched and are copied as-is.

`errors` has the usual meaning for codecs. It may be `NULL` which indicates to use the default error handling.

```c
PyObject* PyUnicode_Join(PyObject *separator, PyObject *seq)
Join a sequence of strings using the given separator and return the resulting Unicode string.
```

```c
Py_ssize_t PyUnicode_Tailmatch(PyObject *str, PyObject *substr, Py_ssize_t start, Py_ssize_t end, int direction)
Return 1 if substr matches str[start:end] at the given tail end (direction == -1 means to do a prefix match, direction == 1 a suffix match), 0 otherwise. Return -1 if an error occurred.
```

```c
Py_ssize_t PyUnicode_Find(PyObject *str, PyObject *substr, Py_ssize_t start, Py_ssize_t end, int direction)
Return the first position of substr in str[start:end] using the given direction (direction == 1 means to do a forward search, direction == -1 a backward search). The return value is the index of the first match; a value of -1 indicates that no match was found, and -2 indicates that an error occurred and an exception has been set.
```

```c
Py_ssize_t PyUnicode_FindChar(PyObject *str, Py_UCS4 ch,
```
Py_ssize_t start, Py_ssize_t end, int direction)

Return the first position of the character ch in str[start:end] using the given direction (direction == 1 means to do a forward search, direction == -1 a backward search). The return value is the index of the first match; a value of -1 indicates that no match was found, and -2 indicates that an error occurred and an exception has been set.

New in version 3.3.

Py_ssize_t PyUnicode_Count(PyObject *str, PyObject *substr, Py_ssize_t start, Py_ssize_t end)

Return the number of non-overlapping occurrences of substr in str[start:end]. Return -1 if an error occurred.

PyObject* PyUnicodeReplace(PyObject *str, PyObject *substr, PyObject *replstr, Py_ssize_t maxcount)

Replace at most maxcount occurrences of substr in str with replstr and return the resulting Unicode object. maxcount == -1 means replace all occurrences.

int PyUnicodeCompare(PyObject *left, PyObject *right)

Compare two strings and return -1, 0, 1 for less than, equal, and greater than, respectively.

This function returns -1 upon failure, so one should call PyErr_Occurred() to check for errors.

int PyUnicodeCompareWithASCIIString(PyObject *uni, const char *string)

Compare a unicode object, uni, with string and return -1, 0, 1 for
less than, equal, and greater than, respectively. It is best to pass only ASCII-encoded strings, but the function interprets the input string as ISO-8859-1 if it contains non-ASCII characters.

This function does not raise exceptions.

PyObject* PyUnicode_RichCompare(PyObject *left, PyObject *right, int op)
Rich compare two unicode strings and return one of the following:

- NULL in case an exception was raised
- Py_True or Py_False for successful comparisons
- Py_NotImplemented in case the type combination is unknown

Possible values for op are Py_GT, Py_GE, Py_EQ, Py_NE, Py_LT, and Py_LE.

PyObject* PyUnicode_Format(PyObject *format, PyObject *args)
Return a new string object from format and args; this is analogous to format % args.

int PyUnicode_Contains(PyObject *container, PyObject *element)
Check whether element is contained in container and return true or false accordingly.

element has to coerce to a one element Unicode string. -1 is returned if there was an error.

void PyUnicode_InternInPlace(PyObject **string)
Intern the argument *string in place. The argument must be the
address of a pointer variable pointing to a Python unicode string object. If there is an existing interned string that is the same as *string, it sets *string to it (decrementing the reference count of the old string object and incrementing the reference count of the interned string object), otherwise it leaves *string alone and interns it (incrementing its reference count). (Clarification: even though there is a lot of talk about reference counts, think of this function as reference-count-neutral; you own the object after the call if and only if you owned it before the call.)

PyObject* **PyUnicode_InternFromString**(const char *v)

A combination of **PyUnicode_FromString()** and **PyUnicode_InternInPlace()**, returning either a new unicode string object that has been interned, or a new (“owned”) reference to an earlier interned string object with the same value.
Tuple Objects

**PyTupleObject**
This subtype of PyObject represents a Python tuple object.

**PyTypeObject** **PyTuple_Type**
This instance of PyTypeObject represents the Python tuple type; it is the same object as tuple in the Python layer.

int **PyTuple_Check**(PyObject *p)
Return true if p is a tuple object or an instance of a subtype of the tuple type.

int **PyTuple_CheckExact**(PyObject *p)
Return true if p is a tuple object, but not an instance of a subtype of the tuple type.

PyObject* **PyTuple_New**(**Py_ssize_t** len)
_**Return value: New reference.**_
Return a new tuple object of size len, or NULL on failure.

PyObject* **PyTuple_Pack**(**Py_ssize_t** n, ...)
_**Return value: New reference.**_
Return a new tuple object of size n, or NULL on failure. The tuple values are initialized to the subsequent n C arguments pointing to Python objects. PyTuple_Pack(2, a, b) is equivalent to Py_BuildValue("(00)", a, b).

**Py_ssize_t** **PyTuple_Size**(PyObject *p)
Take a pointer to a tuple object, and return the size of that tuple.
Py_ssize_t **PyTuple_GET_SIZE**(PyObject *p)

Return the size of the tuple \( p \), which must be non-NULL and point to a tuple; no error checking is performed.

PyObject* **PyTuple_GetItem**(PyObject *p, Py_ssize_t pos)

*Return value: Borrowed reference.*

Return the object at position \( pos \) in the tuple pointed to by \( p \). If \( pos \) is out of bounds, return NULL and sets an IndexError exception.

PyObject* **PyTuple_GET_ITEM**(PyObject *p, Py_ssize_t pos)

*Return value: Borrowed reference.*

Like PyTuple_GetItem(), but does no checking of its arguments.

PyObject* **PyTuple_GetSlice**(PyObject *p, Py_ssize_t low, Py_ssize_t high)

*Return value: New reference.*

Take a slice of the tuple pointed to by \( p \) from low to high and return it as a new tuple.

int **PyTuple_SetItem**(PyObject *p, Py_ssize_t pos, PyObject *o)

Insert a reference to object \( o \) at position \( pos \) of the tuple pointed to by \( p \). Return 0 on success.

**Note:** This function “steals” a reference to \( o \).

void **PyTuple_SET_ITEM**(PyObject *p, Py_ssize_t pos, PyObject *o)

Like PyTuple_SetItem(), but does no error checking, and should only be used to fill in brand new tuples.

**Note:** This function “steals” a reference to \( o \).
int _PyTuple_Resize(PyObject **p, Py_ssize_t newsize)

Can be used to resize a tuple. newsize will be the new length of the tuple. Because tuples are supposed to be immutable, this should only be used if there is only one reference to the object. Do not use this if the tuple may already be known to some other part of the code. The tuple will always grow or shrink at the end. Think of this as destroying the old tuple and creating a new one, only more efficiently. Returns 0 on success. Client code should never assume that the resulting value of *p will be the same as before calling this function. If the object referenced by *p is replaced, the original *p is destroyed. On failure, returns -1 and sets *p to NULL, and raises MemoryError or SystemError.

int PyTuple_ClearFreeList()

Clear the free list. Return the total number of freed items.
Struct Sequence Objects

Struct sequence objects are the C equivalent of `namedtuple()` objects, i.e. a sequence whose items can also be accessed through attributes. To create a struct sequence, you first have to create a specific struct sequence type.

```python
PyTypeObject*
PyStructSequence_NewType(PyStructSequence_Desc *desc)
```

Create a new struct sequence type from the data in `desc`, described below. Instances of the resulting type can be created with `PyStructSequence_New()`.

```python
void PyStructSequence_InitType(PyTypeObject *type,
PyStructSequence_Desc *desc)
```

Initializes a struct sequence type `type` from `desc` in place.

```python
int PyStructSequence_InitType2(PyTypeObject *type,
PyStructSequence_Desc *desc)
```

The same as `PyStructSequence_InitType`, but returns 0 on success and -1 on failure.

*New in version 3.4.*

**PyStructSequence_Desc**

Contains the meta information of a struct sequence type to create.

<table>
<thead>
<tr>
<th>Field</th>
<th>C Type</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>char *</td>
<td>name of the struct sequence type</td>
</tr>
</tbody>
</table>
**PyStructSequence_Field**

Describes a field of a struct sequence. As a struct sequence is modeled as a tuple, all fields are typed as `PyObject*`. The index in the `fields` array of the `PyStructSequence_Desc` determines which field of the struct sequence is described.

<table>
<thead>
<tr>
<th>Field</th>
<th>C Type</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>char *</td>
<td>name for the field or NULL to end the list of named fields, set to PyStructSequence_UnnamedField to leave unnamed</td>
</tr>
<tr>
<td>doc</td>
<td>char *</td>
<td>field docstring or NULL to omit</td>
</tr>
</tbody>
</table>

char* **PyStructSequence_UnnamedField**

Special value for a field name to leave it unnamed.
PyObject* PyStructSequence_New(PyTypeObject *type)

Creates an instance of type, which must have been created with PyStructSequence_NewType().

PyObject* PyStructSequence_GetItem(PyObject *p, Py_ssize_t pos)

Return the object at position pos in the struct sequence pointed to by p. No bounds checking is performed.

PyObject* PyStructSequence_GET_ITEM(PyObject *p, Py_ssize_t pos)

Macro equivalent of PyStructSequence_GetItem().

void PyStructSequence_SetItem(PyObject *p, Py_ssize_t pos, PyObject *o)

Sets the field at index pos of the struct sequence p to value o. Like PyTuple_SET_ITEM(), this should only be used to fill in brand new instances.

**Note:** This function “steals” a reference to o.

PyObject* PyStructSequence_SET_ITEM(PyObject *p, Py_ssize_t *pos, PyObject *o)

Macro equivalent of PyStructSequence_SetItem().

**Note:** This function “steals” a reference to o.
List Objects

**PyListObject**
This subtype of *PyObject* represents a Python list object.

**PyTypeObject** **PyList_Type**
This instance of *PyTypeObject* represents the Python list type. This is the same object as *list* in the Python layer.

```c
int PyList_Check(PyObject *p)
```
Return true if *p* is a list object or an instance of a subtype of the list type.

```c
int PyList_CheckExact(PyObject *p)
```
Return true if *p* is a list object, but not an instance of a subtype of the list type.

```c
PyObject* PyList_New(Py_ssize_t len)
```
*Return value*: New reference.
Return a new list of length *len* on success, or *NULL* on failure.

**Note:** If *len* is greater than zero, the returned list object’s items are set to *NULL*. Thus you cannot use abstract API functions such as *PySequence_SetItem()* or expose the object to Python code before setting all items to a real object with *PyList_SetItem()*.

```c
Py_ssize_t PyList_Size(PyObject *list)
```
Return the length of the list object in *list*; this is equivalent to *len(list)* on a list object.
**Pyssize_t** `PyList_GET_SIZE(PyObject *list)`  
Macro form of `PyList_Size()` without error checking.

**PyObject** `PyList_GetItem(PyObject *list, Py_ssize_t index)`  
*Return value: Borrowed reference.*  
Return the object at position `index` in the list pointed to by `list`. The position must be positive, indexing from the end of the list is not supported. If `index` is out of bounds, return `NULL` and set an `IndexError` exception.

**PyObject** `PyList_GET_ITEM(PyObject *list, Py_ssize_t i)`  
*Return value: Borrowed reference.*  
Macro form of `PyList_GetItem()` without error checking.

**int** `PyList_SetItem(PyObject *list, Py_ssize_t index, PyObject *item)`  
Set the item at index `index` in list to `item`. Return `0` on success or `-1` on failure.

**Note:** This function “steals” a reference to `item` and discards a reference to an item already in the list at the affected position.

**void** `PyList_SET_ITEM(PyObject *list, Py_ssize_t i, PyObject *o)`  
Macro form of `PyList_SetItem()` without error checking. This is normally only used to fill in new lists where there is no previous content.

**Note:** This macro “steals” a reference to `item`, and, unlike `PyList_SetItem()`, does not discard a reference to any item that is being replaced; any reference in `list` at position `i` will be leaked.
int PyList_Insert(PyObject *list, Py_ssize_t index, 
PyObject *item)

Insert the item item into list list in front of index index. Return 0 if successful; return -1 and set an exception if unsuccessful. Analogous to list.insert(index, item).

int PyList_Append(PyObject *list, PyObject *item)

Append the object item at the end of list list. Return 0 if successful; return -1 and set an exception if unsuccessful. Analogous to list.append(item).

PyObject* PyList_GetSlice(PyObject *list, Py_ssize_t low, 
Py_ssize_t high)

Return a list of the objects in list containing the objects between low and high. Return NULL and set an exception if unsuccessful. Analogous to list[low:high]. Negative indices, as when slicing from Python, are not supported.

int PyList_SetSlice(PyObject *list, Py_ssize_t low, 
Py_ssize_t high, PyObject *itemlist)

Set the slice of list between low and high to the contents of itemlist. Analogous to list[low:high] = itemlist. The itemlist may be NULL, indicating the assignment of an empty list (slice deletion). Return 0 on success, -1 on failure. Negative indices, as when slicing from Python, are not supported.

int PyList_Sort(PyObject *list)

Sort the items of list in place. Return 0 on success, -1 on failure. This is equivalent to list.sort().

int PyList_Reverse(PyObject *list)
Reverse the items of list in place. Return 0 on success, -1 on failure. This is the equivalent of list.reverse()

PyObject* PyList_AsTuple(PyObject *list)

Return a new tuple object containing the contents of list; equivalent to tuple(list).

int PyList_ClearFreeList()

Clear the free list. Return the total number of freed items.

New in version 3.3.
Dictionary Objects

PyDictObject
This subtype of PyObject represents a Python dictionary object.

PyTypeObject PyDict_Type
This instance of PyTypeObject represents the Python dictionary type. This is the same object as dict in the Python layer.

int PyDict_Check(PyObject *p)
Return true if p is a dict object or an instance of a subtype of the dict type.

int PyDict_CheckExact(PyObject *p)
Return true if p is a dict object, but not an instance of a subtype of the dict type.

PyObject* PyDict_New()
Return a new empty dictionary, or NULL on failure.

PyObject* PyDictProxy_New(PyObject *mapping)
Return a types.MappingProxyType object for a mapping which enforces read-only behavior. This is normally used to create a view to prevent modification of the dictionary for non-dynamic class types.

void PyDict_Clear(PyObject *p)
Empty an existing dictionary of all key-value pairs.
int PyDictContains(PyObject *p, PyObject *key)
    Determine if dictionary $p$ contains $key$. If an item in $p$ is matches $key$, return 1, otherwise return 0. On error, return -1. This is equivalent to the Python expression $key$ in $p$.

PyObject* PyDictCopy(PyObject *p)
    Return a new dictionary that contains the same key-value pairs as $p$.

int PyDictSetItem(PyObject *p, PyObject *key, PyObject *val)
    Insert value into the dictionary $p$ with a key of $key$. $key$ must be hashable; if it isn't, TypeError will be raised. Return 0 on success or -1 on failure.

int PyDictSetItemString(PyObject *p, const char *key, PyObject *val)
    Insert value into the dictionary $p$ using $key$ as a key. $key$ should be a char*. The key object is created using PyUnicode_FromString(key). Return 0 on success or -1 on failure.

int PyDictDelItem(PyObject *p, PyObject *key)
    Remove the entry in dictionary $p$ with key $key$. $key$ must be hashable; if it isn't, TypeError is raised. Return 0 on success or -1 on failure.

int PyDictDelItemString(PyObject *p, const char *key)
    Remove the entry in dictionary $p$ which has a key specified by the string $key$. Return 0 on success or -1 on failure.

PyObject* PyDictGetItem(PyObject *p, PyObject *key)
Return value: Borrowed reference.
Return the object from dictionary $p$ which has a key $key$. Return NULL if the key $key$ is not present, but without setting an exception.

PyObject* PyDict_GetItemWithError(PyObject *p, PyObject *key)
Variant of PyDict_GetItem() that does not suppress exceptions. Return NULL with an exception set if an exception occurred. Return NULL without an exception set if the key wasn't present.

PyObject* PyDict_GetItemString(PyObject *p, const char *key)
Return value: Borrowed reference.
This is the same as PyDict_GetItem(), but key is specified as a char*, rather than a PyObject*.

PyObject* PyDict_SetDefault(PyObject *p, PyObject *key, PyObject *default)
Return value: Borrowed reference.
This is the same as the Python-level dict.setdefault(). If present, it returns the value corresponding to key from the dictionary $p$. If the key is not in the dict, it is inserted with value defaultobj and defaultobj is returned. This function evaluates the hash function of key only once, instead of evaluating it independently for the lookup and the insertion.

New in version 3.4.

PyObject* PyDict_Items(PyObject *p)
Return a PyListObject containing all the items from the dictionary.
PyObject* PyDict_Keys(PyObject *p)

*Return value: New reference.*
Return a PyListObject containing all the keys from the dictionary.

PyObject* PyDict_Values(PyObject *p)

*Return value: New reference.*
Return a PyListObject containing all the values from the dictionary p.

Py_ssize_t PyDict_Size(PyObject *p)

Return the number of items in the dictionary. This is equivalent to len(p) on a dictionary.

int PyDict_Next(PyObject *p, Py_ssize_t *ppos, PyObject **pkey, PyObject **pvalue)

Iterate over all key-value pairs in the dictionary p. The Py_ssize_t referred to by ppos must be initialized to 0 prior to the first call to this function to start the iteration; the function returns true for each pair in the dictionary, and false once all pairs have been reported. The parameters pkey and pvalue should either point to PyObject* variables that will be filled in with each key and value, respectively, or may be NULL. Any references returned through them are borrowed. ppos should not be altered during iteration. Its value represents offsets within the internal dictionary structure, and since the structure is sparse, the offsets are not consecutive.

For example:

```c
PyObject *key, *value;
Py_ssize_t pos = 0;
```
while (PyDict_Next(self->dict, &pos, &key, &value)
    /* do something interesting with the values.. */
    ...
}

The dictionary $p$ should not be mutated during iteration. It is safe to modify the values of the keys as you iterate over the dictionary, but only so long as the set of keys does not change. For example:

```c
PyObject *key, *value;
Py_ssize_t pos = 0;

while (PyDict_Next(self->dict, &pos, &key, &value)
    long i = PyLong_AsLong(value);
    if (i == -1 && PyErr_Occurred()) {
        return -1;
    }
    PyObject *o = PyLong_FromLong(i + 1);
    if (o == NULL)
        return -1;
    if (PyDict_SetItem(self->dict, key, o) < 0) {
        Py_DECREF(o);
        return -1;
    }
    Py_DECREF(o);
}
```

int PyDict_Merge(PyObject *a, PyObject *b, int override)
Iterate over mapping object $b$ adding key-value pairs to dictionary $a$. $b$ may be a dictionary, or any object supporting `PyMapping_Keys()` and `PyObject_GetItem()`. If `override` is true, existing pairs in $a$ will be replaced if a matching key is found in $b$, otherwise pairs will only be added if there is not a matching key.
in a. Return 0 on success or -1 if an exception was raised.

int **PyDict_Update**(PyObject *a, PyObject *b)

This is the same as **PyDict_Merge**(a, b, 1) in C, and is similar to a.update(b) in Python except that **PyDict_Update()** doesn't fall back to the iterating over a sequence of key value pairs if the second argument has no “keys” attribute. Return 0 on success or -1 if an exception was raised.

int **PyDict_MergeFromSeq2**(PyObject *a, PyObject *seq2, int override)

Update or merge into dictionary a, from the key-value pairs in seq2. seq2 must be an iterable object producing iterable objects of length 2, viewed as key-value pairs. In case of duplicate keys, the last wins if override is true, else the first wins. Return 0 on success or -1 if an exception was raised. Equivalent Python (except for the return value):

```python
def PyDict_MergeFromSeq2(a, seq2, override):
    for key, value in seq2:
        if override or key not in a:
            a[key] = value
```

int **PyDict_ClearFreeList()**

Clear the free list. Return the total number of freed items.

*New in version 3.3.*
Last updated on Oct 03, 2017. Found a bug?
Created using Sphinx 1.6.3.
Set Objects

This section details the public API for `set` and `frozenset` objects. Any functionality not listed below is best accessed using the either the abstract object protocol (including `PyObject_CallMethod()`, `PyObject_RichCompareBool()`, `PyObject_Hash()`, `PyObject_Repr()`, `PyObject_IsTrue()`, `PyObject_Print()`, and `PyObject_GetIter()` or the abstract number protocol (including `PyNumber_And()`, `PyNumber_Subtract()`, `PyNumber_Or()`, `PyNumber_Xor()`, `PyNumber_InPlaceAnd()`, `PyNumber_InPlaceSubtract()`, `PyNumber_InPlaceOr()`, and `PyNumber_InPlaceXor()`).

**PySetObject**

This subtype of `PyObject` is used to hold the internal data for both `set` and `frozenset` objects. It is like a `PyDictObject` in that it is a fixed size for small sets (much like tuple storage) and will point to a separate, variable sized block of memory for medium and large sized sets (much like list storage). None of the fields of this structure should be considered public and are subject to change. All access should be done through the documented API rather than by manipulating the values in the structure.

**PyTypeObject PySet_Type**

This is an instance of `PyTypeObject` representing the Python `set` type.

**PyTypeObject PyFrozenSet_Type**

This is an instance of `PyTypeObject` representing the Python `frozenset` type.
The following type check macros work on pointers to any Python object. Likewise, the constructor functions work with any iterable Python object.

```c
int PySet_Check(PyObject *p)
    Return true if p is a set object or an instance of a subtype.

int PyFrozenSet_Check(PyObject *p)
    Return true if p is a frozenset object or an instance of a subtype.

int PyAnySet_Check(PyObject *p)
    Return true if p is a set object, a frozenset object, or an instance of a subtype.

int PyAnySet_CheckExact(PyObject *p)
    Return true if p is a set object or a frozenset object but not an instance of a subtype.

int PyFrozenSet_CheckExact(PyObject *p)
    Return true if p is a frozenset object but not an instance of a subtype.
```

```c
PyObject* PySet_New(PyObject *iterable)
    Return a new set containing objects returned by the iterable. The iterable may be NULL to create a new empty set. Return the new set on success or NULL on failure. Raise TypeError if iterable is not actually iterable. The constructor is also useful for copying a set (c=set(s)).

PyObject* PyFrozenSet_New(PyObject *iterable)
```
Return a new `frozenset` containing objects returned by the `iterable`. The `iterable` may be `NULL` to create a new empty frozenset. Return the new set on success or `NULL` on failure. Raise `TypeError` if `iterable` is not actually iterable.

The following functions and macros are available for instances of `set` or `frozenset` or instances of their subtypes.

**Py_ssize_t PySet_Size(PyObject *anyset)**

Return the length of a `set` or `frozenset` object. Equivalent to `len(anyset)`. Raises a `PyExc_SystemError` if `anyset` is not a `set`, `frozenset`, or an instance of a subtype.

**Py_ssize_t PySet_GET_SIZE(PyObject *anyset)**

Macro form of `PySet_Size()` without error checking.

**int PySet_Contains(PyObject *anyset, PyObject *key)**

Return `1` if found, `0` if not found, and `-1` if an error is encountered. Unlike the Python `__contains__()` method, this function does not automatically convert unhashable sets into temporary frozensets. Raise a `TypeError` if the `key` is unhashable. Raise `PyExc_SystemError` if `anyset` is not a `set`, `frozenset`, or an instance of a subtype.

**int PySet_Add(PyObject *set, PyObject *key)**

Add `key` to a `set` instance. Also works with `frozenset` instances (like `PyTuple_SetItem()` it can be used to fill-in the values of brand new frozensets before they are exposed to other code). Return `0` on success or `-1` on failure. Raise a `TypeError` if the `key` is unhashable. Raise a `MemoryError` if there is no room to grow. Raise a `SystemError` if `set` is not an instance of `set` or its
The following functions are available for instances of `set` or its subtypes but not for instances of `frozenset` or its subtypes.

```
int PySet_Discard(PyObject *set, PyObject *key)
```

Return 1 if found and removed, 0 if not found (no action taken), and -1 if an error is encountered. Does not raise `KeyError` for missing keys. Raise a `TypeError` if the `key` is unhashable. Unlike the Python `discard()` method, this function does not automatically convert unhashable sets into temporary frozensets. Raise `PyExc_SystemError` if `set` is not an instance of `set` or its subtype.

```
PyObject* PySet_Pop(PyObject *set)
```

*Return value: New reference.*

Return a new reference to an arbitrary object in the `set`, and removes the object from the `set`. Return `NULL` on failure. Raise `KeyError` if the set is empty. Raise a `SystemError` if `set` is not an instance of `set` or its subtype.

```
int PySet_Clear(PyObject *set)
```

Empty an existing set of all elements.

```
int PySet_ClearFreeList()
```

Clear the free list. Return the total number of freed items.

*New in version 3.3.*
Function Objects

There are a few functions specific to Python functions.

**PyFunctionObject**

The C structure used for functions.

**PyTypeObject PyFunction_Type**

This is an instance of `PyTypeObject` and represents the Python function type. It is exposed to Python programmers as `types.FunctionType`.

```c
int PyFunction_Check(PyObject *o)
```

Return true if `o` is a function object (has type `PyFunction_Type`). The parameter must not be `NULL`.

```c
PyObject* PyFunction_New(PyObject *code, PyObject *globals)
```

*Return value: New reference.*

Return a new function object associated with the code object `code`. `globals` must be a dictionary with the global variables accessible to the function.

The function’s docstring and name are retrieved from the code object. `__module__` is retrieved from `globals`. The argument defaults, annotations and closure are set to `NULL`. `__qualname__` is set to the same value as the function’s name.

```c
PyObject* PyFunction_NewWithQualName(PyObject *code, PyObject *globals, PyObject *qualname)
```

*Return value: New reference.*

As `PyFunction_New()`, but also allows setting the function
object's __qualname__ attribute. **qualname** should be a unicode object or NULL; if NULL, the __qualname__ attribute is set to the same value as its __name__ attribute.

*New in version 3.3.*

**PyObject** * PyFunction_GetCode (PyObject *op)  
*Return value: Borrowed reference.*  
Return the code object associated with the function object op.

**PyObject** * PyFunction_GetGlobals (PyObject *op)  
*Return value: Borrowed reference.*  
Return the globals dictionary associated with the function object op.

**PyObject** * PyFunction_GetModule (PyObject *op)  
*Return value: Borrowed reference.*  
Return the __module__ attribute of the function object op. This is normally a string containing the module name, but can be set to any other object by Python code.

**PyObject** * PyFunction_GetDefaults (PyObject *op)  
*Return value: Borrowed reference.*  
Return the argument default values of the function object op. This can be a tuple of arguments or **NULL**.

**int** PyFunction_SetDefaults (PyObject *op, PyObject *defaults)  
Set the argument default values for the function object op. **defaults** must be **None** or a tuple.

Raises **SystemError** and returns -1 on failure.
PyObject* **PyFunction_GetClosure**(PyObject *op)

*Return value: Borrowed reference.*

Return the closure associated with the function object *op*. This can be NULL or a tuple of cell objects.

int **PyFunction_SetClosure**(PyObject *op, PyObject *closure)

Set the closure associated with the function object *op*. *closure* must be *Py_None* or a tuple of cell objects.

Raises **SystemError** and returns -1 on failure.

PyObject* **PyFunction_GetAnnotations**(PyObject *op)

Return the annotations of the function object *op*. This can be a mutable dictionary or NULL.

int **PyFunction_SetAnnotations**(PyObject *op, PyObject *annotations)

Set the annotations for the function object *op*. *annotations* must be a dictionary or *Py_None*.

Raises **SystemError** and returns -1 on failure.
Instance Method Objects

An instance method is a wrapper for a PyCFunction and the new way to bind a PyCFunction to a class object. It replaces the former call PyMethod_New(func, NULL, class).

PyTypeObject PyInstanceMethod_Type

This instance of PyTypeObject represents the Python instance method type. It is not exposed to Python programs.

int PyInstanceMethod_Check(PyObject *o)

Return true if o is an instance method object (has type PyInstanceMethod_Type). The parameter must not be NULL.

PyObject* PyInstanceMethod_New(PyObject *func)

Return a new instance method object, with func being any callable object func is the function that will be called when the instance method is called.

PyObject* PyInstanceMethod_Function(PyObject *im)

Return the function object associated with the instance method im.

PyObject*
PyInstanceMethod_GET_FUNCTION(PyObject *im)

Macro version of PyInstanceMethod_Function() which avoids error checking.
Method Objects

Methods are bound function objects. Methods are always bound to an instance of a user-defined class. Unbound methods (methods bound to a class object) are no longer available.

PyTypeObject PyMethod_Type

This instance of PyTypeObject represents the Python method type. This is exposed to Python programs as types.MethodType.

int PyMethod_Check(PyObject *o)

Return true if o is a method object (has type PyMethod_Type). The parameter must not be NULL.

PyObject* PyMethod_New(PyObject *func, PyObject *self)

Return a new method object, with func being any callable object and self the instance the method should be bound. func is the function that will be called when the method is called. self must not be NULL.

PyObject* PyMethod_Function(PyObject *meth)

Return value: Borrowed reference.
Return the function object associated with the method meth.

PyObject* PyMethod_GET_FUNCTION(PyObject *meth)

Return value: Borrowed reference.
Macro version of PyMethod_Function() which avoids error checking.
PyObject* PyMethod_Self(PyObject *meth)

*Return value: Borrowed reference.*
Return the instance associated with the method `meth`.

PyObject* PyMethod_GET_SELF(PyObject *meth)

*Return value: Borrowed reference.*
Macro version of `PyMethod_Self()` which avoids error checking.

int PyMethod_ClearFreeList()

Clear the free list. Return the total number of freed items.
Cell Objects

“Cell” objects are used to implement variables referenced by multiple scopes. For each such variable, a cell object is created to store the value; the local variables of each stack frame that references the value contains a reference to the cells from outer scopes which also use that variable. When the value is accessed, the value contained in the cell is used instead of the cell object itself. This de-referencing of the cell object requires support from the generated byte-code; these are not automatically de-referenced when accessed. Cell objects are not likely to be useful elsewhere.

**PyCellObject**

The C structure used for cell objects.

**PyTypeObject PyCell_Type**

The type object corresponding to cell objects.

```c
int PyCell_Check(ob)
    Return true if ob is a cell object; ob must not be NULL.
```

```c
PyObject* PyCell_New(PyObject *ob)
    Create and return a new cell object containing the value ob. The parameter may be NULL.
```

```c
PyObject* PyCell_Get(PyObject *cell)
    Return the contents of the cell cell.
```

```c
PyObject* PyCell_GET(PyObject *cell)
    Return value: Borrowed reference.
```
Return the contents of the cell `cell`, but without checking that `cell` is non-NULL and a cell object.

```c
int PyCell_Set(PyObject *cell, PyObject *value)
```

Set the contents of the cell object `cell` to `value`. This releases the reference to any current content of the cell. `value` may be `NULL`. `cell` must be non-NULL; if it is not a cell object, `-1` will be returned. On success, `0` will be returned.

```c
void PyCell_SET(PyObject *cell, PyObject *value)
```

Sets the value of the cell object `cell` to `value`. No reference counts are adjusted, and no checks are made for safety; `cell` must be non-NULL and must be a cell object.
Code Objects

Code objects are a low-level detail of the CPython implementation. Each one represents a chunk of executable code that hasn’t yet been bound into a function.

**PyCodeObject**

The C structure of the objects used to describe code objects. The fields of this type are subject to change at any time.

**PyTypeObject PyCode_Type**

This is an instance of PyTypeObject representing the Python code type.

```
int PyCode_Check(PyObject *co)
```

Return true if co is a code object.

```
int PyCode_GetNumFree(PyCodeObject *co)
```

Return the number of free variables in co.

```
PyCodeObject* PyCode_New(int argcount, int kwonlyargcount,
int nlocals, int stacksize, int flags, PyObject *code, PyObject *consts,
PyObject *names, PyObject *varnames, PyObject *freevars,
PyObject *cellvars, PyObject *filename, PyObject *name,
int firstlineno, PyObject *lnotab)
```

Return a new code object. If you need a dummy code object to create a frame, use PyCode_NewEmpty() instead. Calling PyCode_New() directly can bind you to a precise Python version since the definition of the bytecode changes often.

```
PyCodeObject* PyCode_NewEmpty(const char *filename, const char *funcname, int firstlineno)
```
Return a new empty code object with the specified filename, function name, and first line number. It is illegal to `exec()` or `eval()` the resulting code object.
File Objects

These APIs are a minimal emulation of the Python 2 C API for built-in file objects, which used to rely on the buffered I/O (FILE*) support from the C standard library. In Python 3, files and streams use the new io module, which defines several layers over the low-level unbuffered I/O of the operating system. The functions described below are convenience C wrappers over these new APIs, and meant mostly for internal error reporting in the interpreter; third-party code is advised to access the io APIs instead.

**PyFile_FromFd**

```c
(int fd, const char *name, const char *mode,
 int buffering, const char *encoding, const char *errors, const char *newline, int closefd)
```

Create a Python file object from the file descriptor of an already opened file `fd`. The arguments `name`, `encoding`, `errors` and `newline` can be NULL to use the defaults; `buffering` can be -1 to use the default. `name` is ignored and kept for backward compatibility. Return NULL on failure. For a more comprehensive description of the arguments, please refer to the io.open() function documentation.

**Warning:** Since Python streams have their own buffering layer, mixing them with OS-level file descriptors can produce various issues (such as unexpected ordering of data).

*Changed in version 3.2:* Ignore `name` attribute.

**int PyObject_AsFileDescriptor**

```c
(PyObject *p)
```

Return the file descriptor associated with `p` as an int. If the object is an integer, its value is returned. If not, the object's fileno()
method is called if it exists; the method must return an integer, which is returned as the file descriptor value. Sets an exception and returns -1 on failure.

PyObject* PyFile_GetLine(PyObject *p, int n)

Equivalent to p.readline([n]), this function reads one line from the object p. p may be a file object or any object with a readline() method. If n is 0, exactly one line is read, regardless of the length of the line. If n is greater than 0, no more than n bytes will be read from the file; a partial line can be returned. In both cases, an empty string is returned if the end of the file is reached immediately. If n is less than 0, however, one line is read regardless of length, but EOFError is raised if the end of the file is reached immediately.

int PyFile_WriteObject(PyObject *obj, PyObject *p, int flags)
Write object obj to file object p. The only supported flag for flags is Py_PRINT_RAW; if given, the str() of the object is written instead of the repr(). Return 0 on success or -1 on failure; the appropriate exception will be set.

int PyFile_WriteString(const char*s, PyObject *p)
Write string s to file object p. Return 0 on success or -1 on failure; the appropriate exception will be set.
Module Objects

**PyTypeObject PyModule_Type**

This instance of `PyTypeObject` represents the Python module type. This is exposed to Python programs as `types.ModuleType`.

```c
int PyModule_Check(PyObject *p)

Return true if `p` is a module object, or a subtype of a module object.
```

```c
int PyModule_CheckExact(PyObject *p)

Return true if `p` is a module object, but not a subtype of `PyModule_Type`.
```

**PyObject* PyModule_NewObject(PyObject *name)**

Return a new module object with the `__name__` attribute set to `name`. The module's `__name__`, `__doc__`, `__package__`, and `__loader__` attributes are filled in (all but `__name__` are set to `None`; the caller is responsible for providing a `__file__` attribute.

*New in version 3.3.*

*Changed in version 3.4:* `__package__` and `__loader__` are set to `None`.

**PyObject* PyModule_New(const char *name)**

*Return value: New reference.*

Similar to `PyModule_NewObject()`, but the name is a UTF-8 encoded string instead of a Unicode object.

**PyObject* PyModule_GetDict(PyObject *module)**
Return value: Borrowed reference.
Return the dictionary object that implements module’s namespace; this object is the same as the __dict__ attribute of the module object. If module is not a module object (or a subtype of a module object), SystemError is raised and NULL is returned.

It is recommended extensions use other PyModule_*( ) and PyObject_*( ) functions rather than directly manipulate a module’s __dict__.

PyObject* PyModuleGetNameObject(PyObject *module)
Return module’s __name__ value. If the module does not provide one, or if it is not a string, SystemError is raised and NULL is returned.

New in version 3.3.

char* PyModuleGetName(PyObject *module)
Similar to PyModuleGetNameObject() but return the name encoded to 'utf-8'.

void* PyModuleGetState(PyObject *module)
Return the “state” of the module, that is, a pointer to the block of memory allocated at module creation time, or NULL. See PyModuleDef.m_size.

PyModuleDef* PyModuleGetDef(PyObject *module)
Return a pointer to the PyModuleDef struct from which the module was created, or NULL if the module wasn’t created from a definition.

PyObject*
PyModuleGetFilenameObject(PyObject *module)
Return the name of the file from which module was loaded using module's `__file__` attribute. If this is not defined, or if it is not a unicode string, raise `SystemError` and return `NULL`; otherwise return a reference to a Unicode object.

*New in version 3.2.*

```c
char* PyModule_GetFilename(PyObject *module)
```

Similar to `PyModule_GetFilenameObject()` but return the filename encoded to 'utf-8'.

*Deprecated since version 3.2:* `PyModule_GetFilename()` raises `UnicodeEncodeError` on unencodable filenames, use `PyModule_GetFilenameObject()` instead.
**Initializing C modules**

Modules objects are usually created from extension modules (shared libraries which export an initialization function), or compiled-in modules (where the initialization function is added using `PyImport_AppendInittab()`). See Building C and C++ Extensions or Extending Embedded Python for details.

The initialization function can either pass a module definition instance to `PyModule_Create()`, and return the resulting module object, or request “multi-phase initialization” by returning the definition struct itself.

**PyModuleDef**

The module definition struct, which holds all information needed to create a module object. There is usually only one statically initialized variable of this type for each module.

PyModuleDef_Base m_base

Always initialize this member to `PyModuleDef_HEAD_INIT`.

char* m_name

Name for the new module.

char* m_doc

Docstring for the module; usually a docstring variable created with `PyDoc_STRVAR()` is used.

Py_ssize_t m_size

Module state may be kept in a per-module memory area that can be retrieved with `PyModule_GetState()`, rather than in static globals. This makes modules safe for use in multiple sub-
interpreters.

This memory area is allocated based on \textit{m\_size} on module creation, and freed when the module object is deallocated, after the \textit{m\_free} function has been called, if present.

Setting \textit{m\_size} to \texttt{-1} means that the module does not support sub-interpreters, because it has global state.

Setting it to a non-negative value means that the module can be re-initialized and specifies the additional amount of memory it requires for its state. Non-negative \textit{m\_size} is required for multi-phase initialization.

See \textbf{PEP 3121} for more details.

\textbf{PyMethodDef*} \textit{m\_methods}

A pointer to a table of module-level functions, described by \textbf{PyMethodDef} values. Can be \textit{NULL} if no functions are present.

\textbf{PyModuleDef\_Slot*} \textit{m\_slots}

An array of slot definitions for multi-phase initialization, terminated by a \{0, \text{NULL}\} entry. When using single-phase initialization, \textit{m\_slots} must be \textit{NULL}.

\textit{Changed in version 3.5:} Prior to version 3.5, this member was always set to \textit{NULL}, and was defined as:

\begin{verbatim}
   inquiry m\_reload
\end{verbatim}

\textbf{traverseproc} \textit{m\_traverse}

A traversal function to call during GC traversal of the module object, or \textit{NULL} if not needed.
inquiry m_clear
A clear function to call during GC clearing of the module object, or NULL if not needed.

freefunc m_free
A function to call during deallocation of the module object, or NULL if not needed.

Single-phase initialization

The module initialization function may create and return the module object directly. This is referred to as “single-phase initialization”, and uses one of the following two module creation functions:

PyObject* PyModule_Create(PyModuleDef *def)
Create a new module object, given the definition in def. This behaves like PyModule_Create2() with module_api_version set to PYTHON_API_VERSION.

PyObject* PyModule_Create2(PyModuleDef *def, int module_api_version)
Create a new module object, given the definition in def, assuming the API version module_api_version. If that version does not match the version of the running interpreter, a RuntimeWarning is emitted.

**Note:** Most uses of this function should be using PyModule_Create() instead; only use this if you are sure you need it.

Before it is returned from in the initialization function, the resulting module object is typically populated using functions like
PyModule_AddObject().

# Multi-phase initialization

An alternate way to specify extensions is to request “multi-phase initialization”. Extension modules created this way behave more like Python modules: the initialization is split between the *creation phase*, when the module object is created, and the *execution phase*, when it is populated. The distinction is similar to the `__new__()` and `__init__()` methods of classes.

Unlike modules created using single-phase initialization, these modules are not singletons: if the `sys.modules` entry is removed and the module is re-imported, a new module object is created, and the old module is subject to normal garbage collection – as with Python modules. By default, multiple modules created from the same definition should be independent: changes to one should not affect the others. This means that all state should be specific to the module object (using e.g. using `PyModule_GetState()`), or its contents (such as the module’s `__dict__` or individual classes created with `PyType_FromSpec()`).

All modules created using multi-phase initialization are expected to support *sub-interpreters*. Making sure multiple modules are independent is typically enough to achieve this.

To request multi-phase initialization, the initialization function (PyInit_modulename) returns a `PyModuleDef` instance with non-empty `m_slots`. Before it is returned, the `PyModuleDef` instance must be initialized with the following function:

```c
PyObject* PyModuleDef_Init(PyModuleDef *def)
```
Ensures a module definition is a properly initialized Python object that correctly reports its type and reference count.

Returns `def` cast to `PyObject*`, or `NULL` if an error occurred.

*New in version 3.5.*

The `m_slots` member of the module definition must point to an array of `PyModuleDef_Slot` structures:

**PyModuleDef_Slot**

- `int slot`
  A slot ID, chosen from the available values explained below.

- `void* value`
  Value of the slot, whose meaning depends on the slot ID.

*New in version 3.5.*

The `m_slots` array must be terminated by a slot with id 0.

The available slot types are:

**Py_mod_create**

Specifies a function that is called to create the module object itself. The `value` pointer of this slot must point to a function of the signature:

```
PyObject* create_module(PyObject *spec, PyModuleDef *def)
```

The function receives a `ModuleSpec` instance, as defined in PEP 451, and the module definition. It should return a new module object, or set an error and return `NULL`. 

This function should be kept minimal. In particular, it should not call arbitrary Python code, as trying to import the same module again may result in an infinite loop.

Multiple `Py_mod_create` slots may not be specified in one module definition.

If `Py_mod_create` is not specified, the import machinery will create a normal module object using `PyModule_New()`. The name is taken from `spec`, not the definition, to allow extension modules to dynamically adjust to their place in the module hierarchy and be imported under different names through symlinks, all while sharing a single module definition.

There is no requirement for the returned object to be an instance of `PyModule_Type`. Any type can be used, as long as it supports setting and getting import-related attributes. However, only `PyModule_Type` instances may be returned if the `PyModuleDef` has non-NULL `m_traverse`, `m_clear`, `m_free`; non-zero `m_size`; or slots other than `Py_mod_create`.

**Py_mod_exec**

Specifies a function that is called to *execute* the module. This is equivalent to executing the code of a Python module: typically, this function adds classes and constants to the module. The signature of the function is:

```c
int exec_module(PyObject* module)
```

If multiple `Py_mod_exec` slots are specified, they are processed in the order they appear in the `m_slots` array.

See PEP 489 for more details on multi-phase initialization.
Low-level module creation functions

The following functions are called under the hood when using multi-phase initialization. They can be used directly, for example when creating module objects dynamically. Note that both PyModule_FromDefAndSpec and PyModule_ExecDef must be called to fully initialize a module.

PyObject * PyModule_FromDefAndSpec(PyObject *module, PyObject *spec)
    Create a new module object, given the definition in `module` and the `ModuleSpec` `spec`. This behaves like PyModule_FromDefAndSpec2() with `module_api_version` set to PYTHON_API_VERSION.

    New in version 3.5.

PyObject * PyModule_FromDefAndSpec2(PyObject *module, PyObject *spec, int module_api_version)
    Create a new module object, given the definition in `module` and the `ModuleSpec spec`, assuming the API version `module_api_version`. If that version does not match the version of the running interpreter, a RuntimeWarning is emitted.

    Note: Most uses of this function should be using PyModule_FromDefAndSpec() instead; only use this if you are sure you need it.

    New in version 3.5.

int PyModule_ExecDef(PyObject *module, PyModuleDef *def)
    Process any execution slots (Py_mod_exec) given in `def`. 
New in version 3.5.

int PyModule_SetDocString(PyObject *module, const char *docstring)

Set the docstring for module to docstring. This function is called automatically when creating a module from PyModuleDef, using either PyModule_Create or PyModule_FromDefAndSpec.

New in version 3.5.

int PyModule_AddFunctions(PyObject *module, PyMethodDef *functions)

Add the functions from the NULL terminated functions array to module. Refer to the PyMethodDef documentation for details on individual entries (due to the lack of a shared module namespace, module level “functions” implemented in C typically receive the module as their first parameter, making them similar to instance methods on Python classes). This function is called automatically when creating a module from PyModuleDef, using either PyModule_Create or PyModule_FromDefAndSpec.

New in version 3.5.

Support functions

The module initialization function (if using single phase initialization) or a function called from a module execution slot (if using multi-phase initialization), can use the following functions to help initialize the module state:

int PyModule_AddObject(PyObject *module, const char *name, PyObject *value)
Add an object to *module* as *name*. This is a convenience function which can be used from the module's initialization function. This steals a reference to *value*. Return -1 on error, 0 on success.

```c
int PyModule_AddIntConstant(PyObject *module, const char *name, long value)
    Add an integer constant to *module* as *name*. This convenience function can be used from the module's initialization function. Return -1 on error, 0 on success.
```

```c
int PyModule_AddStringConstant(PyObject *module, const char *name, const char *value)
    Add a string constant to *module* as *name*. This convenience function can be used from the module's initialization function. The string *value* must be *NULL*-terminated. Return -1 on error, 0 on success.
```

```c
int PyModule_AddIntMacro(PyObject *module, macro)
    Add an int constant to *module*. The name and the value are taken from *macro*. For example `PyModule_AddIntMacro(module, AF_INET)` adds the int constant *AF_INET* with the value of *AF_INET* to *module*. Return -1 on error, 0 on success.
```

```c
int PyModule_AddStringMacro(PyObject *module, macro)
    Add a string constant to *module*.
```
Module lookup

Single-phase initialization creates singleton modules that can be looked up in the context of the current interpreter. This allows the module object to be retrieved later with only a reference to the module definition.

These functions will not work on modules created using multi-phase initialization, since multiple such modules can be created from a single definition.

PyObject* PyState_FindModule(PyModuleDef *def)

Returns the module object that was created from def for the current interpreter. This method requires that the module object has been attached to the interpreter state with PyState_AddModule() beforehand. In case the corresponding module object is not found or has not been attached to the interpreter state yet, it returns NULL.

int PyState_AddModule(PyObject *module, PyModuleDef *def)

Attaches the module object passed to the function to the interpreter state. This allows the module object to be accessible via PyState_FindModule().

Only effective on modules created using single-phase initialization.

New in version 3.3.

int PyState_RemoveModule(PyModuleDef *def)

Removes the module object created from def from the interpreter state.
New in version 3.3.
Iterator Objects

Python provides two general-purpose iterator objects. The first, a sequence iterator, works with an arbitrary sequence supporting the \_\_getitem\_\_() method. The second works with a callable object and a sentinel value, calling the callable for each item in the sequence, and ending the iteration when the sentinel value is returned.

**PyTypeObject PySeqIter_Type**

Type object for iterator objects returned by `PySeqIter_New()` and the one-argument form of the `iter()` built-in function for built-in sequence types.

```c
int PySeqIter_Check(op)
   Return true if the type of op is PySeqIter_Type.
```

**PyObject* PySeqIter_New(PyObject *seq)**

*Return value: New reference.*

Return an iterator that works with a general sequence object, `seq`. The iteration ends when the sequence raises `IndexError` for the subscripting operation.

**PyTypeObject PyCallIter_Type**

Type object for iterator objects returned by `PyCallIter_New()` and the two-argument form of the `iter()` built-in function.

```c
int PyCallIter_Check(op)
   Return true if the type of op is PyCallIter_Type.
```

**PyObject* PyCallIter_New(PyObject *callable, PyObject *sentinel)**
**Return value: New reference.**

Return a new iterator. The first parameter, `callable`, can be any Python callable object that can be called with no parameters; each call to it should return the next item in the iteration. When `callable` returns a value equal to `sentinel`, the iteration will be terminated.
Descriptor Objects

“Descriptors” are objects that describe some attribute of an object. They are found in the dictionary of type objects.

*PyTypeObject* **PyProperty**._**Type**

The type object for the built-in descriptor types.

*PyObject* **PyDescr**._**NewGetSet**(*PyTypeObject* *type*, struct *PyGetSetDef* *getset*)

*Return value: New reference.*

*PyObject* **PyDescr**._**NewMember**(*PyTypeObject* *type*, struct *PyMemberDef* *meth*)

*Return value: New reference.*

*PyObject* **PyDescr**._**NewMethod**(*PyTypeObject* *type*, struct *PyMethodDef* *meth*)

*Return value: New reference.*

*PyObject* **PyDescr**._**NewWrapper**(*PyTypeObject* *type*, struct wrapperbase *wrapper*, void *wrapped*)

*Return value: New reference.*

*PyObject* **PyDescr**._**NewClassMethod**(*PyTypeObject* *type*, struct *PyMethodDef* *method*)

*Return value: New reference.*

*int* **PyDescr**._**IsData**(*PyObject* *descr*)

Return true if the descriptor objects *descr* describes a data attribute, or false if it describes a method. *descr* must be a descriptor object; there is no error checking.
PyObject* PyWrapper_New(PyObject *, PyObject *)

Slice Objects

PyTypeObject **PySlice_Type**

The type object for slice objects. This is the same as *slice* in the Python layer.

int **PySlice_Check**(PyObject *ob)

Return true if *ob* is a slice object; *ob* must not be *NULL*.

PyObject* **PySlice_New**(PyObject *start, PyObject *stop, PyObject *step)

*Return value: New reference.*

Return a new slice object with the given values. The *start*, *stop*, and *step* parameters are used as the values of the slice object attributes of the same names. Any of the values may be *NULL*, in which case the None will be used for the corresponding attribute. Return *NULL* if the new object could not be allocated.

int **PySlice_GetIndices**(PyObject *slice, Py_ssize_t *length, Py_ssize_t *start, Py_ssize_t *stop, Py_ssize_t *step)

Retrieve the start, stop and step indices from the slice object *slice*, assuming a sequence of length *length*. Treats indices greater than *length* as errors.

Returns 0 on success and -1 on error with no exception set (unless one of the indices was not *None* and failed to be converted to an integer, in which case -1 is returned with an exception set).

You probably do not want to use this function.

*Changed in version 3.2:* The parameter type for the *slice* parameter
was PySliceObject* before.

int PySlice_GetIndicesEx(PyObject *slice, Py_ssize_t length, Py_ssize_t *start, Py_ssize_t *stop, Py_ssize_t *step, Py_ssize_t *slicelength)

Usable replacement for PySlice_GetIndices(). Retrieve the start, stop, and step indices from the slice object slice assuming a sequence of length length, and store the length of the slice in slicelength. Out of bounds indices are clipped in a manner consistent with the handling of normal slices.

Returns 0 on success and -1 on error with exception set.

*Changed in version 3.2:* The parameter type for the slice parameter was PySliceObject* before.
Ellipsis Object

PyObject *Py_Ellipsis

The Python Ellipsis object. This object has no methods. It needs to be treated just like any other object with respect to reference counts. Like Py_None it is a singleton object.
MemoryView objects

A memoryview object exposes the C level buffer interface as a Python object which can then be passed around like any other object.

PyObject *PyMemoryView_FromObject(PyObject *obj)
Create a memoryview object from an object that provides the buffer interface. If obj supports writable buffer exports, the memoryview object will be read/write, otherwise it may be either read-only or read/write at the discretion of the exporter.

PyObject *PyMemoryView_FromMemory(char *mem, Py_ssize_t size, int flags)
Create a memoryview object using mem as the underlying buffer. flags can be one of PyBUF_READ or PyBUF_WRITE.

    New in version 3.3.

PyObject *PyMemoryView_FromBuffer(Py_buffer *view)
Create a memoryview object wrapping the given buffer structure view. For simple byte buffers, PyMemoryView_FromMemory() is the preferred function.

PyObject *PyMemoryView_GetContiguous(PyObject *obj, int buffertype, char order)
Create a memoryview object to a contiguous chunk of memory (in either ‘C’ or ‘F’ortran order) from an object that defines the buffer interface. If memory is contiguous, the memoryview object points to the original memory. Otherwise, a copy is made and the memoryview points to a new bytes object.
int PyMemoryView_Check(PyObject *obj)
Return true if the object obj is a memoryview object. It is not currently allowed to create subclasses of memoryview.

Py_buffer *PyMemoryView_GET_BUFFER(PyObject *mview)
Return a pointer to the memoryview's private copy of the exporter's buffer. mview must be a memoryview instance; this macro doesn't check its type, you must do it yourself or you will risk crashes.

Py_buffer *PyMemoryView_GET_BASE(PyObject *mview)
Return either a pointer to the exporting object that the memoryview is based on or NULL if the memoryview has been created by one of the functions PyMemoryView_FromMemory() or PyMemoryView_FromBuffer(). mview must be a memoryview instance.
Weak Reference Objects

Python supports *weak references* as first-class objects. There are two specific object types which directly implement weak references. The first is a simple reference object, and the second acts as a proxy for the original object as much as it can.

```c
int PyWeakref_Check(ob)
    Return true if ob is either a reference or proxy object.

int PyWeakref_CheckRef(ob)
    Return true if ob is a reference object.

int PyWeakref_CheckProxy(ob)
    Return true if ob is a proxy object.
```

```c
PyObject* PyWeakref_NewRef(PyObject *ob, PyObject *callback)
    Return a weak reference object for the object ob. This will always return a new reference, but is not guaranteed to create a new object; an existing reference object may be returned. The second parameter, callback, can be a callable object that receives notification when ob is garbage collected; it should accept a single parameter, which will be the weak reference object itself. callback may also be None or NULL. If ob is not a weakly-referencable object, or if callback is not callable, None, or NULL, this will return NULL and raise TypeError.

PyObject* PyWeakref_NewProxy(PyObject *ob, PyObject *callback)
```
Return a weak reference proxy object for the object `ob`. This will always return a new reference, but is not guaranteed to create a new object; an existing proxy object may be returned. The second parameter, `callback`, can be a callable object that receives notification when `ob` is garbage collected; it should accept a single parameter, which will be the weak reference object itself. `callback` may also be `None` or `NULL`. If `ob` is not a weakly-referencable object, or if `callback` is not callable, `None`, or `NULL`, this will return `NULL` and raise `TypeError`.

`PyObject* PyWeakref_GetObject(PyObject *ref)`

Return value: Borrowed reference.
Return the referenced object from a weak reference, `ref`. If the referent is no longer live, returns `Py_None`.

Note: This function returns a borrowed reference to the referenced object. This means that you should always call `Py_INCREF()` on the object except if you know that it cannot be destroyed while you are still using it.

`PyObject* PyWeakref_GET_OBJECT(PyObject *ref)`

Return value: Borrowed reference.
Similar to `PyWeakref_GetObject()`, but implemented as a macro that does no error checking.
Capsules

Refer to **Providing a C API for an Extension Module** for more information on using these objects.

**PyCapsule**

This subtype of **PyObject** represents an opaque value, useful for C extension modules who need to pass an opaque value (as a void* pointer) through Python code to other C code. It is often used to make a C function pointer defined in one module available to other modules, so the regular import mechanism can be used to access C APIs defined in dynamically loaded modules.

**PyCapsule_Destructor**

The type of a destructor callback for a capsule. Defined as:

```c
typedef void (*PyCapsule_Destructor)(PyObject *);
```

See **PyCapsule_New()** for the semantics of PyCapsule_Destructor callbacks.

```c
int PyCapsule_CheckExact(PyObject *p)
```

Return true if its argument is a **PyCapsule**.

```c
PyObject* PyCapsule_New(void *pointer, const char *name, PyCapsule_Destructor destructor)
```

*Return value: New reference.*

Create a **PyCapsule** encapsulating the **pointer**. The **pointer** argument may not be **NULL**.

On failure, set an exception and return **NULL**.
The *name* string may either be *NULL* or a pointer to a valid C string. If non-NULL, this string must outlive the capsule. (Though it is permitted to free it inside the *destructor.*)

If the *destructor* argument is not *NULL*, it will be called with the capsule as its argument when it is destroyed.

If this capsule will be stored as an attribute of a module, the *name* should be specified as *modulename.attributename*. This will enable other modules to import the capsule using PyCapsule_Import().

```c
void* PyCapsule_GetPointer(PyObject *capsule, const char *name)
```

Retrieve the *pointer* stored in the capsule. On failure, set an exception and return *NULL*.

The *name* parameter must compare exactly to the name stored in the capsule. If the name stored in the capsule is *NULL*, the *name* passed in must also be *NULL*. Python uses the C function `strcmp()` to compare capsule names.

```c
PyCapsule_Destructor
PyCapsule_GetDestructor(PyObject *capsule)
```

Return the current destructor stored in the capsule. On failure, set an exception and return *NULL*.

It is legal for a capsule to have a *NULL* destructor. This makes a *NULL* return code somewhat ambiguous; use PyCapsule_IsValid() or PyErr_Occurred() to disambiguate.

```c
void* PyCapsule_GetContext(PyObject *capsule)
```
Return the current context stored in the capsule. On failure, set an exception and return \textit{NULL}.

It is legal for a capsule to have a \textit{NULL} context. This makes a \textit{NULL} return code somewhat ambiguous; use \texttt{PyCapsule\_IsValid()} or \texttt{PyErr\_Occurred()} to disambiguate.

\texttt{const char* PyCapsule\_GetName(PyObject *capsule)}

Return the current name stored in the capsule. On failure, set an exception and return \textit{NULL}.

It is legal for a capsule to have a \textit{NULL} name. This makes a \textit{NULL} return code somewhat ambiguous; use \texttt{PyCapsule\_IsValid()} or \texttt{PyErr\_Occurred()} to disambiguate.

\texttt{void* PyCapsule\_Import(const char *name, int no\_block)}

Import a pointer to a C object from a capsule attribute in a module. The \textit{name} parameter should specify the full name to the attribute, as in \texttt{module.attribute}. The \textit{name} stored in the capsule must match this string exactly. If \texttt{no\_block} is true, import the module without blocking (using \texttt{PyImport\_ImportModuleNoBlock()}). If \texttt{no\_block} is false, import the module conventionally (using \texttt{PyImport\_ImportModule()}).

Return the capsule’s internal \textit{pointer} on success. On failure, set an exception and return \textit{NULL}. However, if \texttt{PyCapsule\_Import()} failed to import the module, and \texttt{no\_block} was true, no exception is set.

\texttt{int PyCapsule\_IsValid(PyObject *capsule, const char *name)}

Determines whether or not \textit{capsule} is a valid capsule. A valid
capsule is non-NULL, passes `PyCapsule_CheckExact()`, has a non-NULL pointer stored in it, and its internal name matches the name parameter. (See `PyCapsule_GetPointer()` for information on how capsule names are compared.)

In other words, if `PyCapsule_IsValid()` returns a true value, calls to any of the accessors (any function starting with `PyCapsule_Get()`) are guaranteed to succeed.

Return a nonzero value if the object is valid and matches the name passed in. Return 0 otherwise. This function will not fail.

```c
int PyCapsule_SetContext(PyObject *capsule, void *context)
```

Set the context pointer inside `capsule` to `context`.

Return 0 on success. Return nonzero and set an exception on failure.

```c
int PyCapsule_SetDestructor(PyObject *capsule, PyCapsule_Destructor destructor)
```

Set the destructor inside `capsule` to `destructor`.

Return 0 on success. Return nonzero and set an exception on failure.

```c
int PyCapsule_SetName(PyObject *capsule, const char *name)
```

Set the name inside `capsule` to `name`. If non-NULL, the name must outlive the capsule. If the previous `name` stored in the capsule was not NULL, no attempt is made to free it.

Return 0 on success. Return nonzero and set an exception on failure.
int **PyCapsule_SetPointer**(PyObject *capsule, void *pointer)

Set the void pointer inside `capsule` to `pointer`. The pointer may not
be `NULL`.

Return 0 on success. Return nonzero and set an exception on
failure.
Generator Objects

Generator objects are what Python uses to implement generator iterators. They are normally created by iterating over a function that yields values, rather than explicitly calling PyGen_New() or PyGen_NewWithQualName().

**PyGenObject**

The C structure used for generator objects.

**PyTypeObject PyGen_Type**

The type object corresponding to generator objects.

int **PyGen_Check**(PyObject *ob)

Return true if ob is a generator object; ob must not be NULL.

int **PyGen_CheckExact**(PyObject *ob)

Return true if ob’s type is PyGen_Type; ob must not be NULL.

PyObject* **PyGen_New**(PyFrameObject *frame)

*Return value: New reference.*

Create and return a new generator object based on the frame object. A reference to frame is stolen by this function. The argument must not be NULL.

PyObject* **PyGen_NewWithQualName**(PyFrameObject *frame, PyObject *name, PyObject *qualname)

*Return value: New reference.*

Create and return a new generator object based on the frame object, with __name__ and __qualname__ set to name and qualname. A reference to frame is stolen by this function. The
frame argument must not be NULL.
Coroutine Objects

New in version 3.5.

Coroutine objects are what functions declared with an `async` keyword return.

**PyCoroObject**

The C structure used for coroutine objects.

**PyTypeObject** **PyCoro_Type**

The type object corresponding to coroutine objects.

```c
int PyCoro_CheckExact(PyObject *ob)
```

Return true if `ob`'s type is `PyCoro_Type`; `ob` must not be `NULL`.

```c
PyObject* PyCoro_New(PyFrameObject *frame, PyObject *name,
                     PyObject *qualname)
```

*Return value: New reference.*

Create and return a new coroutine object based on the `frame` object, with `__name__` and `__qualname__` set to `name` and `qualname`. A reference to `frame` is stolen by this function. The `frame` argument must not be `NULL`.
DateTime Objects

Various date and time objects are supplied by the `datetime` module. Before using any of these functions, the header file `datetime.h` must be included in your source (note that this is not included by `Python.h`), and the macro `PyDateTime_IMPORT` must be invoked, usually as part of the module initialisation function. The macro puts a pointer to a C structure into a static variable, `PyDateTimeAPI`, that is used by the following macros.

Type-check macros:

```c
int PyDate_Check(PyObject *ob)
    Return true if `ob` is of type `PyDateTime_DateType` or a subtype of `PyDateTime_DateType`. `ob` must not be `NULL`.
```

```c
int PyDate_CheckExact(PyObject *ob)
    Return true if `ob` is of type `PyDateTime_DateType`. `ob` must not be `NULL`.
```

```c
int PyDateTime_Check(PyObject *ob)
    Return true if `ob` is of type `PyDateTime_DateTimeType` or a subtype of `PyDateTime_DateTimeType`. `ob` must not be `NULL`.
```

```c
int PyDateTime_CheckExact(PyObject *ob)
    Return true if `ob` is of type `PyDateTime_DateTimeType`. `ob` must not be `NULL`.
```

```c
int PyTime_Check(PyObject *ob)
    Return true if `ob` is of type `PyDateTime_TimeType` or a subtype of `PyDateTime_TimeType`. `ob` must not be `NULL`.
```
int PyTime_CheckExact(PyObject *ob)
    Return true if ob is of type PyDateTime_TimeType. ob must not be NULL.

int PyDelta_Check(PyObject *ob)
    Return true if ob is of type PyDateTime_DeltaType or a subtype of PyDateTime_DeltaType. ob must not be NULL.

int PyDelta_CheckExact(PyObject *ob)
    Return true if ob is of type PyDateTime_DeltaType. ob must not be NULL.

int PyTZInfo_Check(PyObject *ob)
    Return true if ob is of type PyDateTime_TZInfoType or a subtype of PyDateTime_TZInfoType. ob must not be NULL.

int PyTZInfo_CheckExact(PyObject *ob)
    Return true if ob is of type PyDateTime_TZInfoType. ob must not be NULL.

Macros to create objects:

PyObject* PyDate_FromDate(int year, int month, int day)
    Return a datetime.date object with the specified year, month and day.

PyObject* PyDateTime_FromDateAndTime(int year, int month, int day, int hour, int minute, int second, int usecond)
    Return a datetime.datetime object with the specified year,
month, day, hour, minute, second and microsecond.

PyObject* PyTime_FromTime(int hour, int minute, int second, int usecond)

*Return value: New reference.*

Return a `datetime.time` object with the specified hour, minute, second and microsecond.

PyObject* PyDelta_FromDSU(int days, int seconds, int useconds)

*Return value: New reference.*

Return a `datetime.timedelta` object representing the given number of days, seconds and microseconds. Normalization is performed so that the resulting number of microseconds and seconds lie in the ranges documented for `datetime.timedelta` objects.

Macros to extract fields from date objects. The argument must be an instance of `PyDateTime_Date`, including subclasses (such as `PyDateTime_DateTime`). The argument must not be `NULL`, and the type is not checked:

int PyDateTime_GET_YEAR(PyDateTime_Date *o)

Return the year, as a positive int.

int PyDateTime_GET_MONTH(PyDateTime_Date *o)

Return the month, as an int from 1 through 12.

int PyDateTime_GET_DAY(PyDateTime_Date *o)

Return the day, as an int from 1 through 31.

Macros to extract fields from datetime objects. The argument must be an instance of `PyDateTime_DateTime`, including subclasses. The argument must not be `NULL`, and the type is not checked:
int PyDateTime_DATE_GET_HOUR(PyDateTime_DateTime *o)
    Return the hour, as an int from 0 through 23.

int PyDateTime_DATE_GET_MINUTE(PyDateTime_DateTime *o)
    Return the minute, as an int from 0 through 59.

int PyDateTime_DATE_GET_SECOND(PyDateTime_DateTime *o)
    Return the second, as an int from 0 through 59.

int PyDateTime_DATE_GET_MICROSECOND(PyDateTime_DateTime *o)
    Return the microsecond, as an int from 0 through 999999.

Macros to extract fields from time objects. The argument must be an instance of PyDateTime_Time, including subclasses. The argument must not be NULL, and the type is not checked:

int PyDateTime_TIME_GET_HOUR(PyDateTime_Time *o)
    Return the hour, as an int from 0 through 23.

int PyDateTime_TIME_GET_MINUTE(PyDateTime_Time *o)
    Return the minute, as an int from 0 through 59.

int PyDateTime_TIME_GET_SECOND(PyDateTime_Time *o)
    Return the second, as an int from 0 through 59.

int PyDateTime_TIME_GET_MICROSECOND(PyDateTime_Time *o)
    Return the microsecond, as an int from 0 through 999999.

Macros to extract fields from time delta objects. The argument must be an instance of PyDateTime_Delta, including subclasses. The
argument must not be \textit{NULL}, and the type is not checked:

\begin{verbatim}
int PyDateTime_DELTA_GET_DAYS(PyDateTime_Delta *o)
Return the number of days, as an int from -999999999 to 999999999.
\end{verbatim}

\textit{New in version 3.3.}

\begin{verbatim}
int PyDateTime_DELTA_GET_SECONDS(PyDateTime_Delta *o)
Return the number of seconds, as an int from 0 through 86399.
\end{verbatim}

\textit{New in version 3.3.}

\begin{verbatim}
int PyDateTime_DELTA_GET_MICROSECOND(PyDateTime_Delta *o)
Return the number of microseconds, as an int from 0 through 999999.
\end{verbatim}

\textit{New in version 3.3.}

Macros for the convenience of modules implementing the DB API:

\texttt{PyObject* PyDateTime\_FromTimestamp(PyObject *args)}

Create and return a new \texttt{datetime.datetime} object given an argument tuple suitable for passing to \texttt{datetime.datetime.fromtimestamp()}.

\texttt{PyObject* PyDate\_FromTimestamp(PyObject *args)}

Create and return a new \texttt{datetime.date} object given an argument tuple suitable for passing to \texttt{datetime.date.fromtimestamp()}. 

Initialization, Finalization, and Threads
Initializing and finalizing the interpreter

void `Py_Initialize()`

Initialize the Python interpreter. In an application embedding Python, this should be called before using any other Python/C API functions; with the exception of `Py_SetProgramName()`, `Py_SetPythonHome()` and `Py_SetPath()`. This initializes the table of loaded modules (sys.modules), and creates the fundamental modules `builtins`, `__main__` and `sys`. It also initializes the module search path (sys.path). It does not set `sys.argv`; use `PySys_SetArgvEx()` for that. This is a no-op when called for a second time (without calling `Py_FinalizeEx()` first). There is no return value; it is a fatal error if the initialization fails.

**Note:** On Windows, changes the console mode from `O_TEXT` to `O_BINARY`, which will also affect non-Python uses of the console using the C Runtime.

void `Py_InitializeEx(int initsigs)`

This function works like `Py_Initialize()` if `initsigs` is 1. If `initsigs` is 0, it skips initialization registration of signal handlers, which might be useful when Python is embedded.

int `Py_IsInitialized()`

Return true (nonzero) when the Python interpreter has been initialized, false (zero) if not. After `Py_FinalizeEx()` is called, this returns false until `Py_Initialize()` is called again.

int `Py_FinalizeEx()`
Undo all initializations made by `Py_Initialize()` and subsequent use of Python/C API functions, and destroy all sub-interpreters (see `Py_NewInterpreter()` below) that were created and not yet destroyed since the last call to `Py_Initialize()`. Ideally, this frees all memory allocated by the Python interpreter. This is a no-op when called for a second time (without calling `Py_Initialize()` again first). Normally the return value is 0. If there were errors during finalization (flushing buffered data), -1 is returned.

This function is provided for a number of reasons. An embedding application might want to restart Python without having to restart the application itself. An application that has loaded the Python interpreter from a dynamically loadable library (or DLL) might want to free all memory allocated by Python before unloading the DLL. During a hunt for memory leaks in an application a developer might want to free all memory allocated by Python before exiting from the application.

**Bugs and caveats:** The destruction of modules and objects in modules is done in random order; this may cause destructors (`__del__()` methods) to fail when they depend on other objects (even functions) or modules. Dynamically loaded extension modules loaded by Python are not unloaded. Small amounts of memory allocated by the Python interpreter may not be freed (if you find a leak, please report it). Memory tied up in circular references between objects is not freed. Some memory allocated by extension modules may not be freed. Some extensions may not work properly if their initialization routine is called more than once; this can happen if an application calls `Py_Initialize()` and `Py_FinalizeEx()` more than once.
New in version 3.6.

void **Py_Finalize**()

This is a backwards-compatible version of **Py_FinalizeEx()** that disregards the return value.
Process-wide parameters

`int Py_SetStandardStreamEncoding(const char *encoding, const char *errors)`

This function should be called before `Py_Initialize()`, if it is called at all. It specifies which encoding and error handling to use with standard IO, with the same meanings as in `str.encode()`.

It overrides `PYTHONIOENCODING` values, and allows embedding code to control IO encoding when the environment variable does not work.

`encoding` and/or `errors` may be NULL to use `PYTHONIOENCODING` and/or default values (depending on other settings).

Note that `sys.stderr` always uses the “backslashreplace” error handler, regardless of this (or any other) setting.

If `Py_FinalizeEx()` is called, this function will need to be called again in order to affect subsequent calls to `Py_Initialize()`.

Returns 0 if successful, a nonzero value on error (e.g. calling after the interpreter has already been initialized).

*New in version 3.4.*

`void Py_SetProgramName(wchar_t *name)`

This function should be called before `Py_Initialize()` is called for the first time, if it is called at all. It tells the interpreter the value of the `argv[0]` argument to the `main()` function of the program (converted to wide characters). This is used by `Py_GetPath()`
and some other functions below to find the Python run-time libraries relative to the interpreter executable. The default value is 'python'. The argument should point to a zero-terminated wide character string in static storage whose contents will not change for the duration of the program's execution. No code in the Python interpreter will change the contents of this storage.

Use Py_DecodeLocale() to decode a bytes string to get a wchar_* string.

wchar* Py_GetProgramName()
Return the program name set with Py_SetProgramName(), or the default. The returned string points into static storage; the caller should not modify its value.

wchar_t* Py_GetPrefix()
Return the prefix for installed platform-independent files. This is derived through a number of complicated rules from the program name set with Py_SetProgramName() and some environment variables; for example, if the program name is '/usr/local/bin/python', the prefix is '/usr/local'. The returned string points into static storage; the caller should not modify its value. This corresponds to the prefix variable in the top-level Makefile and the --prefix argument to the configure script at build time. The value is available to Python code as sys.prefix. It is only useful on Unix. See also the next function.

wchar_t* Py_GetExecPrefix()
Return the exec-prefix for installed platform-dependent files. This is derived through a number of complicated rules from the program name set with Py_SetProgramName() and some environment variables; for example, if the program name is
'/usr/local/bin/python', the exec-prefix is '/usr/local'. The returned string points into static storage; the caller should not modify its value. This corresponds to the `exec_prefix` variable in the top-level `Makefile` and the `--exec-prefix` argument to the `configure` script at build time. The value is available to Python code as `sys.exec_prefix`. It is only useful on Unix.

Background: The exec-prefix differs from the prefix when platform dependent files (such as executables and shared libraries) are installed in a different directory tree. In a typical installation, platform dependent files may be installed in the `/usr/local/plat` subtree while platform independent may be installed in `/usr/local`.

Generally speaking, a platform is a combination of hardware and software families, e.g. Sparc machines running the Solaris 2.x operating system are considered the same platform, but Intel machines running Solaris 2.x are another platform, and Intel machines running Linux are yet another platform. Different major revisions of the same operating system generally also form different platforms. Non-Unix operating systems are a different story; the installation strategies on those systems are so different that the prefix and exec-prefix are meaningless, and set to the empty string. Note that compiled Python bytecode files are platform independent (but not independent from the Python version by which they were compiled!).

System administrators will know how to configure the `mount` or `automount` programs to share `/usr/local` between platforms while having `/usr/local/plat` be a different filesystem for each platform.
wchar_t* Py_GetProgramFullPath()

Return the full program name of the Python executable; this is computed as a side-effect of deriving the default module search path from the program name (set by Py_SetProgramName() above). The returned string points into static storage; the caller should not modify its value. The value is available to Python code as \texttt{sys.executable}.

wchar_t* Py_GetPath()

Return the default module search path; this is computed from the program name (set by Py_SetProgramName() above) and some environment variables. The returned string consists of a series of directory names separated by a platform dependent delimiter character. The delimiter character is ':' on Unix and Mac OS X, ';' on Windows. The returned string points into static storage; the caller should not modify its value. The list \texttt{sys.path} is initialized with this value on interpreter startup; it can be (and usually is) modified later to change the search path for loading modules.

void Py_SetPath(const wchar_t *)

Set the default module search path. If this function is called before Py_Initialize(), then Py_GetPath() won't attempt to compute a default search path but uses the one provided instead. This is useful if Python is embedded by an application that has full knowledge of the location of all modules. The path components should be separated by the platform dependent delimiter character, which is ':' on Unix and Mac OS X, ';' on Windows.

This also causes \texttt{sys.executable} to be set only to the raw program name (see Py_SetProgramName()) and for \texttt{sys.prefix} and \texttt{sys.exec_prefix} to be empty. It is up to the
caller to modify these if required after calling Py_Initialize().

Use Py_DecodeLocale() to decode a bytes string to get a wchar_* string.

The path argument is copied internally, so the caller may free it after the call completes.

const char* **Py_GetVersion**()

Return the version of this Python interpreter. This is a string that looks something like

```
"3.0a5+ (py3k:63103M, May 12 2008, 00:53:55) \n
[GCC 4.2.3]"
```

The first word (up to the first space character) is the current Python version; the first three characters are the major and minor version separated by a period. The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.version`.

const char* **Py_GetPlatform**()

Return the platform identifier for the current platform. On Unix, this is formed from the “official” name of the operating system, converted to lower case, followed by the major revision number; e.g., for Solaris 2.x, which is also known as SunOS 5.x, the value is 'sunos5'. On Mac OS X, it is 'darwin'. On Windows, it is 'win'. The returned string points into static storage; the caller should not modify its value. The value is available to Python code as `sys.platform`.

const char* **Py_GetCopyright**()

Return the official copyright string for the current Python version,
for example

'Copright 1991-1995 Stichting Mathematisch Centrum, Amsterdam'

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as sys.copyright.

const char* Py_GetCompiler()

Return an indication of the compiler used to build the current Python version, in square brackets, for example:

"[GCC 2.7.2.2]"

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as part of the variable sys.version.

const char* Py_GetBuildInfo()

Return information about the sequence number and build date and time of the current Python interpreter instance, for example

"#67, Aug 1 1997, 22:34:28"

The returned string points into static storage; the caller should not modify its value. The value is available to Python code as part of the variable sys.version.

void PySys_SetArgvEx(int argc, wchar_t **argv, int updatepath)

Set sys.argv based on argc and argv. These parameters are similar to those passed to the program's main() function with the difference that the first entry should refer to the script file to be
executed rather than the executable hosting the Python interpreter. If there isn't a script that will be run, the first entry in argv can be an empty string. If this function fails to initialize sys.argv, a fatal condition is signalled using Py_FatalError().

If updatepath is zero, this is all the function does. If updatepath is non-zero, the function also modifies sys.path according to the following algorithm:

- If the name of an existing script is passed in argv[0], the absolute path of the directory where the script is located is prepended to sys.path.
- Otherwise (that is, if argc is 0 or argv[0] doesn't point to an existing file name), an empty string is prepended to sys.path, which is the same as prepending the current working directory (".").

Use Py_DecodeLocale() to decode a bytes string to get a wchar_* string.

**Note:** It is recommended that applications embedding the Python interpreter for purposes other than executing a single script pass 0 as updatepath, and update sys.path themselves if desired. See CVE-2008-5983.

On versions before 3.1.3, you can achieve the same effect by manually popping the first sys.path element after having called PySys_SetArgv(), for example using:

```python
PyRun_SimpleString("import sys; sys.path.pop(0)\n")
```

*New in version 3.1.3.*
void PySys_SetArgv(int argc, wchar_t **argv)
   
   This function works like PySys_SetArgvEx() with updatepath set to 1 unless the python interpreter was started with the -I.

   Use Py_DecodeLocale() to decode a bytes string to get a wchar_* string.

   Changed in version 3.4: The updatepath value depends on -I.

void Py_SetPythonHome(wchar_t *home)
   
   Set the default “home” directory, that is, the location of the standard Python libraries. See PYTHONHOME for the meaning of the argument string.

   The argument should point to a zero-terminated character string in static storage whose contents will not change for the duration of the program’s execution. No code in the Python interpreter will change the contents of this storage.

   Use Py_DecodeLocale() to decode a bytes string to get a wchar_* string.

w_char* Py_GetPythonHome()
   
   Return the default “home”, that is, the value set by a previous call to Py_SetPythonHome(), or the value of the PYTHONHOME environment variable if it is set.
Thread State and the Global Interpreter Lock

The Python interpreter is not fully thread-safe. In order to support multi-threaded Python programs, there's a global lock, called the global interpreter lock or GIL, that must be held by the current thread before it can safely access Python objects. Without the lock, even the simplest operations could cause problems in a multi-threaded program: for example, when two threads simultaneously increment the reference count of the same object, the reference count could end up being incremented only once instead of twice.

Therefore, the rule exists that only the thread that has acquired the GIL may operate on Python objects or call Python/C API functions. In order to emulate concurrency of execution, the interpreter regularly tries to switch threads (see `sys.setswitchinterval()`). The lock is also released around potentially blocking I/O operations like reading or writing a file, so that other Python threads can run in the meantime.

The Python interpreter keeps some thread-specific bookkeeping information inside a data structure called `PyThreadState`. There's also one global variable pointing to the current `PyThreadState`: it can be retrieved using `PyThreadState_Get()`.

Releasing the GIL from extension code

Most extension code manipulating the GIL has the following simple structure:

Save the `thread` state in a local variable.
Release the global interpreter lock.
... Do some blocking I/O operation ...  
Reacquire the global interpreter lock.  
Restore the **thread** state from the local variable.

This is so common that a pair of macros exists to simplify it:

```python
Py_BEGIN_ALLOW_THREADS
... Do some blocking I/O operation ...
Py_END_ALLOW_THREADS
```

The `Py_BEGIN_ALLOW_THREADS` macro opens a new block and declares a hidden local variable; the `Py_END_ALLOW_THREADS` macro closes the block. These two macros are still available when Python is compiled without thread support (they simply have an empty expansion).

When thread support is enabled, the block above expands to the following code:

```python
PyThreadState *__save;
__save = PyEval_SaveThread();
...Do some blocking I/O operation...
PyEval_RestoreThread(__save);
```

Here is how these functions work: the global interpreter lock is used to protect the pointer to the current thread state. When releasing the lock and saving the thread state, the current thread state pointer must be retrieved before the lock is released (since another thread could immediately acquire the lock and store its own thread state in the global variable). Conversely, when acquiring the lock and restoring the thread state, the lock must be acquired before storing the thread state pointer.
**Note:** Calling system I/O functions is the most common use case for releasing the GIL, but it can also be useful before calling long-running computations which don’t need access to Python objects, such as compression or cryptographic functions operating over memory buffers. For example, the standard `zlib` and `hashlib` modules release the GIL when compressing or hashing data.

**Non-Python created threads**

When threads are created using the dedicated Python APIs (such as the `threading` module), a thread state is automatically associated to them and the code showed above is therefore correct. However, when threads are created from C (for example by a third-party library with its own thread management), they don’t hold the GIL, nor is there a thread state structure for them.

If you need to call Python code from these threads (often this will be part of a callback API provided by the aforementioned third-party library), you must first register these threads with the interpreter by creating a thread state data structure, then acquiring the GIL, and finally storing their thread state pointer, before you can start using the Python/C API. When you are done, you should reset the thread state pointer, release the GIL, and finally free the thread state data structure.

The `PyGILState_Ensure()` and `PyGILState_Release()` functions do all of the above automatically. The typical idiom for calling into Python from a C thread is:

```c
PyGILState_STATE gstate;
gstate = PyGILState_Ensure();
```
Note that the PyGILState_*() functions assume there is only one global interpreter (created automatically by `Py_Initialize()`). Python supports the creation of additional interpreters (using `Py_NewInterpreter()`), but mixing multiple interpreters and the PyGILState_*() API is unsupported.

Another important thing to note about threads is their behaviour in the face of the C `fork()` call. On most systems with `fork()`, after a process forks only the thread that issued the fork will exist. That also means any locks held by other threads will never be released. Python solves this for `os.fork()` by acquiring the locks it uses internally before the fork, and releasing them afterwards. In addition, it resets any Lock Objects in the child. When extending or embedding Python, there is no way to inform Python of additional (non-Python) locks that need to be acquired before or reset after a fork. OS facilities such as `pthread_atfork()` would need to be used to accomplish the same thing. Additionally, when extending or embedding Python, calling `fork()` directly rather than through `os.fork()` (and returning to or calling into Python) may result in a deadlock by one of Python's internal locks being held by a thread that is defunct after the fork. `PyOS_AfterFork()` tries to reset the necessary locks, but is not always able to.

High-level API
These are the most commonly used types and functions when writing C extension code, or when embedding the Python interpreter:

**PyInterpreterState**
This data structure represents the state shared by a number of cooperating threads. Threads belonging to the same interpreter share their module administration and a few other internal items. There are no public members in this structure.

Threads belonging to different interpreters initially share nothing, except process state like available memory, open file descriptors and such. The global interpreter lock is also shared by all threads, regardless of to which interpreter they belong.

**PyThreadState**
This data structure represents the state of a single thread. The only public data member is `PyInterpreterState *interp`, which points to this thread's interpreter state.

```c
void PyEval_InitThreads()
```
Initialize and acquire the global interpreter lock. It should be called in the main thread before creating a second thread or engaging in any other thread operations such as `PyEval_ReleaseThread(tstate)`. It is not needed before calling `PyEval_SaveThread()` or `PyEval_RestoreThread()`.

This is a no-op when called for a second time.

*Changed in version 3.2:* This function cannot be called before `Py_Initialize()` anymore.

**Note:** When only the main thread exists, no GIL operations are needed. This is a common situation (most Python programs do
not use threads), and the lock operations slow the interpreter
down a bit. Therefore, the lock is not created initially. This
situation is equivalent to having acquired the lock: when there is
only a single thread, all object accesses are safe. Therefore,
when this function initializes the global interpreter lock, it also
acquires it. Before the Python _thread module creates a new
thread, knowing that either it has the lock or the lock hasn’t been
created yet, it calls PyEval_InitThreads(). When this call
returns, it is guaranteed that the lock has been created and that
the calling thread has acquired it.
It is not safe to call this function when it is unknown which thread
(if any) currently has the global interpreter lock.
This function is not available when thread support is disabled at
compile time.

int PyEval_ThreadsInitialized()
Returns a non-zero value if PyEval_InitThreads() has been
called. This function can be called without holding the GIL, and
therefore can be used to avoid calls to the locking API when
running single-threaded. This function is not available when thread
support is disabled at compile time.

PyThreadState* PyEval_SaveThread()
Release the global interpreter lock (if it has been created and
thread support is enabled) and reset the thread state to NULL,
returning the previous thread state (which is not NULL). If the lock
has been created, the current thread must have acquired it. (This
function is available even when thread support is disabled at
compile time.)

void PyEval_RestoreThread(PyThreadState *tstate)
Acquire the global interpreter lock (if it has been created and thread support is enabled) and set the thread state to tstate, which must not be NULL. If the lock has been created, the current thread must not have acquired it, otherwise deadlock ensues. (This function is available even when thread support is disabled at compile time.)

**PyThreadState** PyThreadState_Get()

Return the current thread state. The global interpreter lock must be held. When the current thread state is NULL, this issues a fatal error (so that the caller needn’t check for NULL).

**PyThreadState** PyThreadState_Swap(PyThreadState *tstate)

Swap the current thread state with the thread state given by the argument tstate, which may be NULL. The global interpreter lock must be held and is not released.

void PyEval_ReInitThreads()

This function is called from PyOS_AfterFork() to ensure that newly created child processes don’t hold locks referring to threads which are not running in the child process.

The following functions use thread-local storage, and are not compatible with sub-interpreters:

**PyGILState_STATE** PyGILState_Ensure()

Ensure that the current thread is ready to call the Python C API regardless of the current state of Python, or of the global interpreter lock. This may be called as many times as desired by a thread as long as each call is matched with a call to PyGILState_Release(). In general, other thread-related APIs may be used between PyGILState_Ensure() and
PyGILState_Release() calls as long as the thread state is restored to its previous state before the Release(). For example, normal usage of the Py_BEGIN_ALLOW_THREADS and Py_END_ALLOW_THREADS macros is acceptable.

The return value is an opaque “handle” to the thread state when PyGILState_Ensure() was called, and must be passed to PyGILState_Release() to ensure Python is left in the same state. Even though recursive calls are allowed, these handles cannot be shared - each unique call to PyGILState_Ensure() must save the handle for its call to PyGILState_Release().

When the function returns, the current thread will hold the GIL and be able to call arbitrary Python code. Failure is a fatal error.

void PyGILState_Release(PyGILState_STATE)

Release any resources previously acquired. After this call, Python’s state will be the same as it was prior to the corresponding PyGILState_Ensure() call (but generally this state will be unknown to the caller, hence the use of the GILState API).

Every call to PyGILState_Ensure() must be matched by a call to PyGILState_Release() on the same thread.

PyThreadState* PyGILState_GetThisThreadState()

Get the current thread state for this thread. May return NULL if no GILState API has been used on the current thread. Note that the main thread always has such a thread-state, even if no auto-thread-state call has been made on the main thread. This is mainly a helper/diagnostic function.

int PyGILState_Check()
Return 1 if the current thread is holding the GIL and 0 otherwise. This function can be called from any thread at any time. Only if it has had its Python thread state initialized and currently is holding the GIL will it return 1. This is mainly a helper/diagnostic function. It can be useful for example in callback contexts or memory allocation functions when knowing that the GIL is locked can allow the caller to perform sensitive actions or otherwise behave differently.

*New in version 3.4.*

The following macros are normally used without a trailing semicolon; look for example usage in the Python source distribution.

**Py_BEGIN_ALLOW_THREADS**

This macro expands to `{ PyThreadState * _save; _save = PyEval_SaveThread();`. Note that it contains an opening brace; it must be matched with a following **Py_END_ALLOW_THREADS** macro. See above for further discussion of this macro. It is a no-op when thread support is disabled at compile time.

**Py_END_ALLOW_THREADS**

This macro expands to `PyEval_RestoreThread(_save);`. Note that it contains a closing brace; it must be matched with an earlier **Py_BEGIN_ALLOW_THREADS** macro. See above for further discussion of this macro. It is a no-op when thread support is disabled at compile time.

**Py_BLOCK_THREADS**

This macro expands to `PyEval_RestoreThread(_save);` it is equivalent to **Py_END_ALLOW_THREADS** without the closing brace. It is a no-op when thread support is disabled at compile time.
**Py_UNBLOCK_THREADS**

This macro expands to `__save = PyEval_SaveThread();`: it is equivalent to `Py_BEGIN_ALLOW_THREADS` without the opening brace and variable declaration. It is a no-op when thread support is disabled at compile time.

**Low-level API**

All of the following functions are only available when thread support is enabled at compile time, and must be called only when the global interpreter lock has been created.

**PyInterpreterState**\* **PyInterpreterState_New()**

Create a new interpreter state object. The global interpreter lock need not be held, but may be held if it is necessary to serialize calls to this function.

**void PyInterpreterState_Clear(PyInterpreterState *interp)**

Reset all information in an interpreter state object. The global interpreter lock must be held.

**void PyInterpreterState_Delete(PyInterpreterState *interp)**

Destroy an interpreter state object. The global interpreter lock need not be held. The interpreter state must have been reset with a previous call to `PyInterpreterState_Clear()`.

**PyThreadState**\* **PyThreadState_New(PyInterpreterState *interp)**

Create a new thread state object belonging to the given interpreter object. The global interpreter lock need not be held, but may be held if it is necessary to serialize calls to this function.
void **PyThreadState_Clear**(PyThreadState *tstate)

Reset all information in a thread state object. The global interpreter lock must be held.

void **PyThreadState_Delete**(PyThreadState *tstate)

Destroy a thread state object. The global interpreter lock need not be held. The thread state must have been reset with a previous call to **PyThreadState_Clear**().

**PyObject** * **PyThreadState_GetDict**()

*Return value: Borrowed reference.*

Return a dictionary in which extensions can store thread-specific state information. Each extension should use a unique key to use to store state in the dictionary. It is okay to call this function when no current thread state is available. If this function returns **NULL**, no exception has been raised and the caller should assume no current thread state is available.

int **PyThreadState_SetAsyncExc**(long id, PyObject *exc)

Asynchronously raise an exception in a thread. The *id* argument is the thread id of the target thread; *exc* is the exception object to be raised. This function does not steal any references to *exc*. To prevent naive misuse, you must write your own C extension to call this. Must be called with the GIL held. Returns the number of thread states modified; this is normally one, but will be zero if the thread id isn't found. If *exc* is **NULL**, the pending exception (if any) for the thread is cleared. This raises no exceptions.

void **PyEval_AcquireThread**(PyThreadState *tstate)

Acquire the global interpreter lock and set the current thread state to *tstate*, which should not be **NULL**. The lock must have been created earlier. If this thread already has the lock, deadlock
ensues.

PyEval_RestoreThread() is a higher-level function which is always available (even when thread support isn’t enabled or when threads have not been initialized).

```c
void PyEval_ReleaseThread(PyThreadState *tstate)
```
Reset the current thread state to NULL and release the global interpreter lock. The lock must have been created earlier and must be held by the current thread. The tstate argument, which must not be NULL, is only used to check that it represents the current thread state — if it isn’t, a fatal error is reported.

PyEval_SaveThread() is a higher-level function which is always available (even when thread support isn’t enabled or when threads have not been initialized).

```c
void PyEval_AcquireLock()
```
Acquire the global interpreter lock. The lock must have been created earlier. If this thread already has the lock, a deadlock ensues.

*Deprecated since version 3.2:* This function does not update the current thread state. Please use PyEval_RestoreThread() or PyEval_AcquireThread() instead.

```c
void PyEval_ReleaseLock()
```
Release the global interpreter lock. The lock must have been created earlier.

*Deprecated since version 3.2:* This function does not update the current thread state. Please use PyEval_SaveThread() or PyEval_ReleaseThread() instead.
Sub-interpreter support

While in most uses, you will only embed a single Python interpreter, there are cases where you need to create several independent interpreters in the same process and perhaps even in the same thread. Sub- interpreters allow you to do that. You can switch between sub-interpreters using the PyThreadState_Swap() function. You can create and destroy them using the following functions:

**PyThreadState**

**Py_NewInterpreter()**
Create a new sub-interpreter. This is an (almost) totally separate environment for the execution of Python code. In particular, the new interpreter has separate, independent versions of all imported modules, including the fundamental modules **builtins**, **__main__** and **sys**. The table of loaded modules (**sys.modules**) and the module search path (**sys.path**) are also separate. The new environment has no **sys.argv** variable. It has new standard I/O stream file objects **sys.stdin**, **sys.stdout** and **sys.stderr** (however these refer to the same underlying file descriptors).

The return value points to the first thread state created in the new sub-interpreter. This thread state is made in the current thread state. Note that no actual thread is created; see the discussion of thread states below. If creation of the new interpreter is unsuccessful, **NULL** is returned; no exception is set since the exception state is stored in the current thread state and there may not be a current thread state. (Like all other Python/C API functions, the global interpreter lock must be held before calling this function and is still held when it returns; however, unlike most other Python/C API functions, there needn’t be a current thread
Extension modules are shared between (sub-)interpreters as follows: the first time a particular extension is imported, it is initialized normally, and a (shallow) copy of its module's dictionary is squirreled away. When the same extension is imported by another (sub-)interpreter, a new module is initialized and filled with the contents of this copy; the extension's `init` function is not called. Note that this is different from what happens when an extension is imported after the interpreter has been completely re-initialized by calling `Py_FinalizeEx()` and `Py_Initialize()`; in that case, the extension's `init` function is called again.

```c
void Py_EndInterpreter(PyThreadState *tstate)

Destroy the (sub-)interpreter represented by the given thread state. The given thread state must be the current thread state. See the discussion of thread states below. When the call returns, the current thread state is `NULL`. All thread states associated with this interpreter are destroyed. (The global interpreter lock must be held before calling this function and is still held when it returns.) `Py_FinalizeEx()` will destroy all sub-interpreters that haven't been explicitly destroyed at that point.
```

### Bugs and caveats

Because sub-interpreters (and the main interpreter) are part of the same process, the insulation between them isn't perfect — for example, using low-level file operations like `os.close()` they can (accidentally or maliciously) affect each other's open files. Because of the way extensions are shared between (sub-)interpreters, some extensions may not work properly; this is especially likely when the extension makes use of (static) global variables, or when the
extension manipulates its module's dictionary after its initialization. It is possible to insert objects created in one sub-interpreter into a namespace of another sub-interpreter; this should be done with great care to avoid sharing user-defined functions, methods, instances or classes between sub-interpreters, since import operations executed by such objects may affect the wrong (sub-)interpreter's dictionary of loaded modules.

Also note that combining this functionality with PyGILState_*() APIs is delicate, because these APIs assume a bijection between Python thread states and OS-level threads, an assumption broken by the presence of sub-interpreters. It is highly recommended that you don’t switch sub-interpreters between a pair of matching PyGILState_Ensure() and PyGILState_Release() calls. Furthermore, extensions (such as ctypes) using these APIs to allow calling of Python code from non-Python created threads will probably be broken when using sub-interpreters.
Asynchronous Notifications

A mechanism is provided to make asynchronous notifications to the main interpreter thread. These notifications take the form of a function pointer and a void pointer argument.

```c
int Py_AddPendingCall(int (*func)(void *), void *arg)
```

Schedule a function to be called from the main interpreter thread. On success, 0 is returned and `func` is queued for being called in the main thread. On failure, -1 is returned without setting any exception.

When successfully queued, `func` will be eventually called from the main interpreter thread with the argument `arg`. It will be called asynchronously with respect to normally running Python code, but with both these conditions met:

- on a `bytecode` boundary;
- with the main thread holding the global interpreter lock (`func` can therefore use the full C API).

`func` must return 0 on success, or -1 on failure with an exception set. `func` won’t be interrupted to perform another asynchronous notification recursively, but it can still be interrupted to switch threads if the global interpreter lock is released.

This function doesn’t need a current thread state to run, and it doesn’t need the global interpreter lock.

**Warning:** This is a low-level function, only useful for very special cases. There is no guarantee that `func` will be called as quick as possible. If the main thread is busy executing a system
call, *func* won’t be called before the system call returns. This function is generally not suitable for calling Python code from arbitrary C threads. Instead, use the PyGILState API.

*New in version 3.1.*
Profiling and Tracing

The Python interpreter provides some low-level support for attaching profiling and execution tracing facilities. These are used for profiling, debugging, and coverage analysis tools.

This C interface allows the profiling or tracing code to avoid the overhead of calling through Python-level callable objects, making a direct C function call instead. The essential attributes of the facility have not changed; the interface allows trace functions to be installed per-thread, and the basic events reported to the trace function are the same as had been reported to the Python-level trace functions in previous versions.

```
int (*Py_tracefunc)(PyObject *obj, PyFrameObject *frame, int what, PyObject *arg)
```

The type of the trace function registered using `PyEval_SetProfile()` and `PyEval_SetTrace()`. The first parameter is the object passed to the registration function as `obj`, `frame` is the frame object to which the event pertains, `what` is one of the constants `PyTrace_CALL`, `PyTrace_EXCEPTION`, `PyTrace_LINE`, `PyTrace_RETURN`, `PyTrace_C_CALL`, `PyTrace_C_EXCEPTION`, or `PyTrace_C_RETURN`, and `arg` depends on the value of `what`:

<table>
<thead>
<tr>
<th>Value of <code>what</code></th>
<th>Meaning of <code>arg</code></th>
</tr>
</thead>
<tbody>
<tr>
<td>PyTrace_CALL</td>
<td>Always <code>NULL</code>.</td>
</tr>
<tr>
<td>PyTrace_EXCEPTION</td>
<td>Exception information as returned by <code>sys.exc_info()</code>.</td>
</tr>
<tr>
<td>PyTrace_LINE</td>
<td>Always <code>NULL</code>.</td>
</tr>
<tr>
<td>PyTrace_RETURN</td>
<td>Value being returned to the caller, or NULL if caused by an exception.</td>
</tr>
<tr>
<td>----------------</td>
<td>---------------------------------------------------------------------</td>
</tr>
<tr>
<td>PyTrace_C_CALL</td>
<td>Function object being called.</td>
</tr>
<tr>
<td>PyTrace_C_EXCEPTION</td>
<td>Function object being called.</td>
</tr>
<tr>
<td>PyTrace_C_RETURN</td>
<td>Function object being called.</td>
</tr>
</tbody>
</table>

**int PyTrace_CALL**

The value of the *what* parameter to a *Py_tracefunc* function when a new call to a function or method is being reported, or a new entry into a generator. Note that the creation of the iterator for a generator function is not reported as there is no control transfer to the Python bytecode in the corresponding frame.

**int PyTrace_EXCEPTION**

The value of the *what* parameter to a *Py_tracefunc* function when an exception has been raised. The callback function is called with this value for *what* when after any bytecode is processed after which the exception becomes set within the frame being executed. The effect of this is that as exception propagation causes the Python stack to unwind, the callback is called upon return to each frame as the exception propagates. Only trace functions receives these events; they are not needed by the profiler.

**int PyTrace_LINE**

The value passed as the *what* parameter to a trace function (but not a profiling function) when a line-number event is being reported.

**int PyTrace_RETURN**

The value for the *what* parameter to *Py_tracefunc* functions when a call is returning without propagating an exception.
int **PyTrace_C_CALL**

The value for the *what* parameter to *Py_tracefunc* functions when a C function is about to be called.

int **PyTrace_C_EXCEPTION**

The value for the *what* parameter to *Py_tracefunc* functions when a C function has raised an exception.

int **PyTrace_C_RETURN**

The value for the *what* parameter to *Py_tracefunc* functions when a C function has returned.

void **PyEval_SetProfile**(Py_tracefunc *func, PyObject *obj)

Set the profiler function to *func*. The *obj* parameter is passed to the function as its first parameter, and may be any Python object, or *NULL*. If the profile function needs to maintain state, using a different value for *obj* for each thread provides a convenient and thread-safe place to store it. The profile function is called for all monitored events except the line-number events.

void **PyEval_SetTrace**(Py_tracefunc *func, PyObject *obj)

Set the tracing function to *func*. This is similar to *PyEval_SetProfile()*, except the tracing function does receive line-number events.

PyObject* **PyEval_GetCallStats**(PyObject *self)

Return a tuple of function call counts. There are constants defined for the positions within the tuple:

<table>
<thead>
<tr>
<th>Name</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>PCALL_ALL</td>
<td>0</td>
</tr>
<tr>
<td>PCALL_FUNCTION</td>
<td>1</td>
</tr>
<tr>
<td>Function</td>
<td>Count</td>
</tr>
<tr>
<td>-----------------------------</td>
<td>-------</td>
</tr>
<tr>
<td>PCALL_FAST_FUNCTION</td>
<td>2</td>
</tr>
<tr>
<td>PCALL_FASTER_FUNCTION</td>
<td>3</td>
</tr>
<tr>
<td>PCALL_METHOD</td>
<td>4</td>
</tr>
<tr>
<td>PCALL_BOUND_METHOD</td>
<td>5</td>
</tr>
<tr>
<td>PCALL_CFUNCTION</td>
<td>6</td>
</tr>
<tr>
<td>PCALL_TYPE</td>
<td>7</td>
</tr>
<tr>
<td>PCALL_GENERATOR</td>
<td>8</td>
</tr>
<tr>
<td>PCALL_OTHER</td>
<td>9</td>
</tr>
<tr>
<td>PCALL_POP</td>
<td>10</td>
</tr>
</tbody>
</table>

PCALL_FAST_FUNCTION means no argument tuple needs to be created. PCALL_FASTER_FUNCTION means that the fast-path frame setup code is used.

If there is a method call where the call can be optimized by changing the argument tuple and calling the function directly, it gets recorded twice.

This function is only present if Python is compiled with CALL_PROFILE defined.
Advanced Debugger Support

These functions are only intended to be used by advanced debugging tools.

**PyInterpreterState**\* `PyInterpreterState_Head()`
- Return the interpreter state object at the head of the list of all such objects.

**PyInterpreterState**\* `PyInterpreterState_Next(PyInterpreterState *interp)`
- Return the next interpreter state object after `interp` from the list of all such objects.

**PyThreadState** \* `PyInterpreterState_ThreadHead(PyInterpreterState *interp)`
- Return the pointer to the first **PyThreadState** object in the list of threads associated with the interpreter `interp`.

**PyThreadState** \* `PyThreadState_Next(PyThreadState *tstate)`
- Return the next thread state object after `tstate` from the list of all such objects belonging to the same **PyInterpreterState** object.
Memory Management
Overview

Memory management in Python involves a private heap containing all Python objects and data structures. The management of this private heap is ensured internally by the *Python memory manager*. The Python memory manager has different components which deal with various dynamic storage management aspects, like sharing, segmentation, preallocation or caching.

At the lowest level, a raw memory allocator ensures that there is enough room in the private heap for storing all Python-related data by interacting with the memory manager of the operating system. On top of the raw memory allocator, several object-specific allocators operate on the same heap and implement distinct memory management policies adapted to the peculiarities of every object type. For example, integer objects are managed differently within the heap than strings, tuples or dictionaries because integers imply different storage requirements and speed/space tradeoffs. The Python memory manager thus delegates some of the work to the object-specific allocators, but ensures that the latter operate within the bounds of the private heap.

It is important to understand that the management of the Python heap is performed by the interpreter itself and that the user has no control over it, even if she regularly manipulates object pointers to memory blocks inside that heap. The allocation of heap space for Python objects and other internal buffers is performed on demand by the Python memory manager through the Python/C API functions listed in this document.

To avoid memory corruption, extension writers should never try to operate on Python objects with the functions exported by the C library:
malloc(), calloc(), realloc() and free(). This will result in mixed calls between the C allocator and the Python memory manager with fatal consequences, because they implement different algorithms and operate on different heaps. However, one may safely allocate and release memory blocks with the C library allocator for individual purposes, as shown in the following example:

```c
PyObject *res;
char *buf = (char *) malloc(BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
...
Do some I/O operation involving buf...
res = PyBytes_FromString(buf);
free(buf); /* malloc'ed */
return res;
```

In this example, the memory request for the I/O buffer is handled by the C library allocator. The Python memory manager is involved only in the allocation of the string object returned as a result.

In most situations, however, it is recommended to allocate memory from the Python heap specifically because the latter is under control of the Python memory manager. For example, this is required when the interpreter is extended with new object types written in C. Another reason for using the Python heap is the desire to inform the Python memory manager about the memory needs of the extension module. Even when the requested memory is used exclusively for internal, highly-specific purposes, delegating all memory requests to the Python memory manager causes the interpreter to have a more accurate image of its memory footprint as a whole. Consequently, under certain circumstances, the Python memory manager may or may not trigger appropriate actions, like garbage collection, memory compaction or
other preventive procedures. Note that by using the C library allocator as shown in the previous example, the allocated memory for the I/O buffer escapes completely the Python memory manager.

See also: The PYTHONMALLOC environment variable can be used to configure the memory allocators used by Python.

The PYTHONMALLOCSTATS environment variable can be used to print statistics of the pymalloc memory allocator every time a new pymalloc object arena is created, and on shutdown.
Raw Memory Interface

The following function sets are wrappers to the system allocator. These functions are thread-safe, the GIL does not need to be held.

The default raw memory block allocator uses the following functions: malloc(), calloc(), realloc() and free(); call malloc(1) (or calloc(1, 1)) when requesting zero bytes.

New in version 3.4.

```c
void* PyMem_RawMalloc(size_t n)
```

Allocates $n$ bytes and returns a pointer of type void* to the allocated memory, or NULL if the request fails.

Requesting zero bytes returns a distinct non-NULL pointer if possible, as if PyMem_RawMalloc(1) had been called instead. The memory will not have been initialized in any way.

```c
void* PyMem_RawCalloc(size_t nelem, size_t elsize)
```

Allocates $nelem$ elements each whose size in bytes is $elsize$ and returns a pointer of type void* to the allocated memory, or NULL if the request fails. The memory is initialized to zeros.

Requesting zero elements or elements of size zero bytes returns a distinct non-NULL pointer if possible, as if PyMem_RawCalloc(1, 1) had been called instead.

New in version 3.5.

```c
void* PyMem_RawRealloc(void* p, size_t n)
```

Resizes the memory block pointed to by $p$ to $n$ bytes. The contents
will be unchanged to the minimum of the old and the new sizes.

If \( p \) is \texttt{NULL}, the call is equivalent to \texttt{PyMem_RawMalloc(n)}; else if \( n \) is equal to zero, the memory block is resized but is not freed, and the returned pointer is non-\texttt{NULL}.

Unless \( p \) is \texttt{NULL}, it must have been returned by a previous call to \texttt{PyMem_RawMalloc()}, \texttt{PyMem_RawRealloc()} or \texttt{PyMem_RawCalloc()}.

If the request fails, \texttt{PyMem_RawRealloc()} returns \texttt{NULL} and \( p \) remains a valid pointer to the previous memory area.

\begin{verbatim}
void PyMem_RawFree(void *p)

Frees the memory block pointed to by \( p \), which must have been returned by a previous call to \texttt{PyMem_RawMalloc()}, \texttt{PyMem_RawRealloc()} or \texttt{PyMem_RawCalloc()}. Otherwise, or if \texttt{PyMem_Free(p)} has been called before, undefined behavior occurs.

If \( p \) is \texttt{NULL}, no operation is performed.
\end{verbatim}
Memory Interface

The following function sets, modeled after the ANSI C standard, but specifying behavior when requesting zero bytes, are available for allocating and releasing memory from the Python heap.

By default, these functions use pymalloc memory allocator.

**Warning:** The **GIL** must be held when using these functions.

*Changed in version 3.6:* The default allocator is now pymalloc instead of system malloc().

```c
void* PyMem_Malloc(size_t n)

Allocates \( n \) bytes and returns a pointer of type `void*` to the allocated memory, or `NULL` if the request fails.

Requesting zero bytes returns a distinct non-NULL pointer if possible, as if `PyMem_Malloc(1)` had been called instead. The memory will not have been initialized in any way.
```

```c
void* PyMem_Calloc(size_t nelem, size_t elsize)

Allocates \( nelem \) elements each whose size in bytes is \( elsize \) and returns a pointer of type `void*` to the allocated memory, or `NULL` if the request fails. The memory is initialized to zeros.

Requesting zero elements or elements of size zero bytes returns a distinct non-NULL pointer if possible, as if `PyMem_Calloc(1, 1)` had been called instead.
```

*New in version 3.5.*
void* PyMem_Realloc(void *p, size_t n)
Resizes the memory block pointed to by p to n bytes. The contents will be unchanged to the minimum of the old and the new sizes.

If p is NULL, the call is equivalent to PyMem_Malloc(n); else if n is equal to zero, the memory block is resized but is not freed, and the returned pointer is non-NULL.

Unless p is NULL, it must have been returned by a previous call to PyMem_Malloc(), PyMem_Realloc() or PyMem_Calloc().

If the request fails, PyMem_Realloc() returns NULL and p remains a valid pointer to the previous memory area.

void PyMem_Free(void *p)
Freess the memory block pointed to by p, which must have been returned by a previous call to PyMem_Malloc(), PyMem_Realloc() or PyMem_Calloc(). Otherwise, or if PyMem_Free(p) has been called before, undefined behavior occurs.

If p is NULL, no operation is performed.

The following type-oriented macros are provided for convenience. Note that TYPE refers to any C type.

TYPE* PyMem_New(TYPE, size_t n)
Same as PyMem_Malloc(), but allocates (n * sizeof(TYPE)) bytes of memory. Returns a pointer cast to TYPE*. The memory will not have been initialized in any way.

TYPE* PyMem_RESIZE(void *p, TYPE, size_t n)
Same as PyMem_Realloc(), but the memory block is resized to
(n * sizeof(TYPE)) bytes. Returns a pointer cast to TYPE*. On return, \( p \) will be a pointer to the new memory area, or \( NULL \) in the event of failure.

This is a C preprocessor macro; \( p \) is always reassigned. Save the original value of \( p \) to avoid losing memory when handling errors.

```c
void PyMem_Del(void *p)
```

Same as \texttt{PyMem\_Free()}. In addition, the following macro sets are provided for calling the Python memory allocator directly, without involving the C API functions listed above. However, note that their use does not preserve binary compatibility across Python versions and is therefore deprecated in extension modules.

- \texttt{PyMem\__MALLOC(size)}
- \texttt{PyMem\_NEW(type, size)}
- \texttt{PyMem\_REALLOC(ptr, size)}
- \texttt{PyMem\_RESIZE(ptr, type, size)}
- \texttt{PyMem\_FREE(ptr)}
- \texttt{PyMem\_DEL(ptr)}
Customize Memory Allocators

*New in version 3.4.*

**PyMemAllocatorEx**

Structure used to describe a memory block allocator. The structure has four fields:

<table>
<thead>
<tr>
<th>Field</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>void *ctx</td>
<td>user context passed as first argument</td>
</tr>
<tr>
<td>void* malloc(void *ctx, size_t size)</td>
<td>allocate a memory block</td>
</tr>
<tr>
<td>void* calloc(void *ctx, size_t nelem, size_t elsize)</td>
<td>allocate a memory block initialized with zeros</td>
</tr>
<tr>
<td>void* realloc(void *ctx, void *ptr, size_t new_size)</td>
<td>allocate or resize a memory block</td>
</tr>
<tr>
<td>void free(void *ctx, void *ptr)</td>
<td>free a memory block</td>
</tr>
</tbody>
</table>

*Changed in version 3.5:* The PyMemAllocator structure was renamed to **PyMemAllocatorEx** and a new `calloc` field was added.

**PyMemAllocatorDomain**

Enum used to identify an allocator domain. Domains:

**PYMEM_DOMAIN_RAW**

Functions:

- `PyMem_RawMalloc()`
- `PyMem_RawRealloc()`
- PyMem_RawCalloc()
- PyMem_RawFree()

**PYMEM_DOMAIN_MEM**

Functions:

- PyMem_Malloc(),
- PyMem_Realloc()
- PyMem_Calloc()
- PyMem_Free()

**PYMEM_DOMAIN_OBJ**

Functions:

- PyObject_Malloc()
- PyObject_Realloc()
- PyObject_Calloc()
- PyObject_Free()

```c
void PyMem_GetAllocator(PyMemAllocatorDomain domain, PyMemAllocatorEx *allocator)

Get the memory block allocator of the specified domain.
```

```c
void PyMem_SetAllocator(PyMemAllocatorDomain domain, PyMemAllocatorEx *allocator)

Set the memory block allocator of the specified domain.
```

The new allocator must return a distinct non-NULL pointer when requesting zero bytes.

For the **PYMEM_DOMAIN_RAW** domain, the allocator must be thread-safe: the GIL is not held when the allocator is called.

If the new allocator is not a hook (does not call the previous
allocator), the **PyMem_SetupDebugHooks()** function must be called to reinstall the debug hooks on top on the new allocator.

```c
void PyMem_SetupDebugHooks(void)
```

Setup hooks to detect bugs in the Python memory allocator functions.

Newly allocated memory is filled with the byte \texttt{0xCB}, freed memory is filled with the byte \texttt{0xDB}.

Runtime checks:

- Detect API violations, ex: \texttt{PyObject\_Free()} called on a buffer allocated by \texttt{PyMem\_Malloc()}
- Detect write before the start of the buffer (buffer underflow)
- Detect write after the end of the buffer (buffer overflow)
- Check that the \texttt{GIL} is held when allocator functions of \texttt{PYMEM\_DOMAIN\_OBJ} (ex: \texttt{PyObject\_Malloc()}) and \texttt{PYMEM\_DOMAIN\_MEM} (ex: \texttt{PyMem\_Malloc()}) domains are called

On error, the debug hooks use the \texttt{tracemalloc} module to get the traceback where a memory block was allocated. The traceback is only displayed if \texttt{tracemalloc} is tracing Python memory allocations and the memory block was traced.

These hooks are installed by default if Python is compiled in debug mode. The \texttt{PYTHONMALLOC} environment variable can be used to install debug hooks on a Python compiled in release mode.

*Changed in version 3.6:* This function now also works on Python compiled in release mode. On error, the debug hooks now use \texttt{tracemalloc} to get the traceback where a memory block was allocated. The debug hooks now also check if the GIL is held when
functions of PyMEM_DOMAIN_OBJ and PyMEM_DOMAIN_MEM domains are called.
The pymalloc allocator

Python has a `pymalloc` allocator optimized for small objects (smaller or equal to 512 bytes) with a short lifetime. It uses memory mappings called “arenas” with a fixed size of 256 KB. It falls back to `PyMem_RawMalloc()` and `PyMem_RawRealloc()` for allocations larger than 512 bytes.

`pymalloc` is the default allocator of the `PYMEM_DOMAIN_MEM` (ex: `PyMem_Malloc()`) and `PYMEM_DOMAIN_OBJ` (ex: `PyObject_Malloc()`) domains.

The arena allocator uses the following functions:

- `VirtualAlloc()` and `VirtualFree()` on Windows,
- `mmap()` and `munmap()` if available,
- `malloc()` and `free()` otherwise.

Customize pymalloc Arena Allocator

*New in version 3.4.*

**PyObjectArenaAllocator**

Structure used to describe an arena allocator. The structure has three fields:

<table>
<thead>
<tr>
<th>Field</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>void *ctx</code></td>
<td>user context passed as first argument</td>
</tr>
<tr>
<td><code>void* alloc(void *ctx, size_t size)</code></td>
<td>allocate an arena of size bytes</td>
</tr>
</tbody>
</table>
```c
void free(void *ctx, size_t size, void *ptr)
```

**free an arena**

**PyObject_GetArenaAllocator** *(PyObjectArenaAllocator *allocator)*

Get the arena allocator.

**PyObject_SetArenaAllocator** *(PyObjectArenaAllocator *allocator)*

Set the arena allocator.
Examples

Here is the example from section Overview, rewritten so that the I/O buffer is allocated from the Python heap by using the first function set:

```c
PyObject *res;
char *buf = (char *) PyMem_Malloc(BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
/* ...Do some I/O operation involving buf... */
res = PyBytes_FromString(buf);
PyMem_Free(buf); /* allocated with PyMem_Malloc */
return res;
```

The same code using the type-oriented function set:

```c
PyObject *res;
char *buf = PyMem_New(char, BUFSIZ); /* for I/O */

if (buf == NULL)
    return PyErr_NoMemory();
/* ...Do some I/O operation involving buf... */
res = PyBytes_FromString(buf);
PyMem_Del(buf); /* allocated with PyMem_New */
return res;
```

Note that in the two examples above, the buffer is always manipulated via functions belonging to the same set. Indeed, it is required to use the same memory API family for a given memory block, so that the risk of mixing different allocators is reduced to a minimum. The following code sequence contains two errors, one of which is labeled as fatal because it mixes two different allocators operating on different heaps.
In addition to the functions aimed at handling raw memory blocks from the Python heap, objects in Python are allocated and released with `PyObject_New()`, `PyObject_NewVar()` and `PyObject_Del()`.

These will be explained in the next chapter on defining and implementing new object types in C.
Object Implementation Support

This chapter describes the functions, types, and macros used when defining new object types.

- Allocating Objects on the Heap
- Common Object Structures
- Type Objects
- Number Object Structures
- Mapping Object Structures
- Sequence Object Structures
- Buffer Object Structures
- Async Object Structures
- Supporting Cyclic Garbage Collection
Allocating Objects on the Heap

PyObject* _PyObject_New(PyTypeObject *type)

*Return value: New reference.*

PyVarObject* _PyObject_NewVar(PyTypeObject *type, Py_ssize_t size)

*Return value: New reference.*

PyObject* PyObject_Init(PyObject *op, PyTypeObject *type)

*Return value: Borrowed reference.*
Initialize a newly-allocated object op with its type and initial reference. Returns the initialized object. If type indicates that the object participates in the cyclic garbage detector, it is added to the detector’s set of observed objects. Other fields of the object are not affected.

PyVarObject* PyObject_InitVar(PyVarObject *op, PyTypeObject *type, Py_ssize_t size)

*Return value: Borrowed reference.*
This does everything PyObject_Init() does, and also initializes the length information for a variable-size object.

TYPE* PyObject_New(TYPE, PyTypeObject *type)

*Return value: New reference.*
Allocate a new Python object using the C structure type TYPE and the Python type object type. Fields not defined by the Python object header are not initialized; the object's reference count will be one. The size of the memory allocation is determined from the tp_basicsize field of the type object.
TYPE* **PyObject_NewVar** (TYPE, PyTypeObject *type, Py_ssize_t size)

*Return value: New reference.*

Allocate a new Python object using the C structure type `TYPE` and the Python type object `type`. Fields not defined by the Python object header are not initialized. The allocated memory allows for the `TYPE` structure plus `size` fields of the size given by the `tp_itemsize` field of `type`. This is useful for implementing objects like tuples, which are able to determine their size at construction time. Embedding the array of fields into the same allocation decreases the number of allocations, improving the memory management efficiency.

void **PyObject_Del** (PyObject *op)

Releases memory allocated to an object using `PyObject_New()` or `PyObject_NewVar()`. This is normally called from the `tp_dealloc` handler specified in the object's type. The fields of the object should not be accessed after this call as the memory is no longer a valid Python object.

**PyObject _Py_NoneStruct**

Object which is visible in Python as `None`. This should only be accessed using the `Py_None` macro, which evaluates to a pointer to this object.

**See also:**

**PyModule_Create()**

To allocate and create extension modules.
Common Object Structures

There are a large number of structures which are used in the definition of object types for Python. This section describes these structures and how they are used.

All Python objects ultimately share a small number of fields at the beginning of the object's representation in memory. These are represented by the PyObject and PyVarObject types, which are defined, in turn, by the expansions of some macros also used, whether directly or indirectly, in the definition of all other Python objects.

**PyObject**

All object types are extensions of this type. This is a type which contains the information Python needs to treat a pointer to an object as an object. In a normal “release” build, it contains only the object's reference count and a pointer to the corresponding type object. Nothing is actually declared to be a PyObject, but every pointer to a Python object can be cast to a PyObject*. Access to the members must be done by using the macros Py_REFCNT and Py_TYPE.

**PyVarObject**

This is an extension of PyObject that adds the ob_size field. This is only used for objects that have some notion of length. This type does not often appear in the Python/C API. Access to the members must be done by using the macros Py_REFCNT, Py_TYPE, and Py_SIZE.

**PyObject_HEAD**

This is a macro used when declaring new types which represent
objects without a varying length. The PyObject_HEAD macro expands to:

```c
PyObject ob_base;
```

See documentation of `PyObject` above.

**PyObject_VAR_HEAD**

This is a macro used when declaring new types which represent objects with a length that varies from instance to instance. The PyObject_VAR_HEAD macro expands to:

```c
PyVarObject ob_base;
```

See documentation of `PyVarObject` above.

**Py_TYPE(o)**

This macro is used to access the `ob_type` member of a Python object. It expands to:

```c
(((PyObject*)(o))->ob_type)
```

**Py_REFCNT(o)**

This macro is used to access the `ob_refcnt` member of a Python object. It expands to:

```c
(((PyObject*)(o))->ob_refcnt)
```

**Py_SIZE(o)**

This macro is used to access the `ob_size` member of a Python object. It expands to:

```c
(((PyVarObject*)(o))->ob_size)
```
**PyPyObject** _HEAD_INIT_(type)

This is a macro which expands to initialization values for a new `PyObject` type. This macro expands to:

```c
_PyObject_EXTRA_INIT
1, type,
```

**PyVarObject** _HEAD_INIT_(type, size)

This is a macro which expands to initialization values for a new `PyVarObject` type, including the ob_size field. This macro expands to:

```c
_PyObject_EXTRA_INIT
1, type, size,
```

**PyCFunction**

Type of the functions used to implement most Python callables in C. Functions of this type take two `PyObject*` parameters and return one such value. If the return value is `NULL`, an exception shall have been set. If not `NULL`, the return value is interpreted as the return value of the function as exposed in Python. The function must return a new reference.

**PyCFunctionWithKeywords**

Type of the functions used to implement Python callables in C that take keyword arguments: they take three `PyObject*` parameters and return one such value. See `PyCFunction` above for the meaning of the return value.

**PyMethodDef**

Structure used to describe a method of an extension type. This structure has four fields:
### Field | C Type | Meaning
--- | --- | ---
ml_name | char * | name of the method
ml_meth | PyCFunction | pointer to the C implementation
ml_flags | int | flag bits indicating how the call should be constructed
ml_doc | char * | points to the contents of the docstring

The **ml_meth** is a C function pointer. The functions may be of different types, but they always return **PyObject**. If the function is not of the **PyCFunction**, the compiler will require a cast in the method table. Even though **PyCFunction** defines the first parameter as **PyObject**, it is common that the method implementation uses the specific C type of the **self** object.

The **ml_flags** field is a bitfield which can include the following flags. The individual flags indicate either a calling convention or a binding convention. Of the calling convention flags, only **METH_VARARGS** and **METH_KEYWORDS** can be combined. Any of the calling convention flags can be combined with a binding flag.

**METH_VARARGS**

This is the typical calling convention, where the methods have the type **PyCFunction**. The function expects two **PyObject** values. The first one is the **self** object for methods; for module functions, it is the module object. The second parameter (often called **args**) is a tuple object representing all arguments. This parameter is typically processed using **PyArg_ParseTuple()** or **PyArg_UnpackTuple()**.
METH_KEYWORDS

Methods with these flags must be of type `PyCFunctionWithKeywords`. The function expects three parameters: `self`, `args`, and a dictionary of all the keyword arguments. The flag must be combined with `METH_VARARGS`, and the parameters are typically processed using `PyArg_ParseTupleAndKeywords()`.

METH_NOARGS

Methods without parameters don’t need to check whether arguments are given if they are listed with the `METH_NOARGS` flag. They need to be of type `PyCFunction`. The first parameter is typically named `self` and will hold a reference to the module or object instance. In all cases the second parameter will be `NULL`.

METH_O

Methods with a single object argument can be listed with the `METH_O` flag, instead of invoking `PyArg_ParseTuple()` with a "O" argument. They have the type `PyCFunction`, with the `self` parameter, and a `PyObject*` parameter representing the single argument.

These two constants are not used to indicate the calling convention but the binding when use with methods of classes. These may not be used for functions defined for modules. At most one of these flags may be set for any given method.

METH_CLASS

The method will be passed the type object as the first parameter rather than an instance of the type. This is used to create class methods, similar to what is created when using the `classmethod()` built-in function.
**METH_STATIC**

The method will be passed `NULL` as the first parameter rather than an instance of the type. This is used to create *static methods*, similar to what is created when using the `staticmethod()` built-in function.

One other constant controls whether a method is loaded in place of another definition with the same method name.

**METH_COEXIST**

The method will be loaded in place of existing definitions. Without `METH_COEXIST`, the default is to skip repeated definitions. Since slot wrappers are loaded before the method table, the existence of a `sq_contains` slot, for example, would generate a wrapped method named `__contains__()` and preclude the loading of a corresponding `PyCFunction` with the same name. With the flag defined, the `PyCFunction` will be loaded in place of the wrapper object and will co-exist with the slot. This is helpful because calls to `PyCFunctions` are optimized more than wrapper object calls.

**PyMemberDef**

Structure which describes an attribute of a type which corresponds to a C struct member. Its fields are:

<table>
<thead>
<tr>
<th>Field</th>
<th>C Type</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>char *</td>
<td>name of the member</td>
</tr>
<tr>
<td>type</td>
<td>int</td>
<td>the type of the member in the C struct</td>
</tr>
<tr>
<td>offset</td>
<td>Py_ssize_t</td>
<td>the offset in bytes that the member is located on the type’s object struct</td>
</tr>
<tr>
<td></td>
<td></td>
<td>flag bits indicating if the field</td>
</tr>
<tr>
<td>Macro name</td>
<td>C type</td>
<td></td>
</tr>
<tr>
<td>---------------------</td>
<td>-------------------</td>
<td></td>
</tr>
<tr>
<td>T_SHORT</td>
<td>short</td>
<td></td>
</tr>
<tr>
<td>T_INT</td>
<td>int</td>
<td></td>
</tr>
<tr>
<td>T_LONG</td>
<td>long</td>
<td></td>
</tr>
<tr>
<td>T_FLOAT</td>
<td>float</td>
<td></td>
</tr>
<tr>
<td>T_DOUBLE</td>
<td>double</td>
<td></td>
</tr>
<tr>
<td>T_STRING</td>
<td>char *</td>
<td></td>
</tr>
<tr>
<td>T_OBJECT</td>

<td>unsigned short</td>
<td></td>
</tr>
<tr>
<td>T_ULONGLONG</td>
<td>unsigned long</td>
<td></td>
</tr>
<tr>
<td>T_BOOL</td>
<td>char</td>
<td></td>
</tr>
<tr>
<td>T_LONGLONG</td>
<td>long long</td>
<td></td>
</tr>
<tr>
<td>T_ULONGLONG</td>
<td>unsigned long long</td>
<td></td>
</tr>
<tr>
<td>T_PYSSIZET</td>
<td>Py_ssize_t</td>
<td></td>
</tr>
</tbody>
</table>
T_OBJECT and T_OBJECT_EX differ in that T_OBJECT returns None if the member is NULL and T_OBJECT_EX raises an AttributeError. Try to use T_OBJECT_EX over T_OBJECT because T_OBJECT_EX handles use of the del statement on that attribute more correctly than T_OBJECT.

Flags can be 0 for write and read access or READONLY for read-only access. Using T_STRING for type implies READONLY. Only T_OBJECT and T_OBJECT_EX members can be deleted. (They are set to NULL).

PyGetSetDef
Structure to define property-like access for a type. See also description of the PyTypeObject.tp_getset slot.

<table>
<thead>
<tr>
<th>Field</th>
<th>C Type</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>char *</td>
<td>attribute name</td>
</tr>
<tr>
<td>get</td>
<td>getter</td>
<td>C Function to get the attribute</td>
</tr>
<tr>
<td>set</td>
<td>setter</td>
<td>optional C function to set or delete the attribute, if omitted the attribute is readonly</td>
</tr>
<tr>
<td>doc</td>
<td>char *</td>
<td>optional docstring</td>
</tr>
<tr>
<td>closure</td>
<td>void *</td>
<td>optional function pointer, providing additional data for getter and setter</td>
</tr>
</tbody>
</table>

The get function takes one PyObject* parameter (the instance) and a function pointer (the associated closure):

```c
typedef PyObject *(*getter)(PyObject *, void *);
```
It should return a new reference on success or NULL with a set exception on failure.

set functions take two PyObject* parameters (the instance and the value to be set) and a function pointer (the associated closure):

```c
typedef int (*setter)(PyObject *, PyObject *, void *)
```

In case the attribute should be deleted the second parameter is NULL. Should return 0 on success or -1 with a set exception on failure.
Type Objects

Perhaps one of the most important structures of the Python object system is the structure that defines a new type: the `PyTypeObject` structure. Type objects can be handled using any of the `PyObject_*( )` or `PyType_*( )` functions, but do not offer much that's interesting to most Python applications. These objects are fundamental to how objects behave, so they are very important to the interpreter itself and to any extension module that implements new types.

Type objects are fairly large compared to most of the standard types. The reason for the size is that each type object stores a large number of values, mostly C function pointers, each of which implements a small part of the type's functionality. The fields of the type object are examined in detail in this section. The fields will be described in the order in which they occur in the structure.

Typedefs: unaryfunc, binaryfunc, ternaryfunc, inquiry, intargfunc, intintargfunc, intobjargproc, intintobjargproc, objobjargproc, destructor, freefunc, printfunc, getattrfunc, getattrofunc, setattrfunc, setattrofunc, reprfunc, hashfunc

The structure definition for `PyTypeObject` can be found in `Include/object.h`. For convenience of reference, this repeats the definition found there:

```c
typedef struct _typeobject {
PyObject_VAR_HEAD
const char *tp_name; /* For printing, in format */
Py_ssize_t tp_basicsize, tp_itemsize; /* For all */
/* Methods to implement standard operations */
```
destructor tp_dealloc;
printfunc tp_print;
getattrfunc tp_getattr;
setattrfunc tp_setattr;
PyAsyncMethods *tp_as_async; /* formerly known as tp_compare (Python 2)
or tp_reserved (Python 3) */
reprfunc tp_repr;

/* Method suites for standard classes */

PyNumberMethods *tp_as_number;
PySequenceMethods *tp_as_sequence;
PyMappingMethods *tp_as_mapping;

/* More standard operations (here for binary compatibility) */

hashfunc tp_hash;
ternaryfunc tp_call;
reprfunc tp_str;
getattrofunc tp_getattro;
setattrofunc tp_setattro;

/* Functions to access object as input/output buffer */
PyBufferProcs *tp_as_buffer;

/* Flags to define presence of optional/expanded features */
unsigned long tp_flags;

const char *tp_doc; /* Documentation string */

/* call function for all accessible objects */
traverseproc tp_traverse;

/* delete references to contained objects */
inquiry tp_clear;
/ * rich comparisons */
richcmpfunc tp_richcompare;

/* weak reference enabler */
Py_ssize_t tp_weaklistoffset;

/* Iterators */
getiterfunc tp_iter;
iternextfunc tp_iternext;

/* Attribute descriptor and subclassing stuff */
struct PyMethodDef *tp_methods;
struct PyMemberDef *tp_members;
struct PyGetSetDef *tp_getset;
struct _typeobject *tp_base;
PyObject *tp_dict;
descrgetfunc tp_descr_get;
descrsetfunc tp_descr_set;
Py_ssize_t tp_dictoffset;
initproc tp_init;
allocfunc tp_alloc;
newfunc tp_new;
freefunc tp_free; /* Low-level free-memory routine */
inquiry tp_is_gc; /* For PyObject_IS_GC */
PyObject *tp_bases;
PyObject *tp_mro; /* method resolution order */
PyObject *tp_cache;
PyObject *tp_subclasses;
PyObject *tp_weaklist;
destructor tp_del;

/* Type attribute cache version tag. Added in version */
unsigned int tp_version_tag;

destructor tp_finalize;

} PyTypeObject;
The type object structure extends the `PyVarObject` structure. The `ob_size` field is used for dynamic types (created by `type_new()`, usually called from a class statement). Note that `PyType_Type` (the metatype) initializes `tp_itemsize`, which means that its instances (i.e. type objects) must have the `ob_size` field.

`PyObject* PyObject._ob_next`  
`PyObject* PyObject._ob_prev`  
These fields are only present when the macro `Py_TRACE_REFS` is defined. Their initialization to `NULL` is taken care of by the `PyObject_HEAD_INIT` macro. For statically allocated objects, these fields always remain `NULL`. For dynamically allocated objects, these two fields are used to link the object into a doubly-linked list of all live objects on the heap. This could be used for various debugging purposes; currently the only use is to print the objects that are still alive at the end of a run when the environment variable `PYTHONDUMPREFS` is set.

These fields are not inherited by subtypes.

`Py_ssize_t PyObject.ob_refcnt`  
This is the type object's reference count, initialized to 1 by the `PyObject_HEAD_INIT` macro. Note that for statically allocated type objects, the type's instances (objects whose `ob_type` points back to the type) do not count as references. But for dynamically allocated type objects, the instances do count as references.

This field is not inherited by subtypes.

`PyTypeObject* PyObject.ob_type`  
This is the type's type, in other words its metatype. It is initialized
by the argument to the PyObject_HEAD_INIT macro, and its value should normally be &PyType_Type. However, for dynamically loadable extension modules that must be usable on Windows (at least), the compiler complains that this is not a valid initializer. Therefore, the convention is to pass NULL to the PyObject_HEAD_INIT macro and to initialize this field explicitly at the start of the module’s initialization function, before doing anything else. This is typically done like this:

```c
Foo_Type.ob_type = &PyType_Type;
```

This should be done before any instances of the type are created. PyType_Ready() checks if ob_type is NULL, and if so, initializes it to the ob_type field of the base class. PyType_Ready() will not change this field if it is non-zero.

This field is inherited by subtypes.

Py_ssize_t PyVarObject.ob_size

For statically allocated type objects, this should be initialized to zero. For dynamically allocated type objects, this field has a special internal meaning.

This field is not inherited by subtypes.

const char* PyTypeObject.tp_name

Pointer to a NUL-terminated string containing the name of the type. For types that are accessible as module globals, the string should be the full module name, followed by a dot, followed by the type name; for built-in types, it should be just the type name. If the module is a submodule of a package, the full package name is part of the full module name. For example, a type named T defined in
module M in subpackage Q in package P should have the
\texttt{tp\_name} initializer "P.Q.M.T".

For dynamically allocated type objects, this should just be the type
name, and the module name explicitly stored in the type dict as the
value for key '\texttt{\_\_module\_\_}'.

For statically allocated type objects, the \texttt{tp\_name} field should
contain a dot. Everything before the last dot is made accessible as
the \texttt{\_\_module\_\_} attribute, and everything after the last dot is
made accessible as the \texttt{\_\_name\_\_} attribute.

If no dot is present, the entire \texttt{tp\_name} field is made accessible as
the \texttt{\_\_name\_\_} attribute, and the \texttt{\_\_module\_\_} attribute is
undefined (unless explicitly set in the dictionary, as explained
above). This means your type will be impossible to pickle.
Additionally, it will not be listed in module documentations created
with pydoc.

This field is not inherited by subtypes.

\texttt{Py\_ssize\_t PyTypeObject\_tp\_basicsize}
\texttt{Py\_ssize\_t PyTypeObject\_tp\_itemsize}

These fields allow calculating the size in bytes of instances of the
type.

There are two kinds of types: types with fixed-length instances
have a zero \texttt{tp\_itemsize} field, types with variable-length
instances have a non-zero \texttt{tp\_itemsize} field. For a type with
fixed-length instances, all instances have the same size, given in
\texttt{tp\_basicsize}.

For a type with variable-length instances, the instances must have
an ob_size field, and the instance size is \texttt{tp\_basicsize} plus \(N\) times \texttt{tp\_itemsize}, where \(N\) is the “length” of the object. The value of \(N\) is typically stored in the instance's ob_size field. There are exceptions: for example, ints use a negative ob_size to indicate a negative number, and \(N\) is \(\text{abs}(\text{ob\_size})\) there. Also, the presence of an ob_size field in the instance layout doesn't mean that the instance structure is variable-length (for example, the structure for the list type has fixed-length instances, yet those instances have a meaningful ob_size field).

The basic size includes the fields in the instance declared by the macro \texttt{PyObject\_HEAD} or \texttt{PyObject\_VAR\_HEAD} (whichever is used to declare the instance struct) and this in turn includes the \_ob_prev and \_ob_next fields if they are present. This means that the only correct way to get an initializer for the \texttt{tp\_basicsize} is to use the \texttt{sizeof} operator on the struct used to declare the instance layout. The basic size does not include the GC header size.

These fields are inherited separately by subtypes. If the base type has a non-zero \texttt{tp\_itemsize}, it is generally not safe to set \texttt{tp\_itemsize} to a different non-zero value in a subtype (though this depends on the implementation of the base type).

A note about alignment: if the variable items require a particular alignment, this should be taken care of by the value of \texttt{tp\_basicsize}. Example: suppose a type implements an array of double. \texttt{tp\_itemsize} is \texttt{sizeof(double)}. It is the programmer's responsibility that \texttt{tp\_basicsize} is a multiple of \texttt{sizeof(double)} (assuming this is the alignment requirement for double).
**destroyer** **PyTypeObject.tp_dealloc**

A pointer to the instance destructor function. This function must be defined unless the type guarantees that its instances will never be deallocated (as is the case for the singletons `None` and `Ellipsis`).

The destructor function is called by the `Py_DECREF()` and `Py_XDECREF()` macros when the new reference count is zero. At this point, the instance is still in existence, but there are no references to it. The destructor function should free all references which the instance owns, free all memory buffers owned by the instance (using the freeing function corresponding to the allocation function used to allocate the buffer), and finally (as its last action) call the type’s `tp_free` function. If the type is not subtypable (doesn’t have the `Py_TPFLAGS_BASETYPE` flag bit set), it is permissible to call the object deallocator directly instead of via `tp_free`. The object deallocator should be the one used to allocate the instance; this is normally `PyObject_Del()` if the instance was allocated using `PyObject_New()` or `PyObject_VarNew()`, or `PyObject_GC_Del()` if the instance was allocated using `PyObject_GC_New()` or `PyObject_GC_NewVar()`.

This field is inherited by subtypes.

**printfunc** **PyTypeObject.tp_print**

Reserved slot, formerly used for print formatting in Python 2.x.

**getattrfunc** **PyTypeObject.tp_getattr**

An optional pointer to the get-attribute-string function.

This field is deprecated. When it is defined, it should point to a
function that acts the same as the `tp_getattro` function, but taking a C string instead of a Python string object to give the attribute name. The signature is

```
PyObject * tp_getattro(PyObject *o, char attr_name)
```

This field is inherited by subtypes together with `tp_getattro`: a subtype inherits both `tp_getattr` and `tp_getattro` from its base type when the subtype's `tp_getattr` and `tp_getattro` are both `NULL`.

**setattrofunc** **PyTypeObject.tp_setattr**

An optional pointer to the function for setting and deleting attributes.

This field is deprecated. When it is defined, it should point to a function that acts the same as the `tp_setattro` function, but taking a C string instead of a Python string object to give the attribute name. The signature is

```
PyObject * tp_setattr(PyObject *o, char attr_name)
```

The `v` argument is set to `NULL` to delete the attribute. This field is inherited by subtypes together with `tp_setattro`: a subtype inherits both `tp_setattr` and `tp_setattro` from its base type when the subtype's `tp_setattr` and `tp_setattro` are both `NULL`.

**PyAsyncMethods** * `tp_as_async`  
Pointer to an additional structure that contains fields relevant only to objects which implement `awaitable` and `asynchronous iterator`
protocols at the C-level. See Async Object Structures for details.

*New in version 3.5:* Formerly known as `tp_compare` and `tp_reserved`.

**reprfunc** `PyTypeObject.tp_repr`

An optional pointer to a function that implements the built-in function `repr()`.

The signature is the same as for `PyObject_Repr()`; it must return a string or a Unicode object. Ideally, this function should return a string that, when passed to `eval()`, given a suitable environment, returns an object with the same value. If this is not feasible, it should return a string starting with '<' and ending with '>' from which both the type and the value of the object can be deduced.

When this field is not set, a string of the form `<%s object at %p>` is returned, where `%s` is replaced by the type name, and `%p` by the object’s memory address.

This field is inherited by subtypes.

**PyNumberMethods** `*tp_as_number`

Pointer to an additional structure that contains fields relevant only to objects which implement the number protocol. These fields are documented in Number Object Structures.

The `tp_as_number` field is not inherited, but the contained fields are inherited individually.

**PySequenceMethods** `*tp_as_sequence`

Pointer to an additional structure that contains fields relevant only
to objects which implement the sequence protocol. These fields are documented in *Sequence Object Structures*.

The `tp_as_sequence` field is not inherited, but the contained fields are inherited individually.

**PyMappingMethods** *tp_as_mapping*

Pointer to an additional structure that contains fields relevant only to objects which implement the mapping protocol. These fields are documented in *Mapping Object Structures*.

The `tp_as_mapping` field is not inherited, but the contained fields are inherited individually.

**hashfunc** `PyTypeObject.tp_hash`

An optional pointer to a function that implements the built-in function *hash()*.

The signature is the same as for `PyObject_Hash()`; it must return a value of the type `Py_hash_t`. The value `-1` should not be returned as a normal return value; when an error occurs during the computation of the hash value, the function should set an exception and return `-1`.

This field can be set explicitly to `PyObject_HashNotImplemented()` to block inheritance of the hash method from a parent type. This is interpreted as the equivalent of `__hash__ = None` at the Python level, causing `isinstance(o, collections.Hashable)` to correctly return `False`. Note that the converse is also true - setting `__hash__ = None` on a class at the Python level will result in the `tp_hash` slot being set to `PyObject_HashNotImplemented()`.
When this field is not set, an attempt to take the hash of the object raises `TypeError`.

This field is inherited by subtypes together with `tp_richcompare`: a subtype inherits both of `tp_richcompare` and `tp_hash`, when the subtype’s `tp_richcompare` and `tp_hash` are both `NULL`.

ternaryfunc `PyTypeObject.tp_call`  
An optional pointer to a function that implements calling the object. This should be `NULL` if the object is not callable. The signature is the same as for `PyObject_Call()`.  

This field is inherited by subtypes.

reprfunc `PyTypeObject.tp_str`  
An optional pointer to a function that implements the built-in operation `str()`. (Note that `str` is a type now, and `str()` calls the constructor for that type. This constructor calls `PyObject_Str()` to do the actual work, and `PyObject_Str()` will call this handler.)  

The signature is the same as for `PyObject_Str()`; it must return a string or a Unicode object. This function should return a “friendly” string representation of the object, as this is the representation that will be used, among other things, by the `print()` function.

When this field is not set, `PyObject_Repr()` is called to return a string representation.

This field is inherited by subtypes.

getattrofunc `PyTypeObject.tp_getattro`  
An optional pointer to the get-attribute function.
The signature is the same as for `PyObject_GetAttr()`. It is usually convenient to set this field to `PyObject_GenericGetAttr()`, which implements the normal way of looking for object attributes.

This field is inherited by subtypes together with `tp_getattr`: a subtype inherits both `tp_getattr` and `tp_getattro` from its base type when the subtype's `tp_getattr` and `tp_getattro` are both `NULL`.

**setattrofunc** `PyTypeObject.tp_setattro`

An optional pointer to the function for setting and deleting attributes.

The signature is the same as for `PyObject_SetAttr()`, but setting `v` to `NULL` to delete an attribute must be supported. It is usually convenient to set this field to `PyObject_GenericSetAttr()`, which implements the normal way of setting object attributes.

This field is inherited by subtypes together with `tp_setattr`: a subtype inherits both `tp_setattr` and `tp_setattro` from its base type when the subtype's `tp_setattr` and `tp_setattro` are both `NULL`.

**PyBufferProcs** `PyTypeObject.tp_as_buffer`

Pointer to an additional structure that contains fields relevant only to objects which implement the buffer interface. These fields are documented in Buffer Object Structures.

The `tp_as_buffer` field is not inherited, but the contained fields are inherited individually.
unsigned long **PyTypeObject**.tp_flags

This field is a bit mask of various flags. Some flags indicate variant semantics for certain situations; others are used to indicate that certain fields in the type object (or in the extension structures referenced via tp_as_number, tp_as_sequence, tp_as_mapping, and tp_as_buffer) that were historically not always present are valid; if such a flag bit is clear, the type fields it guards must not be accessed and must be considered to have a zero or NULL value instead.

Inheritance of this field is complicated. Most flag bits are inherited individually, i.e. if the base type has a flag bit set, the subtype inherits this flag bit. The flag bits that pertain to extension structures are strictly inherited if the extension structure is inherited, i.e. the base type's value of the flag bit is copied into the subtype together with a pointer to the extension structure. The Py_TPFLAGS_HAVE_GC flag bit is inherited together with the tp_traverse and tp_clear fields, i.e. if the Py_TPFLAGS_HAVE_GC flag bit is clear in the subtype and the tp_traverse and tp_clear fields in the subtype exist and have NULL values.

The following bit masks are currently defined; these can be ORed together using the | operator to form the value of the tp_flags field. The macro PyType_HasFeature() takes a type and a flags value, tp and f, and checks whether tp->tp_flags & f is non-zero.

**Py_TPFLAGS_HEAPTYPE**

This bit is set when the type object itself is allocated on the heap. In this case, the ob_type field of its instances is considered a reference to the type, and the type object is
INCREF’ed when a new instance is created, and DECREF’ed when an instance is destroyed (this does not apply to instances of subtypes; only the type referenced by the instance’s ob_type gets INCREF’ed or DECREF’ed).

**Py_TPFLAGS_BASETYPE**
This bit is set when the type can be used as the base type of another type. If this bit is clear, the type cannot be subtyped (similar to a “final” class in Java).

**Py_TPFLAGS_READY**
This bit is set when the type object has been fully initialized by `PyType_Ready()`.

**Py_TPFLAGS_READYING**
This bit is set while `PyType_Ready()` is in the process of initializing the type object.

**Py_TPFLAGS_HAVE_GC**
This bit is set when the object supports garbage collection. If this bit is set, instances must be created using `PyObject_GC_New()` and destroyed using `PyObject_GC_Del()`. More information in section Supporting Cyclic Garbage Collection. This bit also implies that the GC-related fields `tp_traverse` and `tp_clear` are present in the type object.

**Py_TPFLAGS_DEFAULT**
This is a bitmask of all the bits that pertain to the existence of certain fields in the type object and its extension structures. Currently, it includes the following bits: `Py_TPFLAGS_HAVE_STACKLESS_EXTENSION`,
**Py_TPFLAGS_HAVE_VERSION_TAG**

**Py_TPFLAGS_LONG_SUBCLASS**

**Py_TPFLAGS_LIST_SUBCLASS**

**Py_TPFLAGS_TUPLE_SUBCLASS**

**Py_TPFLAGS_BYTES_SUBCLASS**

**Py_TPFLAGS_UNICODE_SUBCLASS**

**Py_TPFLAGS_DICT_SUBCLASS**

**Py_TPFLAGS_BASE_EXC_SUBCLASS**

**Py_TPFLAGS_TYPE_SUBCLASS**

These flags are used by functions such as `PyLong_Check()` to quickly determine if a type is a subclass of a built-in type; such specific checks are faster than a generic check, like `PyObject_IsInstance()`. Custom types that inherit from built-ins should have their `tp_flags` set appropriately, or the code that interacts with such types will behave differently depending on what kind of check is used.

**Py_TPFLAGS_HAVE_FINALIZE**

This bit is set when the `tp_finalize` slot is present in the type structure.

*New in version 3.4.*

**const char* PyTypeObject.tp_doc**

An optional pointer to a NUL-terminated C string giving the docstring for this type object. This is exposed as the `__doc__` attribute on the type and instances of the type.
This field is *not* inherited by subtypes.

**traverseproc** `PyTypeObject.tp_traverse`

An optional pointer to a traversal function for the garbage collector. This is only used if the `Py_TPFLAGS_HAVE_GC` flag bit is set. More information about Python's garbage collection scheme can be found in section **Supporting Cyclic Garbage Collection**.

The `tp_traverse` pointer is used by the garbage collector to detect reference cycles. A typical implementation of a `tp_traverse` function simply calls `Py_VISIT()` on each of the instance's members that are Python objects. For example, this is function `local_traverse()` from the `_thread` extension module:

```c
static int local_traverse(localobject *self, visitproc visit
{
    Py_VISIT(self->args);
    Py_VISIT(self->kw);
    Py_VISIT(self->dict);
    return 0;
}
```

Note that `Py_VISIT()` is called only on those members that can participate in reference cycles. Although there is also a `self->key` member, it can only be `NULL` or a Python string and therefore cannot be part of a reference cycle.

On the other hand, even if you know a member can never be part of a cycle, as a debugging aid you may want to visit it anyway just so the `gc` module's `get_referents()` function will include it.
Note that `Py_VISIT()` requires the `visit` and `arg` parameters to `local_traverse()` to have these specific names; don’t name them just anything.

This field is inherited by subtypes together with `tp_clear` and the `Py_TPFLAGS_HAVE_GC` flag bit: the flag bit, `tp_traverse`, and `tp_clear` are all inherited from the base type if they are all zero in the subtype.

**inquiry** `PyTypeObject.tp_clear`

An optional pointer to a clear function for the garbage collector. This is only used if the `Py_TPFLAGS_HAVE_GC` flag bit is set.

The `tp_clear` member function is used to break reference cycles in cyclic garbage detected by the garbage collector. Taken together, all `tp_clear` functions in the system must combine to break all reference cycles. This is subtle, and if in any doubt supply a `tp_clear` function. For example, the tuple type does not implement a `tp_clear` function, because it’s possible to prove that no reference cycle can be composed entirely of tuples. Therefore the `tp_clear` functions of other types must be sufficient to break any cycle containing a tuple. This isn’t immediately obvious, and there’s rarely a good reason to avoid implementing `tp_clear`.

Implementations of `tp_clear` should drop the instance’s references to those of its members that may be Python objects, and set its pointers to those members to `NULL`, as in the following example:

```
static int
local_clear(localobject *self)
```
The `Py_CLEAR()` macro should be used, because clearing references is delicate: the reference to the contained object must not be decremented until after the pointer to the contained object is set to `NULL`. This is because decrementing the reference count may cause the contained object to become trash, triggering a chain of reclamation activity that may include invoking arbitrary Python code (due to finalizers, or weakref callbacks, associated with the contained object). If it's possible for such code to reference `self` again, it's important that the pointer to the contained object be `NULL` at that time, so that `self` knows the contained object can no longer be used. The `Py_CLEAR()` macro performs the operations in a safe order.

Because the goal of `tp_clear` functions is to break reference cycles, it's not necessary to clear contained objects like Python strings or Python integers, which can't participate in reference cycles. On the other hand, it may be convenient to clear all contained Python objects, and write the type's `tp_dealloc` function to invoke `tp_clear`.

More information about Python's garbage collection scheme can be found in section Supporting Cyclic Garbage Collection.

This field is inherited by subtypes together with `tp_traverse` and the `Py_TPFLAGS_HAVE_GC` flag bit: the flag bit, `tp_traverse`,
and \texttt{tp\_clear} are all inherited from the base type if they are all zero in the subtype.

\textbf{richcmpfunc} \texttt{PyTypeObject.tp\_richcompare}

An optional pointer to the rich comparison function, whose signature is \texttt{PyObject \*tp\_richcompare(PyObject \*a, PyObject \*b, int \textit{op})}. The first parameter is guaranteed to be an instance of the type that is defined by \texttt{PyTypeObject}.

The function should return the result of the comparison (usually \texttt{Py\_True} or \texttt{Py\_False}). If the comparison is undefined, it must return \texttt{Py\_NotImplemented}, if another error occurred it must return \texttt{NULL} and set an exception condition.

\textbf{Note:} If you want to implement a type for which only a limited set of comparisons makes sense (e.g. \texttt{==} and \texttt{!\!=}, but not \texttt{<} and friends), directly raise \texttt{TypeError} in the rich comparison function.

This field is inherited by subtypes together with \texttt{tp\_hash}: a subtype inherits \texttt{tp\_richcompare} and \texttt{tp\_hash} when the subtype's \texttt{tp\_richcompare} and \texttt{tp\_hash} are both \texttt{NULL}.

The following constants are defined to be used as the third argument for \texttt{tp\_richcompare} and for \texttt{PyObject\_RichCompare()}:

<table>
<thead>
<tr>
<th>Constant</th>
<th>Comparison</th>
</tr>
</thead>
<tbody>
<tr>
<td>\texttt{Py_LT}</td>
<td>\texttt{&lt;}</td>
</tr>
<tr>
<td>\texttt{Py_LE}</td>
<td>\texttt{\leq}</td>
</tr>
<tr>
<td>\texttt{Py_EQ}</td>
<td>\texttt{=}</td>
</tr>
</tbody>
</table>
Py_ssize_t PyTypeObject.tp_weaklistoffset

If the instances of this type are weakly referenceable, this field is greater than zero and contains the offset in the instance structure of the weak reference list head (ignoring the GC header, if present); this offset is used by PyObject_ClearWeakRefs() and the PyWeakref_*() functions. The instance structure needs to include a field of type PyObject* which is initialized to NULL.

Do not confuse this field with tp_weaklist; that is the list head for weak references to the type object itself.

This field is inherited by subtypes, but see the rules listed below. A subtype may override this offset; this means that the subtype uses a different weak reference list head than the base type. Since the list head is always found via tp_weaklistoffset, this should not be a problem.

When a type defined by a class statement has no __slots__ declaration, and none of its base types are weakly referenceable, the type is made weakly referenceable by adding a weak reference list head slot to the instance layout and setting the tp_weaklistoffset of that slot's offset.

When a type's __slots__ declaration contains a slot named __weakref__, that slot becomes the weak reference list head for instances of the type, and the slot's offset is stored in the type's tp_weaklistoffset.
When a type's __slots__ declaration does not contain a slot named __weakref__, the type inherits its tp_weaklistoffset from its base type.

getiterfunc **PyTypeObject.tp_iter**

An optional pointer to a function that returns an iterator for the object. Its presence normally signals that the instances of this type are iterable (although sequences may be iterable without this function).

This function has the same signature as PyObject_GetIter().

This field is inherited by subtypes.

iternextfunc **PyTypeObject.tp_iternext**

An optional pointer to a function that returns the next item in an iterator. When the iterator is exhausted, it must return NULL; a StopIteration exception may or may not be set. When another error occurs, it must return NULL too. Its presence signals that the instances of this type are iterators.

Iterator types should also define the tp_iter function, and that function should return the iterator instance itself (not a new iterator instance).

This function has the same signature as PyIter_Next().

This field is inherited by subtypes.

struct **PyMethodDef** PyTypeObject.tp_methods

An optional pointer to a static NULL-terminated array of PyMethodDef structures, declaring regular methods of this type.

For each entry in the array, an entry is added to the type's
dictionary (see \texttt{tp\_dict} below) containing a method descriptor.

This field is not inherited by subtypes (methods are inherited through a different mechanism).

\textbf{struct} \texttt{PyMemberDef* PyTypeObject\_tp\_members}

An optional pointer to a static \texttt{NULL}-terminated array of \texttt{PyMemberDef} structures, declaring regular data members (fields or slots) of instances of this type.

For each entry in the array, an entry is added to the type's dictionary (see \texttt{tp\_dict} below) containing a member descriptor.

This field is not inherited by subtypes (members are inherited through a different mechanism).

\textbf{struct} \texttt{PyGetSetDef* PyTypeObject\_tp\_getset}

An optional pointer to a static \texttt{NULL}-terminated array of \texttt{PyGetSetDef} structures, declaring computed attributes of instances of this type.

For each entry in the array, an entry is added to the type's dictionary (see \texttt{tp\_dict} below) containing a getset descriptor.

This field is not inherited by subtypes (computed attributes are inherited through a different mechanism).

\textbf{PyTypeObject* PyTypeObject\_tp\_base}

An optional pointer to a base type from which type properties are inherited. At this level, only single inheritance is supported; multiple inheritance require dynamically creating a type object by calling the metatype.

This field is not inherited by subtypes (obviously), but it defaults to
&PyBaseObject_Type (which to Python programmers is known as the type object).

PyObject* PyTypeObject.tp_dict
The type's dictionary is stored here by PyType_Ready().

This field should normally be initialized to NULL before PyType_Ready is called; it may also be initialized to a dictionary containing initial attributes for the type. Once PyType_Ready() has initialized the type, extra attributes for the type may be added to this dictionary only if they don't correspond to overloaded operations (like __add__()).

This field is not inherited by subtypes (though the attributes defined in here are inherited through a different mechanism).

**Warning:** It is not safe to use PyDict_SetItem() on or otherwise modify tp_dict with the dictionary C-API.

descrgetfunc PyTypeObject.tp_descr_get
An optional pointer to a “descriptor get” function.

The function signature is

```c
PyObject* tp_descr_get(PyObject* self, PyObject* arg)
```

This field is inherited by subtypes.

descrsetfunc PyTypeObject.tp_descr_set
An optional pointer to a function for setting and deleting a descriptor's value.
The function signature is

```c
int tp_descr_set(PyObject *self, PyObject *obj, Py_ssize_t value)
```

The `value` argument is set to `NULL` to delete the value. This field is inherited by subtypes.

**Py_ssize_t PyTypeObject.tp_dictoffset**

If the instances of this type have a dictionary containing instance variables, this field is non-zero and contains the offset in the instances of the type of the instance variable dictionary; this offset is used by `PyObject_GenericGetAttr()`.

Do not confuse this field with `tp_dict`; that is the dictionary for attributes of the type object itself.

If the value of this field is greater than zero, it specifies the offset from the start of the instance structure. If the value is less than zero, it specifies the offset from the end of the instance structure. A negative offset is more expensive to use, and should only be used when the instance structure contains a variable-length part. This is used for example to add an instance variable dictionary to subtypes of `str` or `tuple`. Note that the `tp_basicsize` field should account for the dictionary added to the end in that case, even though the dictionary is not included in the basic object layout. On a system with a pointer size of 4 bytes, `tp_dictoffset` should be set to `-4` to indicate that the dictionary is at the very end of the structure.

The real dictionary offset in an instance can be computed from a negative `tp_dictoffset` as follows:
dictoffset = tp_basicsize + abs(ob_size)*tp_itemsize
if dictoffset is not aligned on sizeof(void*):
    round up to sizeof(void*)

where `tp_basicsize`, `tp_itemsize` and `tp_dictoffset` are taken from the type object, and `ob_size` is taken from the instance. The absolute value is taken because ints use the sign of `ob_size` to store the sign of the number. (There's never a need to do this calculation yourself; it is done for you by `_PyObject_GetDictPtr()`.)

This field is inherited by subtypes, but see the rules listed below. A subtype may override this offset; this means that the subtype instances store the dictionary at a different offset than the base type. Since the dictionary is always found via `tp_dictoffset`, this should not be a problem.

When a type defined by a class statement has no `__slots__` declaration, and none of its base types has an instance variable dictionary, a dictionary slot is added to the instance layout and the `tp_dictoffset` is set to that slot's offset.

When a type defined by a class statement has a `__slots__` declaration, the type inherits its `tp_dictoffset` from its base type.

(Adding a slot named `__dict__` to the `__slots__` declaration does not have the expected effect, it just causes confusion. Maybe this should be added as a feature just like `__weakref__` though.)

`initproc PyTypeObject.tp_init`

An optional pointer to an instance initialization function.
This function corresponds to the `__init__()` method of classes. Like `__init__()` it is possible to create an instance without calling `__init__()`, and it is possible to reinitialize an instance by calling its `__init__()` method again.

The function signature is

```c
int tp_init(PyObject *self, PyObject *args, PyObject *kwds)
```

The `self` argument is the instance to be initialized; the `args` and `kwds` arguments represent positional and keyword arguments of the call to `__init__()`.

The `tp_init` function, if not `NULL`, is called when an instance is created normally by calling its type, after the type's `tp_new` function has returned an instance of the type. If the `tp_new` function returns an instance of some other type that is not a subtype of the original type, no `tp_init` function is called; if `tp_new` returns an instance of a subtype of the original type, the subtype's `tp_init` is called.

This field is inherited by subtypes.

**allocfunc** `PyObject.tp_alloc`

An optional pointer to an instance allocation function.

The function signature is

```c
PyObject *tp_alloc(PyTypeObject *self, Py_ssize_t size)
```

The purpose of this function is to separate memory allocation from memory initialization. It should return a pointer to a block of
memory of adequate length for the instance, suitably aligned, and initialized to zeros, but with ob_refcnt set to 1 and ob_type set to the type argument. If the type's \texttt{tp_itemsize} is non-zero, the object's ob_size field should be initialized to \textit{nitems} and the length of the allocated memory block should be \texttt{tp_basicsize + nitems*tp_itemsize}, rounded up to a multiple of \texttt{sizeof(void*)}; otherwise, \textit{nitems} is not used and the length of the block should be \texttt{tp_basicsize}.

Do not use this function to do any other instance initialization, not even to allocate additional memory; that should be done by \texttt{tp_new}.

This field is inherited by static subtypes, but not by dynamic subtypes (subtypes created by a class statement); in the latter, this field is always set to \texttt{PyType_GenericAlloc()}, to force a standard heap allocation strategy. That is also the recommended value for statically defined types.

\textbf{newfunc PyTypeObject.tp_new}

An optional pointer to an instance creation function.

If this function is \texttt{NULL} for a particular type, that type cannot be called to create new instances; presumably there is some other way to create instances, like a factory function.

The function signature is

\begin{verbatim}
PyObject *tp_new(PyTypeObject *subtype, PyObject

The subtype argument is the type of the object being created; the \textit{args} and \textit{kwds} arguments represent positional and keyword
arguments of the call to the type. Note that subtype doesn’t have to equal the type whose \texttt{tp\_new} function is called; it may be a subtype of that type (but not an unrelated type).

The \texttt{tp\_new} function should call \texttt{subtype\->tp\_alloc(subtype, nitems)} to allocate space for the object, and then do only as much further initialization as is absolutely necessary. Initialization that can safely be ignored or repeated should be placed in the \texttt{tp\_init} handler. A good rule of thumb is that for immutable types, all initialization should take place in \texttt{tp\_new}, while for mutable types, most initialization should be deferred to \texttt{tp\_init}.

This field is inherited by subtypes, except it is not inherited by static types whose \texttt{tp\_base} is \texttt{NULL} or \texttt{&PyBaseObject\_Type}.

destructor \texttt{PyTypeObject.tp\_free}

An optional pointer to an instance deallocation function. Its signature is \texttt{freefunc}:

\begin{verbatim}
void tp_free(void *)
\end{verbatim}

An initializer that is compatible with this signature is \texttt{PyObject\_Free()}.

This field is inherited by static subtypes, but not by dynamic subtypes (subtypes created by a class statement); in the latter, this field is set to a deallocator suitable to match \texttt{PyType\_GenericAlloc()} and the value of the \texttt{Py\_TPFLAGS\_HAVE\_GC} flag bit.

\texttt{inquiry PyTypeObject.tp\_is\_gc}
An optional pointer to a function called by the garbage collector.

The garbage collector needs to know whether a particular object is collectible or not. Normally, it is sufficient to look at the object’s type’s `tp_flags` field, and check the `Py_TPFLAGS_HAVE_GC` flag bit. But some types have a mixture of statically and dynamically allocated instances, and the statically allocated instances are not collectible. Such types should define this function; it should return `1` for a collectible instance, and `0` for a non-collectible instance. The signature is

```
int tp_is_gc(PyObject *self)
```

(The only example of this are types themselves. The metatype, `PyType_Type`, defines this function to distinguish between statically and dynamically allocated types.)

This field is inherited by subtypes.

**PyObject** `PyTypeObject.tp_bases`

Tuple of base types.

This is set for types created by a class statement. It should be `NULL` for statically defined types.

This field is not inherited.

**PyObject** `PyTypeObject.tp_mro`

Tuple containing the expanded set of base types, starting with the type itself and ending with `object`, in Method Resolution Order.

This field is not inherited; it is calculated fresh by `PyType_Ready()`.
**destructor PyTypeObject.tp_finalize**

An optional pointer to an instance finalization function. Its signature is destructor:

```c
void tp_finalize(PyObject *)
```

If `tp_finalize` is set, the interpreter calls it once when finalizing an instance. It is called either from the garbage collector (if the instance is part of an isolated reference cycle) or just before the object is deallocated. Either way, it is guaranteed to be called before attempting to break reference cycles, ensuring that it finds the object in a sane state.

`tp_finalize` should not mutate the current exception status; therefore, a recommended way to write a non-trivial finalizer is:

```c
static void
local_finalize(PyObject *self)
{
    PyObject *error_type, *error_value, *error_traceback;

    /* Save the current exception, if any. */
    PyErr_Fetch(&error_type, &error_value, &error_traceback);

    /* ... */

    /* Restore the saved exception. */
    PyErr_Restore(error_type, error_value, error_traceback);
}
```

For this field to be taken into account (even through inheritance), you must also set the `Py_TPFLAGS_HAVE_FINALIZE` flags bit.

This field is inherited by subtypes.
New in version 3.4.

See also: “Safe object finalization” (PEP 442)

PyObject* PyTypeObject.tp_cache
Unused. Not inherited. Internal use only.

PyObject* PyTypeObject.tp_subclasses
List of weak references to subclasses. Not inherited. Internal use only.

PyObject* PyTypeObject.tp_weaklist
Weak reference list head, for weak references to this type object. Not inherited. Internal use only.

The remaining fields are only defined if the feature test macro COUNT_ALLOC is defined, and are for internal use only. They are documented here for completeness. None of these fields are inherited by subtypes.

Py_ssize_t PyTypeObject.tp.allocs
Number of allocations.

Py_ssize_t PyTypeObject.tp.frees
Number of frees.

Py_ssize_t PyTypeObject.tp.maxalloc
Maximum simultaneously allocated objects.

PyTypeObject* PyTypeObject.tp.next
Pointer to the next type object with a non-zero tp.allocs field.

Also, note that, in a garbage collected Python, tp.dealloc may be
called from any Python thread, not just the thread which created the object (if the object becomes part of a refcount cycle, that cycle might be collected by a garbage collection on any thread). This is not a problem for Python API calls, since the thread on which tp_dealloc is called will own the Global Interpreter Lock (GIL). However, if the object being destroyed in turn destroys objects from some other C or C++ library, care should be taken to ensure that destroying those objects on the thread which called tp_dealloc will not violate any assumptions of the library.
Number Object Structures

PyNumberMethods

This structure holds pointers to the functions which an object uses to implement the number protocol. Each function is used by the function of similar name documented in the Number Protocol section.

Here is the structure definition:

```c
typedef struct {
    binaryfunc nb_add;
    binaryfunc nb_subtract;
    binaryfunc nb_multiply;
    binaryfunc nb_remainder;
    binaryfunc nb_divmod;
    ternaryfunc nb_power;
    unaryfunc nb_negative;
    unaryfunc nb_positive;
    unaryfunc nb_absolute;
    inquiry nb_bool;
    unaryfunc nb_invert;
    binaryfunc nb_lshift;
    binaryfunc nb_rshift;
    binaryfunc nb_and;
    binaryfunc nb_xor;
    binaryfunc nb_or;
    unaryfunc nb_int;
    void *nb_reserved;
    unaryfunc nb_float;
    binaryfunc nb_inplace_add;
    binaryfunc nb_inplace_subtract;
    binaryfunc nb_inplace_multiply;
} PyNumberMethods;
```
Note: Binary and ternary functions must check the type of all their operands, and implement the necessary conversions (at least one of the operands is an instance of the defined type). If the operation is not defined for the given operands, binary and ternary functions must return Py_NotImplemented, if another error occurred they must return NULL and set an exception.

Note: The nb_reserved field should always be NULL. It was previously called nb_long, and was renamed in Python 3.0.1.
Mapping Object Structures

**PyMappingMethods**

This structure holds pointers to the functions which an object uses to implement the mapping protocol. It has three members:

**lenfunc** `PyMappingMethods.mp_length`

This function is used by `PyMapping_Length()` and `PyObject_Size()`, and has the same signature. This slot may be set to `NULL` if the object has no defined length.

**binaryfunc** `PyMappingMethods.mp_subscript`

This function is used by `PyObject_GetItem()` and has the same signature. This slot must be filled for the `PyMapping_Check()` function to return 1, it can be `NULL` otherwise.

**objobjargproc** `PyMappingMethods.mp_ass_subscript`

This function is used by `PyObject_SetItem()` and `PyObject_DelItem()`. It has the same signature as `PyObject_SetItem()`, but v can also be set to `NULL` to delete an item. If this slot is `NULL`, the object does not support item assignment and deletion.
Sequence Object Structures

PySequenceMethods
This structure holds pointers to the functions which an object uses to implement the sequence protocol.

lenfunc PySequenceMethods.sq_length
This function is used by PySequence_Size() and PyObject_Size(), and has the same signature.

binaryfunc PySequenceMethods.sq_concat
This function is used by PySequence_Concat() and has the same signature. It is also used by the + operator, after trying the numeric addition via the nb_add slot.

ssizeargfunc PySequenceMethods.sq_repeat
This function is used by PySequence_Repeat() and has the same signature. It is also used by the * operator, after trying numeric multiplication via the nb_multiply slot.

ssizeargfunc PySequenceMethods.sq_item
This function is used by PySequence_GetItem() and has the same signature. This slot must be filled for the PySequence_Check() function to return 1, it can be NULL otherwise.

Negative indexes are handled as follows: if the sq_length slot is filled, it is called and the sequence length is used to compute a positive index which is passed to sq_item. If sq_length is NULL, the index is passed as is to the function.
ssizeobjargproc **PySequenceMethods.sq_ass_item**
This function is used by **PySequence_SetItem()** and has the same signature. This slot may be left to **NULL** if the object does not support item assignment and deletion.

$obj$objproc **PySequenceMethods.sq_contains**
This function may be used by **PySequence_Contains()** and has the same signature. This slot may be left to **NULL**, in this case **PySequence_Contains()** simply traverses the sequence until it finds a match.

binaryfunc **PySequenceMethods.sq_inplace_concat**
This function is used by **PySequence_InPlaceConcat()** and has the same signature. It should modify its first operand, and return it.

ssizeargfunc **PySequenceMethods.sq_inplace_repeat**
This function is used by **PySequence_InPlaceRepeat()** and has the same signature. It should modify its first operand, and return it.
Buffer Object Structures

**PyBufferProcs**

This structure holds pointers to the functions required by the Buffer protocol. The protocol defines how an exporter object can expose its internal data to consumer objects.

**getbufferproc** `PyBufferProcs bf_getbuffer`

The signature of this function is:

```c
int (PyObject *exporter, Py_buffer *view, int flags)
```

Handle a request to `exporter` to fill in `view` as specified by `flags`. Except for point (3), an implementation of this function MUST take these steps:

1. Check if the request can be met. If not, raise `PyExc_BufferError`, set `view->obj` to `NULL` and return `-1`.
2. Fill in the requested fields.
3. Increment an internal counter for the number of exports.
4. Set `view->obj` to `exporter` and increment `view->obj`.
5. Return 0.

If `exporter` is part of a chain or tree of buffer providers, two main schemes can be used:

- Re-export: Each member of the tree acts as the exporting object and sets `view->obj` to a new reference to itself.
- Redirect: The buffer request is redirected to the root object of the tree. Here, `view->obj` will be a new reference to the root object.
The individual fields of view are described in section Buffer structure, the rules how an exporter must react to specific requests are in section Buffer request types.

All memory pointed to in the Py_buffer structure belongs to the exporter and must remain valid until there are no consumers left. format, shape, strides, suboffsets and internal are read-only for the consumer.

PyBuffer_FillInfo() provides an easy way of exposing a simple bytes buffer while dealing correctly with all request types.

PyObject_GetBuffer() is the interface for the consumer that wraps this function.

releasebufferproc PyBufferProcs.bf_releasebuffer
The signature of this function is:

```c
void (PyObject *exporter, Py_buffer *view);
```

Handle a request to release the resources of the buffer. If no resources need to be released, PyBufferProcs.bf_releasebuffer may be NULL. Otherwise, a standard implementation of this function will take these optional steps:

1. Decrement an internal counter for the number of exports.
2. If the counter is 0, free all memory associated with view.

The exporter MUST use the internal field to keep track of buffer-specific resources. This field is guaranteed to remain constant, while a consumer MAY pass a copy of the original buffer as the view argument.
This function MUST NOT decrement view->obj, since that is done automatically in `PyBuffer_Release()` (this scheme is useful for breaking reference cycles).

`PyBuffer_Release()` is the interface for the consumer that wraps this function.
Async Object Structures

New in version 3.5.

**PyAsyncMethods**

This structure holds pointers to the functions required to implement *awaitable* and *asynchronous iterator* objects.

Here is the structure definition:

```c
typedef struct {
    unaryfunc am_await;
    unaryfunc am_aiter;
    unaryfunc am_anext;
} PyAsyncMethods;
```

**unaryfunc PyAsyncMethods.am_await**

The signature of this function is:

```c
PyObject *am_await(PyObject *self)
```

The returned object must be an iterator, i.e. `PyIter_Check()` must return 1 for it.

This slot may be set to `NULL` if an object is not an *awaitable*.

**unaryfunc PyAsyncMethods.am_aiter**

The signature of this function is:

```c
PyObject *am_aiter(PyObject *self)
```

Must return an *awaitable* object. See `__anext__()` for details.
This slot may be set to `NULL` if an object does not implement asynchronous iteration protocol.

Unaryfunc `PyAsyncMethods.am_anext`

The signature of this function is:

```c
PyObject *am_anext(PyObject *self)
```

Must return an `awaitable` object. See `__anext__()` for details. This slot may be set to `NULL`.
Supporting Cyclic Garbage Collection

Python's support for detecting and collecting garbage which involves circular references requires support from object types which are "containers" for other objects which may also be containers. Types which do not store references to other objects, or which only store references to atomic types (such as numbers or strings), do not need to provide any explicit support for garbage collection.

To create a container type, the `tp_flags` field of the type object must include the `Py_TPFLAGS_HAVE_GC` and provide an implementation of the `tp_traverse` handler. If instances of the type are mutable, a `tp_clear` implementation must also be provided.

**Py_TPFLAGS_HAVE_GC**

Objects with a type with this flag set must conform with the rules documented here. For convenience these objects will be referred to as container objects.

Constructors for container types must conform to two rules:

1. The memory for the object must be allocated using `PyObject_GC_New()` or `PyObject_GC_NewVar()`.
2. Once all the fields which may contain references to other containers are initialized, it must call `PyObject_GC_Track()`.

```c
TYPE* PyObject_GC_New(TYPE, PyTypeObject *type)
```

Analogous to `PyObject_New()` but for container objects with the `Py_TPFLAGS_HAVE_GC` flag set.
TYPE* **PyObject_GC_NewVar**(TYPE, PyTypeObject *type, Py_ssize_t size)

Analogous to `PyObject_NewVar()` but for container objects with the `Py_TPFLAGS_HAVE_GC` flag set.

TYPE* **PyObject_GC_Resize**(TYPE, PyVarObject *op, Py_ssize_t newsize)

Resize an object allocated by `PyObject_NewVar()`. Returns the resized object or `NULL` on failure.

void **PyObject_GC_Track**(PyObject *op)

Adds the object `op` to the set of container objects tracked by the collector. The collector can run at unexpected times so objects must be valid while being tracked. This should be called once all the fields followed by the `tp_traverse` handler become valid, usually near the end of the constructor.

void **_PyObject_GC_TRACK**(PyObject *op)

A macro version of `PyObject_GC_Track()`. It should not be used for extension modules.

Similarly, the deallocator for the object must conform to a similar pair of rules:

1. Before fields which refer to other containers are invalidated, `PyObject_GC_UnTrack()` must be called.
2. The object's memory must be deallocated using `PyObject_GC_Del()`.

void **PyObject_GC_Del**(void *op)

Releases memory allocated to an object using `PyObject_GC_New()` or `PyObject_GC_NewVar()`. 
void **PyObject\_GC\_UnTrack**(void \*op)

Remove the object \textit{op} from the set of container objects tracked by the collector. Note that **PyObject\_GC\_Track()** can be called again on this object to add it back to the set of tracked objects. The deallocator (**tp\_dealloc** handler) should call this for the object before any of the fields used by the **tp\_traverse** handler become invalid.

void \_**PyObject\_GC\_UNTRACK**(PyObject \*op)

A macro version of **PyObject\_GC\_UnTrack()**. It should not be used for extension modules.

The **tp\_traverse** handler accepts a function parameter of this type:

\textbf{int (**visitproc**)\(**(PyObject \*object, void \*arg)\)}

Type of the visitor function passed to the **tp\_traverse** handler. The function should be called with an object to traverse as **object** and the third parameter to the **tp\_traverse** handler as **arg**. The Python core uses several visitor functions to implement cyclic garbage detection; it’s not expected that users will need to write their own visitor functions.

The **tp\_traverse** handler must have the following type:

\textbf{int (**traverseproc**)\(**(PyObject \*self, visitproc visit, void \*arg)\)}

Traversal function for a container object. Implementations must call the **visit** function for each object directly contained by **self**, with the parameters to **visit** being the contained object and the **arg** value passed to the handler. The **visit** function must not be called with a **NULL** object argument. If **visit** returns a non-zero value that value should be returned immediately.
To simplify writing `tp_traverse` handlers, a `Py_VISIT()` macro is provided. In order to use this macro, the `tp_traverse` implementation must name its arguments exactly `visit` and `arg`:

```c
void Py_VISIT(PyObject *o)
```

If `o` is not `NULL`, call the `visit` callback, with arguments `o` and `arg`. If `visit` returns a non-zero value, then return it. Using this macro, `tp_traverse` handlers look like:

```c
static int my_traverse(Noddy *self, visitproc visit, void *arg)
{
    Py_VISIT(self->foo);
    Py_VISIT(self->bar);
    return 0;
}
```

The `tp_clear` handler must be of the `inquiry` type, or `NULL` if the object is immutable.

```c
int (*inquiry)(PyObject *self)
```

Drop references that may have created reference cycles. Immutable objects do not have to define this method since they can never directly create reference cycles. Note that the object must still be valid after calling this method (don’t just call `Py_DECREF()` on a reference). The collector will call this method if it detects that this object is involved in a reference cycle.
API and ABI Versioning

PY_VERSION_HEX is the Python version number encoded in a single integer.

For example if the PY_VERSION_HEX is set to 0x030401a2, the underlying version information can be found by treating it as a 32 bit number in the following manner:

<table>
<thead>
<tr>
<th>Bytes</th>
<th>Bits (big endian order)</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1-8</td>
<td>PY_MAJOR_VERSION (the 3 in 3.4.1a2)</td>
</tr>
<tr>
<td>2</td>
<td>9-16</td>
<td>PY_MINOR_VERSION (the 4 in 3.4.1a2)</td>
</tr>
<tr>
<td>3</td>
<td>17-24</td>
<td>PY_MICRO_VERSION (the 1 in 3.4.1a2)</td>
</tr>
<tr>
<td>4</td>
<td>25-28</td>
<td>PY_RELEASE_LEVEL (0xA for alpha, 0xB for beta, 0xC for release candidate and 0xF for final), in this case it is alpha.</td>
</tr>
<tr>
<td></td>
<td>29-32</td>
<td>PY_RELEASE_SERIAL (the 2 in 3.4.1a2, zero for final releases)</td>
</tr>
</tbody>
</table>

Thus 3.4.1a2 is hexversion 0x030401a2.

All the given macros are defined in Include/patchlevel.h.
Porting Python 2 Code to Python 3

author: Brett Cannon

Abstract

With Python 3 being the future of Python while Python 2 is still in active use, it is good to have your project available for both major releases of Python. This guide is meant to help you figure out how best to support both Python 2 & 3 simultaneously.

If you are looking to port an extension module instead of pure Python code, please see Porting Extension Modules to Python 3.

If you would like to read one core Python developer’s take on why Python 3 came into existence, you can read Nick Coghlan’s Python 3 Q & A or Brett Cannon’s Why Python 3 exists.

For help with porting, you can email the python-porting mailing list with questions.
To make your project be single-source Python 2/3 compatible, the basic steps are:

1. Only worry about supporting Python 2.7
2. Make sure you have good test coverage (coverage.py can help; pip install coverage)
3. Learn the differences between Python 2 & 3
4. Use Futurize (or Modernize) to update your code (e.g. pip install future)
5. Use Pylint to help make sure you don't regress on your Python 3 support (pip install pylint)
6. Use caniusepython3 to find out which of your dependencies are blocking your use of Python 3 (pip install caniusepython3)
7. Once your dependencies are no longer blocking you, use continuous integration to make sure you stay compatible with Python 2 & 3 (tox can help test against multiple versions of Python; pip install tox)
8. Consider using optional static type checking to make sure your type usage works in both Python 2 & 3 (e.g. use mypy to check your typing under both Python 2 & Python 3).
Details

A key point about supporting Python 2 & 3 simultaneously is that you can start **today**! Even if your dependencies are not supporting Python 3 yet that does not mean you can't modernize your code **now** to support Python 3. Most changes required to support Python 3 lead to cleaner code using newer practices even in Python 2 code.

Another key point is that modernizing your Python 2 code to also support Python 3 is largely automated for you. While you might have to make some API decisions thanks to Python 3 clarifying text data versus binary data, the lower-level work is now mostly done for you and thus can at least benefit from the automated changes immediately.

Keep those key points in mind while you read on about the details of porting your code to support Python 2 & 3 simultaneously.

Drop support for Python 2.6 and older

While you can make Python 2.5 work with Python 3, it is **much** easier if you only have to work with Python 2.7. If dropping Python 2.5 is not an option then the **six** project can help you support Python 2.5 & 3 simultaneously (**pip install six**). Do realize, though, that nearly all the projects listed in this HOWTO will not be available to you.

If you are able to skip Python 2.5 and older, then the required changes to your code should continue to look and feel like idiomatic Python code. At worst you will have to use a function instead of a method in some instances or have to import a function instead of using a built-in one, but otherwise the overall transformation should not feel foreign to you.
But you should aim for only supporting Python 2.7. Python 2.6 is no longer freely supported and thus is not receiving bugfixes. This means you will have to work around any issues you come across with Python 2.6. There are also some tools mentioned in this HOWTO which do not support Python 2.6 (e.g., Pylint), and this will become more commonplace as time goes on. It will simply be easier for you if you only support the versions of Python that you have to support.

Make sure you specify the proper version support in your setup.py file

In your setup.py file you should have the proper trove classifier specifying what versions of Python you support. As your project does not support Python 3 yet you should at least have Programming Language :: Python :: 2 :: Only specified. Ideally you should also specify each major/minor version of Python that you do support, e.g. Programming Language :: Python :: 2.7.

Have good test coverage

Once you have your code supporting the oldest version of Python 2 you want it to, you will want to make sure your test suite has good coverage. A good rule of thumb is that if you want to be confident enough in your test suite that any failures that appear after having tools rewrite your code are actual bugs in the tools and not in your code. If you want a number to aim for, try to get over 80% coverage (and don’t feel bad if you find it hard to get better than 90% coverage). If you don’t already have a tool to measure test coverage then coverage.py is recommended.
Learn the differences between Python 2 & 3

Once you have your code well-tested you are ready to begin porting your code to Python 3! But to fully understand how your code is going to change and what you want to look out for while you code, you will want to learn what changes Python 3 makes in terms of Python 2. Typically the two best ways of doing that is reading the “What’s New” doc for each release of Python 3 and the Porting to Python 3 book (which is free online). There is also a handy cheat sheet from the Python-Future project.

Update your code

Once you feel like you know what is different in Python 3 compared to Python 2, it's time to update your code! You have a choice between two tools in porting your code automatically: Futurize and Modernize. Which tool you choose will depend on how much like Python 3 you want your code to be. Futurize does its best to make Python 3 idioms and practices exist in Python 2, e.g. backporting the bytes type from Python 3 so that you have semantic parity between the major versions of Python. Modernize, on the other hand, is more conservative and targets a Python 2/3 subset of Python, directly relying on six to help provide compatibility. As Python 3 is the future, it might be best to consider Futurize to begin adjusting to any new practices that Python 3 introduces which you are not accustomed to yet.

Regardless of which tool you choose, they will update your code to run under Python 3 while staying compatible with the version of Python 2 you started with. Depending on how conservative you want to be, you may want to run the tool over your test suite first and visually inspect the diff to make sure the transformation is accurate. After you have
transformed your test suite and verified that all the tests still pass as expected, then you can transform your application code knowing that any tests which fail is a translation failure.

Unfortunately the tools can't automate everything to make your code work under Python 3 and so there are a handful of things you will need to update manually to get full Python 3 support (which of these steps are necessary vary between the tools). Read the documentation for the tool you choose to use to see what it fixes by default and what it can do optionally to know what will (not) be fixed for you and what you may have to fix on your own (e.g. using `io.open()` over the built-in `open()` function is off by default in Modernize). Luckily, though, there are only a couple of things to watch out for which can be considered large issues that may be hard to debug if not watched for.

**Division**

In Python 3, `5 / 2 == 2.5` and not 2; all division between `int` values result in a `float`. This change has actually been planned since Python 2.2 which was released in 2002. Since then users have been encouraged to add `from __future__ import division` to any and all files which use the `/` and `//` operators or to be running the interpreter with the `-Q` flag. If you have not been doing this then you will need to go through your code and do two things:

1. Add `from __future__ import division` to your files
2. Update any division operator as necessary to either use `//` to use floor division or continue using `/` and expect a float

The reason that `/` isn’t simply translated to `//` automatically is that if an object defines a `__truediv__` method but not `__floordiv__` then your code would begin to fail (e.g. a user-defined class that uses
Text versus binary data

In Python 2 you could use the `str` type for both text and binary data. Unfortunately this confluence of two different concepts could lead to brittle code which sometimes worked for either kind of data, sometimes not. It also could lead to confusing APIs if people didn't explicitly state that something that accepted `str` accepted either text or binary data instead of one specific type. This complicated the situation especially for anyone supporting multiple languages as APIs wouldn't bother explicitly supporting `unicode` when they claimed text data support.

To make the distinction between text and binary data clearer and more pronounced, Python 3 did what most languages created in the age of the internet have done and made text and binary data distinct types that cannot blindly be mixed together (Python predates widespread access to the internet). For any code that deals only with text or only binary data, this separation doesn't pose an issue. But for code that has to deal with both, it does mean you might have to now care about when you are using text compared to binary data, which is why this cannot be entirely automated.

To start, you will need to decide which APIs take text and which take binary (it is **highly** recommended you don't design APIs that can take both due to the difficulty of keeping the code working; as stated earlier it is difficult to do well). In Python 2 this means making sure the APIs that take text can work with `unicode` and those that work with binary data work with the `bytes` type from Python 3 (which is a subset of `str` in Python 2 and acts as an alias for `bytes` type in Python 2). Usually the biggest issue is realizing which methods exist on which
types in Python 2 & 3 simultaneously (for text that's unicode in Python 2 and str in Python 3, for binary that's str/bytes in Python 2 and bytes in Python 3). The following table lists the unique methods of each data type across Python 2 & 3 (e.g., the decode() method is usable on the equivalent binary data type in either Python 2 or 3, but it can’t be used by the textual data type consistently between Python 2 and 3 because str in Python 3 doesn’t have the method). Do note that as of Python 3.5 the _mod_ method was added to the bytes type.

<table>
<thead>
<tr>
<th>Text data</th>
<th>Binary data</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>decode</td>
</tr>
<tr>
<td>encode</td>
<td></td>
</tr>
<tr>
<td>format</td>
<td></td>
</tr>
<tr>
<td>isdecimal</td>
<td></td>
</tr>
<tr>
<td>isnumeric</td>
<td></td>
</tr>
</tbody>
</table>

Making the distinction easier to handle can be accomplished by encoding and decoding between binary data and text at the edge of your code. This means that when you receive text in binary data, you should immediately decode it. And if your code needs to send text as binary data then encode it as late as possible. This allows your code to work with only text internally and thus eliminates having to keep track of what type of data you are working with.

The next issue is making sure you know whether the string literals in your code represent text or binary data. You should add a b prefix to any literal that presents binary data. For text you should add a u prefix to the text literal. (there is a __future__ import to force all
unspecified literals to be Unicode, but usage has shown it isn’t as effective as adding a `b` or `u` prefix to all literals explicitly)

As part of this dichotomy you also need to be careful about opening files. Unless you have been working on Windows, there is a chance you have not always bothered to add the `b` mode when opening a binary file (e.g., `rb` for binary reading). Under Python 3, binary files and text files are clearly distinct and mutually incompatible; see the `io` module for details. Therefore, you **must** make a decision of whether a file will be used for binary access (allowing binary data to be read and/or written) or textual access (allowing text data to be read and/or written). You should also use `io.open()` for opening files instead of the built-in `open()` function as the `io` module is consistent from Python 2 to 3 while the built-in `open()` function is not (in Python 3 it's actually `io.open()`). Do not bother with the outdated practice of using `codecs.open()` as that's only necessary for keeping compatibility with Python 2.5.

The constructors of both `str` and `bytes` have different semantics for the same arguments between Python 2 & 3. Passing an integer to `bytes` in Python 2 will give you the string representation of the integer: `bytes(3) == '3'`. But in Python 3, an integer argument to `bytes` will give you a bytes object as long as the integer specified, filled with null bytes: `bytes(3) == b'\x00\x00\x00'`. A similar worry is necessary when passing a bytes object to `str`. In Python 2 you just get the bytes object back: `str(b'3') == b'3'`. But in Python 3 you get the string representation of the bytes object: `str(b'3') == "b'3'"`.

Finally, the indexing of binary data requires careful handling (slicing does **not** require any special handling). In Python 2, `b'123'[1] ==`
b'2' while in Python 3 b'123'[1] == 50. Because binary data is simply a collection of binary numbers, Python 3 returns the integer value for the byte you index on. But in Python 2 because `bytes == str`, indexing returns a one-item slice of bytes. The six project has a function named `six.indexbytes()` which will return an integer like in Python 3: `six.indexbytes(b'123', 1).

To summarize:

1. Decide which of your APIs take text and which take binary data
2. Make sure that your code that works with text also works with `unicode` and code for binary data works with `bytes` in Python 2 (see the table above for what methods you cannot use for each type)
3. Mark all binary literals with a `b` prefix, textual literals with a `u` prefix
4. Decode binary data to text as soon as possible, encode text as binary data as late as possible
5. Open files using `io.open()` and make sure to specify the `b` mode when appropriate
6. Be careful when indexing into binary data

Use feature detection instead of version detection

Inevitably you will have code that has to choose what to do based on what version of Python is running. The best way to do this is with feature detection of whether the version of Python you’re running under supports what you need. If for some reason that doesn’t work then you should make the version check be against Python 2 and not Python 3. To help explain this, let’s look at an example.

Let’s pretend that you need access to a feature of `importlib` that is available in Python’s standard library since Python 3.3 and available
for Python 2 through importlib2 on PyPI. You might be tempted to write code to access e.g. the importlib.abc module by doing the following:

```python
import sys
if sys.version_info[0] == 3:
    from importlib import abc
else:
    from importlib2 import abc
```

The problem with this code is what happens when Python 4 comes out? It would be better to treat Python 2 as the exceptional case instead of Python 3 and assume that future Python versions will be more compatible with Python 3 than Python 2:

```python
import sys
if sys.version_info[0] > 2:
    from importlib import abc
else:
    from importlib2 import abc
```

The best solution, though, is to do no version detection at all and instead rely on feature detection. That avoids any potential issues of getting the version detection wrong and helps keep you future-compatible:

```python
try:
    from importlib import abc
except ImportError:
    from importlib2 import abc
```

Prevent compatibility regressions
Once you have fully translated your code to be compatible with Python 3, you will want to make sure your code doesn’t regress and stop working under Python 3. This is especially true if you have a dependency which is blocking you from actually running under Python 3 at the moment.

To help with staying compatible, any new modules you create should have at least the following block of code at the top of it:

```python
from __future__ import absolute_import
from __future__ import division
from __future__ import print_function
```

You can also run Python 2 with the `-3` flag to be warned about various compatibility issues your code triggers during execution. If you turn warnings into errors with `-Werror` then you can make sure that you don’t accidentally miss a warning.

You can also use the Pylint project and its `--py3k` flag to lint your code to receive warnings when your code begins to deviate from Python 3 compatibility. This also prevents you from having to run Modernize or Futurize over your code regularly to catch compatibility regressions. This does require you only support Python 2.7 and Python 3.4 or newer as that is Pylint’s minimum Python version support.

Check which dependencies block your transition

After you have made your code compatible with Python 3 you should begin to care about whether your dependencies have also been ported. The caniusepython3 project was created to help you determine which projects — directly or indirectly — are blocking you from
supporting Python 3. There is both a command-line tool as well as a web interface at https://caniusepython3.com.

The project also provides code which you can integrate into your test suite so that you will have a failing test when you no longer have dependencies blocking you from using Python 3. This allows you to avoid having to manually check your dependencies and to be notified quickly when you can start running on Python 3.

**Update your setup.py file to denote Python 3 compatibility**

Once your code works under Python 3, you should update the classifiers in your setup.py to contain `Programming Language :: Python :: 3` and to not specify sole Python 2 support. This will tell anyone using your code that you support Python 2 and 3. Ideally you will also want to add classifiers for each major/minor version of Python you now support.

**Use continuous integration to stay compatible**

Once you are able to fully run under Python 3 you will want to make sure your code always works under both Python 2 & 3. Probably the best tool for running your tests under multiple Python interpreters is `tox`. You can then integrate tox with your continuous integration system so that you never accidentally break Python 2 or 3 support.

You may also want to use the `-bb` flag with the Python 3 interpreter to trigger an exception when you are comparing bytes to strings or bytes to an int (the latter is available starting in Python 3.5). By default type-differing comparisons simply return `False`, but if you made a mistake...
in your separation of text/binary data handling or indexing on bytes you wouldn’t easily find the mistake. This flag will raise an exception when these kinds of comparisons occur, making the mistake much easier to track down.

And that’s mostly it! At this point your code base is compatible with both Python 2 and 3 simultaneously. Your testing will also be set up so that you don’t accidentally break Python 2 or 3 compatibility regardless of which version you typically run your tests under while developing.

Consider using optional static type checking

Another way to help port your code is to use a static type checker like mypy or pytype on your code. These tools can be used to analyze your code as if it's being run under Python 2, then you can run the tool a second time as if your code is running under Python 3. By running a static type checker twice like this you can discover if you're e.g. misusing binary data type in one version of Python compared to another. If you add optional type hints to your code you can also explicitly state whether your APIs use textual or binary data, helping to make sure everything functions as expected in both versions of Python.
Porting Extension Modules to Python 3

author: Benjamin Peterson

Abstract

Although changing the C-API was not one of Python 3's objectives, the many Python-level changes made leaving Python 2's API intact impossible. In fact, some changes such as `int()` and `long()` unification are more obvious on the C level. This document endeavors to document incompatibilities and how they can be worked around.
Conditional compilation

The easiest way to compile only some code for Python 3 is to check if PY_MAJOR_VERSION is greater than or equal to 3.

```
#if PY_MAJOR_VERSION >= 3
#define IS_PY3K
#endif
```

API functions that are not present can be aliased to their equivalents within conditional blocks.
Changes to Object APIs

Python 3 merged together some types with similar functions while cleanly separating others.

str/unicode Unification

Python 3’s `str()` type is equivalent to Python 2’s `unicode()`; the C functions are called `PyUnicode_*` for both. The old 8-bit string type has become `bytes()`, with C functions called `PyBytes_*`. Python 2.6 and later provide a compatibility header, `bytesobject.h`, mapping `PyBytes` names to `PyString` ones. For best compatibility with Python 3, `PyUnicode` should be used for textual data and `PyBytes` for binary data. It’s also important to remember that `PyBytes` and `PyUnicode` in Python 3 are not interchangeable like `PyString` and `PyUnicode` are in Python 2. The following example shows best practices with regards to `PyUnicode`, `PyString`, and `PyBytes`.

```c
#include "stdlib.h"
#include "Python.h"
#include "bytesobject.h"

/* text example */
static PyObject *
say_hello(PyObject *self, PyObject *args) {
    PyObject *name, *result;

    if (!PyArg_ParseTuple(args, "U:say_hello", &name)
        return NULL;

    result = PyUnicode_FromFormat("Hello, %S!", name)
```

```c
return result;
}

/* just a forward */
static char * do_encode(PyObject *);

/* bytes example */
static PyObject *
encode_object(PyObject *self, PyObject *args) {
    char    *encoded;
    PyObject *result,      *myobj;

    if (!PyArg_ParseTuple(args, "O:encode_object", &myobj))
        return NULL;

    encoded       = do_encode(myobj);
    if (encoded   == NULL)
        return NULL;
    result        = PyBytes_FromString(encoded);
    free(encoded);  
    return         result;
}
```

**long/int Unification**

Python 3 has only one integer type, `int()`. But it actually corresponds to Python 2's `long()` type—the `int()` type used in Python 2 was removed. In the C-API, `PyInt_*` functions are replaced by their `PyLong_*` equivalents.
Module initialization and state

Python 3 has a revamped extension module initialization system. (See PEP 3121.) Instead of storing module state in globals, they should be stored in an interpreter specific structure. Creating modules that act correctly in both Python 2 and Python 3 is tricky. The following simple example demonstrates how.

```c
#include "Python.h"

struct module_state {
    PyObject *error;
};

#if PY_MAJOR_VERSION >= 3
#define GETSTATE(m) ((struct module_state*)PyModule_GetState(m))
#else
#define GETSTATE(m) (&_state)
#endif

static struct module_state _state;

static PyObject *
error_out(PyObject *m) {
    struct module_state *st = GETSTATE(m);
    PyErr_SetString(st->error, "something bad happened");
    return NULL;
}

static PyMethodDef myextension_methods[] = {
    {"error_out", (PyCFunction)error_out, METH_NOARGS},
    {NULL, NULL}
};

#if PY_MAJOR_VERSION >= 3
```
static int myextension_traverse(PyObject *m, visitproc visitp, void *visitdata) {
    Py_VISIT(GETSTATE(m)->error);
    return 0;
}

static int myextension_clear(PyObject *m) {
    Py_CLEAR(GETSTATE(m)->error);
    return 0;
}

static struct PyModuleDef moduledef = {
    PyModuleDef_HEAD_INIT,
    "myextension",
    NULL,
    sizeof(struct module_state),
    myextension_methods,

CObject replaced with Capsule

The Capsule object was introduced in Python 3.1 and 2.7 to replace CObject. CObjects were useful, but the CObject API was problematic: it didn’t permit distinguishing between valid CObjects, which allowed mismatched CObjects to crash the interpreter, and some of its APIs relied on undefined behavior in C. (For further reading on the rationale behind Capsules, please see bpo-5630.)

If you’re currently using CObjects, and you want to migrate to 3.1 or newer, you’ll need to switch to Capsules. CObject was deprecated in 3.1 and 2.7 and completely removed in Python 3.2. If you only support 2.7, or 3.1 and above, you can simply switch to Capsule. If you need to support Python 3.0, or versions of Python earlier than 2.7, you’ll have to support both CObjects and Capsules. (Note that Python 3.0 is no longer supported, and it is not recommended for production use.)

The following example header file capsulethunk.h may solve the problem for you. Simply write your code against the Capsule API and include this header file after Python.h. Your code will automatically use Capsules in versions of Python with Capsules, and switch to CObjects when Capsules are unavailable.

capsulethunk.h simulates Capsules using CObjects. However, CObject provides no place to store the capsule’s “name”. As a result the simulated Capsule objects created by capsulethunk.h behave slightly differently from real Capsules. Specifically:

- The name parameter passed in to PyCapsule_New() is ignored.
- The name parameter passed in to PyCapsule_IsValid()
and \texttt{PyCapsule\_GetPointer()} is ignored, and no error checking of the name is performed.

- \texttt{PyCapsule\_GetName()} always returns NULL.
- \texttt{PyCapsule\_SetName()} always raises an exception and returns failure. (Since there's no way to store a name in a \texttt{CObject}, noisy failure of \texttt{PyCapsule\_SetName()} was deemed preferable to silent failure here. If this is inconvenient, feel free to modify your local copy as you see fit.)

You can find \texttt{capsulethunk.h} in the Python source distribution as \texttt{Doc/includes/capsulethunk.h}. We also include it here for your convenience:

```c
#ifndef __CAPSULETHUNK_H
#define __CAPSULETHUNK_H

Other options

If you are writing a new extension module, you might consider Cython. It translates a Python-like language to C. The extension modules it creates are compatible with Python 3 and Python 2.
Abstract

This document describes how to use the `curses` extension module to control text-mode displays.
What is curses?

The curses library supplies a terminal-independent screen-painting and keyboard-handling facility for text-based terminals; such terminals include VT100s, the Linux console, and the simulated terminal provided by various programs. Display terminals support various control codes to perform common operations such as moving the cursor, scrolling the screen, and erasing areas. Different terminals use widely differing codes, and often have their own minor quirks.

In a world of graphical displays, one might ask “why bother”? It’s true that character-cell display terminals are an obsolete technology, but there are niches in which being able to do fancy things with them are still valuable. One niche is on small-footprint or embedded Unixes that don’t run an X server. Another is tools such as OS installers and kernel configurators that may have to run before any graphical support is available.

The curses library provides fairly basic functionality, providing the programmer with an abstraction of a display containing multiple non-overlapping windows of text. The contents of a window can be changed in various ways—adding text, erasing it, changing its appearance—and the curses library will figure out what control codes need to be sent to the terminal to produce the right output. curses doesn’t provide many user-interface concepts such as buttons, checkboxes, or dialogs; if you need such features, consider a user interface library such as Urwid.

The curses library was originally written for BSD Unix; the later System V versions of Unix from AT&T added many enhancements and new functions. BSD curses is no longer maintained, having been replaced by ncurses, which is an open-source implementation of the AT&T
interface. If you’re using an open-source Unix such as Linux or FreeBSD, your system almost certainly uses ncurses. Since most current commercial Unix versions are based on System V code, all the functions described here will probably be available. The older versions of curses carried by some proprietary Unixes may not support everything, though.

The Windows version of Python doesn’t include the curses module. A ported version called UniCurses is available. You could also try the Console module written by Fredrik Lundh, which doesn’t use the same API as curses but provides cursor-addressable text output and full support for mouse and keyboard input.

## The Python curses module

The Python module is a fairly simple wrapper over the C functions provided by curses; if you’re already familiar with curses programming in C, it’s really easy to transfer that knowledge to Python. The biggest difference is that the Python interface makes things simpler by merging different C functions such as addstr(), mvaddstr(), and mvwaddstr() into a single addstr() method. You’ll see this covered in more detail later.

This HOWTO is an introduction to writing text-mode programs with curses and Python. It doesn’t attempt to be a complete guide to the curses API; for that, see the Python library guide’s section on ncurses, and the C manual pages for ncurses. It will, however, give you the basic ideas.
Starting and ending a curses application

Before doing anything, curses must be initialized. This is done by calling the `initscr()` function, which will determine the terminal type, send any required setup codes to the terminal, and create various internal data structures. If successful, `initscr()` returns a window object representing the entire screen; this is usually called `stdscr` after the name of the corresponding C variable.

```python
import curses
stdscr = curses.initscr()
```

Usually curses applications turn off automatic echoing of keys to the screen, in order to be able to read keys and only display them under certain circumstances. This requires calling the `noecho()` function.

```python
curses.noecho()
```

Applications will also commonly need to react to keys instantly, without requiring the Enter key to be pressed; this is called cbreak mode, as opposed to the usual buffered input mode.

```python
curses.cbreak()
```

Terminals usually return special keys, such as the cursor keys or navigation keys such as Page Up and Home, as a multibyte escape sequence. While you could write your application to expect such sequences and process them accordingly, curses can do it for you, returning a special value such as `curses.KEY_LEFT`. To get curses to do the job, you’ll have to enable keypad mode.

```python
stdscr.kepad(True)
```
Terminating a curses application is much easier than starting one. You'll need to call:

```python
curses.nocbreak()
stdscr.keypad(False)
curses.echo()
```

to reverse the curses-friendly terminal settings. Then call the `endwin()` function to restore the terminal to its original operating mode.

```python
curses.endwin()
```

A common problem when debugging a curses application is to get your terminal messed up when the application dies without restoring the terminal to its previous state. In Python this commonly happens when your code is buggy and raises an uncaught exception. Keys are no longer echoed to the screen when you type them, for example, which makes using the shell difficult.

In Python you can avoid these complications and make debugging much easier by importing the `curses.wrapper()` function and using it like this:

```python
from curses import wrapper

def main(stdscr):
    # Clear screen
    stdscr.clear()

    # This raises ZeroDivisionError when i == 10.
    for i in range(0, 11):
        v = i-10
```
stdscr.addstr(i, 0, '10 divided by {} is {}')

stdscr.refresh()
stdscr.getkey()

wrapper(main)

The **wrapper()** function takes a callable object and does the initializations described above, also initializing colors if color support is present. wrapper() then runs your provided callable. Once the callable returns, wrapper() will restore the original state of the terminal. The callable is called inside a `try...except` that catches exceptions, restores the state of the terminal, and then re-raises the exception. Therefore your terminal won't be left in a funny state on exception and you'll be able to read the exception's message and traceback.
Windows and Pads

Windows are the basic abstraction in curses. A window object represents a rectangular area of the screen, and supports methods to display text, erase it, allow the user to input strings, and so forth.

The `stdscr` object returned by the `initscr()` function is a window object that covers the entire screen. Many programs may need only this single window, but you might wish to divide the screen into smaller windows, in order to redraw or clear them separately. The `newwin()` function creates a new window of a given size, returning the new window object.

```c
begin_x = 20; begin_y = 7
height = 5; width = 40
win = curses.newwin(height, width, begin_y, begin_x)
```

Note that the coordinate system used in curses is unusual. Coordinates are always passed in the order y,x, and the top-left corner of a window is coordinate (0,0). This breaks the normal convention for handling coordinates where the x coordinate comes first. This is an unfortunate difference from most other computer applications, but it's been part of curses since it was first written, and it's too late to change things now.

Your application can determine the size of the screen by using the `curses.LINES` and `curses.COLS` variables to obtain the y and x sizes. Legal coordinates will then extend from \((0,0)\) to \((\text{curses.LINES - 1, curses.COLS - 1})\).

When you call a method to display or erase text, the effect doesn't
immediately show up on the display. Instead you must call the \texttt{refresh()} method of window objects to update the screen.

This is because curses was originally written with slow 300-baud terminal connections in mind; with these terminals, minimizing the time required to redraw the screen was very important. Instead curses accumulates changes to the screen and displays them in the most efficient manner when you call \texttt{refresh()}. For example, if your program displays some text in a window and then clears the window, there’s no need to send the original text because they’re never visible.

In practice, explicitly telling curses to redraw a window doesn’t really complicate programming with curses much. Most programs go into a flurry of activity, and then pause waiting for a keypress or some other action on the part of the user. All you have to do is to be sure that the screen has been redrawn before pausing to wait for user input, by first calling \texttt{stdscr.refresh()} or the \texttt{refresh()} method of some other relevant window.

A pad is a special case of a window; it can be larger than the actual display screen, and only a portion of the pad displayed at a time. Creating a pad requires the pad’s height and width, while refreshing a pad requires giving the coordinates of the on-screen area where a subsection of the pad will be displayed.

\begin{minted}[linenos]{python}
# These loops fill the pad with letters; addch() is explained in the next section
for y in range(0, 99):
    for x in range(0, 99):
        pad.addch(y, x, ord('a') + (x*x+y*y) % 26)

# Displays a section of the pad in the middle of the pad
# (0,0) : coordinate of upper-left corner of pad area
\end{minted}
The `refresh()` call displays a section of the pad in the rectangle extending from coordinate (5,5) to coordinate (20,75) on the screen; the upper left corner of the displayed section is coordinate (0,0) on the pad. Beyond that difference, pads are exactly like ordinary windows and support the same methods.

If you have multiple windows and pads on screen there is a more efficient way to update the screen and prevent annoying screen flicker as each part of the screen gets updated. `refresh()` actually does two things:

1. Calls the `noutrefresh()` method of each window to update an underlying data structure representing the desired state of the screen.
2. Calls the function `doupdate()` function to change the physical screen to match the desired state recorded in the data structure.

Instead you can call `noutrefresh()` on a number of windows to update the data structure, and then call `doupdate()` to update the screen.
Displaying Text

From a C programmer’s point of view, curses may sometimes look like a twisty maze of functions, all subtly different. For example, `addstr()` displays a string at the current cursor location in the `stdscr` window, while `mvaddstr()` moves to a given y,x coordinate first before displaying the string. `waddstr()` is just like `addstr()`, but allows specifying a window to use instead of using `stdscr` by default. `mvwaddstr()` allows specifying both a window and a coordinate.

Fortunately the Python interface hides all these details. `stdscr` is a window object like any other, and methods such as `addstr()` accept multiple argument forms. Usually there are four different forms.

<table>
<thead>
<tr>
<th>Form</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>str or ch</code></td>
<td>Display the string <code>str</code> or character <code>ch</code> at the current position</td>
</tr>
<tr>
<td><code>str or ch, attr</code></td>
<td>Display the string <code>str</code> or character <code>ch</code>, using attribute <code>attr</code> at the current position</td>
</tr>
<tr>
<td><code>y, x, str or ch</code></td>
<td>Move to position <code>y,x</code> within the window, and display <code>str</code> or <code>ch</code></td>
</tr>
<tr>
<td><code>y, x, str or ch, attr</code></td>
<td>Move to position <code>y,x</code> within the window, and display <code>str</code> or <code>ch</code>, using attribute <code>attr</code></td>
</tr>
</tbody>
</table>

Attributes allow displaying text in highlighted forms such as boldface, underline, reverse code, or in color. They’ll be explained in more detail in the next subsection.
The `addstr()` method takes a Python string or bytestring as the value to be displayed. The contents of bytestrings are sent to the terminal as-is. Strings are encoded to bytes using the value of the window's encoding attribute; this defaults to the default system encoding as returned by `locale.getpreferredencoding()`.

The `addch()` methods take a character, which can be either a string of length 1, a bytestring of length 1, or an integer.

Constants are provided for extension characters; these constants are integers greater than 255. For example, ACS_PLMINUS is a +/- symbol, and ACS_ULCORNER is the upper left corner of a box (handy for drawing borders). You can also use the appropriate Unicode character.

Windows remember where the cursor was left after the last operation, so if you leave out the y,x coordinates, the string or character will be displayed wherever the last operation left off. You can also move the cursor with the `move(y,x)` method. Because some terminals always display a flashing cursor, you may want to ensure that the cursor is positioned in some location where it won’t be distracting; it can be confusing to have the cursor blinking at some apparently random location.

If your application doesn’t need a blinking cursor at all, you can call `curs_set(False)` to make it invisible. For compatibility with older curses versions, there’s a `leaveok(bool)` function that’s a synonym for `curs_set()`. When `bool` is true, the curses library will attempt to suppress the flashing cursor, and you won’t need to worry about leaving it in odd locations.

Attributes and Color
Characters can be displayed in different ways. Status lines in a text-based application are commonly shown in reverse video, or a text viewer may need to highlight certain words. curses supports this by allowing you to specify an attribute for each cell on the screen.

An attribute is an integer, each bit representing a different attribute. You can try to display text with multiple attribute bits set, but curses doesn’t guarantee that all the possible combinations are available, or that they’re all visually distinct. That depends on the ability of the terminal being used, so it’s safest to stick to the most commonly available attributes, listed here.

<table>
<thead>
<tr>
<th>Attribute</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>A_BLINK</td>
<td>Blinking text</td>
</tr>
<tr>
<td>A_BOLD</td>
<td>Extra bright or bold text</td>
</tr>
<tr>
<td>A_DIM</td>
<td>Half bright text</td>
</tr>
<tr>
<td>A_REVERSE</td>
<td>Reverse-video text</td>
</tr>
<tr>
<td>A_STANDOUT</td>
<td>The best highlighting mode available</td>
</tr>
<tr>
<td>A_UNDERLINE</td>
<td>Underlined text</td>
</tr>
</tbody>
</table>

So, to display a reverse-video status line on the top line of the screen, you could code:

```python
tdscr.addstr(0, 0, "Current mode: Typing mode", curses.A_REVERSE)
stdscr.refresh()
```

The curses library also supports color on those terminals that provide it. The most common such terminal is probably the Linux console, followed by color xterms.
To use color, you must call the `start_color()` function soon after calling `initscr()`, to initialize the default color set (the `curses.wrapper()` function does this automatically). Once that's done, the `has_colors()` function returns TRUE if the terminal in use can actually display color. (Note: `curses` uses the American spelling ‘color’, instead of the Canadian/British spelling ‘colour’. If you’re used to the British spelling, you’ll have to resign yourself to misspelling it for the sake of these functions.)

The `curses` library maintains a finite number of color pairs, containing a foreground (or text) color and a background color. You can get the attribute value corresponding to a color pair with the `color_pair()` function; this can be bitwise-OR’ed with other attributes such as `A_REVERSE`, but again, such combinations are not guaranteed to work on all terminals.

An example, which displays a line of text using color pair 1:

```python
stdscr.addstr("Pretty text", curses.color_pair(1))
stdscr.refresh()
```

As I said before, a color pair consists of a foreground and background color. The `init_pair(n, f, b)` function changes the definition of color pair `n`, to foreground color `f` and background color `b`. Color pair 0 is hard-wired to white on black, and cannot be changed.

Colors are numbered, and `start_color()` initializes 8 basic colors when it activates color mode. They are: 0:black, 1:red, 2:green, 3:yellow, 4:blue, 5:magenta, 6:cyan, and 7:white. The `curses` module defines named constants for each of these colors: `curses.COLOR_BLACK`, `curses.COLOR_RED`, and so forth.

Let’s put all this together. To change color 1 to red text on a white
background, you would call:

```python
curses.init_pair(1, curses.COLOR_RED, curses.COLOR_WHITE)
```

When you change a color pair, any text already displayed using that color pair will change to the new colors. You can also display new text in this color with:

```python
stdscr.addstr(0, 0, "RED ALERT!", curses.color_pair(1))
```

Very fancy terminals can change the definitions of the actual colors to a given RGB value. This lets you change color 1, which is usually red, to purple or blue or any other color you like. Unfortunately, the Linux console doesn’t support this, so I’m unable to try it out, and can’t provide any examples. You can check if your terminal can do this by calling `can_change_color()`, which returns `True` if the capability is there. If you’re lucky enough to have such a talented terminal, consult your system’s man pages for more information.
User Input

The C curses library offers only very simple input mechanisms. Python’s curses module adds a basic text-input widget. (Other libraries such as Urwid have more extensive collections of widgets.)

There are two methods for getting input from a window:

- `getch()` refreshes the screen and then waits for the user to hit a key, displaying the key if `echo()` has been called earlier. You can optionally specify a coordinate to which the cursor should be moved before pausing.
- `getkey()` does the same thing but converts the integer to a string. Individual characters are returned as 1-character strings, and special keys such as function keys return longer strings containing a key name such as `KEY_UP` or `^G`.

It’s possible to not wait for the user using the `nodelay()` window method. After `nodelay(True)`, `getch()` and `getkey()` for the window become non-blocking. To signal that no input is ready, `getch()` returns `curses.ERR` (a value of -1) and `getkey()` raises an exception. There’s also a `halfdelay()` function, which can be used to (in effect) set a timer on each `getch()`; if no input becomes available within a specified delay (measured in tenths of a second), `curses` raises an exception.

The `getch()` method returns an integer; if it’s between 0 and 255, it represents the ASCII code of the key pressed. Values greater than 255 are special keys such as Page Up, Home, or the cursor keys. You can compare the value returned to constants such as `curses.KEY_PPAGE`, `curses.KEY_HOME`, or `curses.KEY_LEFT`. The main loop of your program may look something like this:
while True:
    c = stdscr.getch()
    if c == ord('p'):
        PrintDocument()
    elif c == ord('q'):
        break  # Exit the while loop
    elif c == curses.KEY_HOME:
        x = y = 0

The curses.ascii module supplies ASCII class membership functions that take either integer or 1-character string arguments; these may be useful in writing more readable tests for such loops. It also supplies conversion functions that take either integer or 1-character-string arguments and return the same type. For example, curses.ascii.ctrl() returns the control character corresponding to its argument.

There's also a method to retrieve an entire string, getstr(). It isn't used very often, because its functionality is quite limited; the only editing keys available are the backspace key and the Enter key, which terminates the string. It can optionally be limited to a fixed number of characters.

curses.echo()  # Enable echoing of characters

# Get a 15-character string, with the cursor on the top line
s = stdscr.getstr(0,0,15)

The curses.textpad module supplies a text box that supports an Emacs-like set of keybindings. Various methods of the Textbox class support editing with input validation and gathering the edit results either with or without trailing spaces. Here's an example:
import curses
from curses.textpad import Textbox, rectangle

def main(stdscr):
    stdscr.addstr(0, 0, "Enter IM message: (hit Ctrl-G to send)"

    editwin = curses.newwin(5, 30, 2, 1)
    rectangle(stdscr, 1, 0, 1+5+1, 1+30+1)
    stdscr.refresh()

    box = Textbox(editwin)

    # Let the user edit until Ctrl-G is struck.
    box.edit()

    # Get resulting contents
    message = box.gather()

See the library documentation on curses.textpad for more details.
For More Information

This HOWTO doesn’t cover some advanced topics, such as reading the contents of the screen or capturing mouse events from an xterm instance, but the Python library page for the curses module is now reasonably complete. You should browse it next.

If you’re in doubt about the detailed behavior of the curses functions, consult the manual pages for your curses implementation, whether it’s ncurses or a proprietary Unix vendor’s. The manual pages will document any quirks, and provide complete lists of all the functions, attributes, and ACS_* characters available to you.

Because the curses API is so large, some functions aren’t supported in the Python interface. Often this isn’t because they’re difficult to implement, but because no one has needed them yet. Also, Python doesn’t yet support the menu library associated with ncurses. Patches adding support for these would be welcome; see the Python Developer’s Guide to learn more about submitting patches to Python.

Abstract

Defines descriptors, summarizes the protocol, and shows how descriptors are called. Examines a custom descriptor and several built-in python descriptors including functions, properties, static methods, and class methods. Shows how each works by giving a pure Python equivalent and a sample application.

Learning about descriptors not only provides access to a larger toolset, it creates a deeper understanding of how Python works and an appreciation for the elegance of its design.
Definition and Introduction

In general, a descriptor is an object attribute with “binding behavior”, one whose attribute access has been overridden by methods in the descriptor protocol. Those methods are __get__(), __set__(), and __delete__(). If any of those methods are defined for an object, it is said to be a descriptor.

The default behavior for attribute access is to get, set, or delete the attribute from an object's dictionary. For instance, a.x has a lookup chain starting with a.__dict__['x'], then type(a).__dict__['x'], and continuing through the base classes of type(a) excluding metaclasses. If the looked-up value is an object defining one of the descriptor methods, then Python may override the default behavior and invoke the descriptor method instead. Where this occurs in the precedence chain depends on which descriptor methods were defined.

Descriptors are a powerful, general purpose protocol. They are the mechanism behind properties, methods, static methods, class methods, and super(). They are used throughout Python itself to implement the new style classes introduced in version 2.2. Descriptors simplify the underlying C-code and offer a flexible set of new tools for everyday Python programs.
Descriptor Protocol

descr.__get__(self, obj, type=None) --> value

descr.__set__(self, obj, value) --> None

descr.__delete__(self, obj) --> None

That is all there is to it. Define any of these methods and an object is considered a descriptor and can override default behavior upon being looked up as an attribute.

If an object defines both __get__() and __set__(), it is considered a data descriptor. Descriptors that only define __get__() are called non-data descriptors (they are typically used for methods but other uses are possible).

Data and non-data descriptors differ in how overrides are calculated with respect to entries in an instance's dictionary. If an instance's dictionary has an entry with the same name as a data descriptor, the data descriptor takes precedence. If an instance's dictionary has an entry with the same name as a non-data descriptor, the dictionary entry takes precedence.

To make a read-only data descriptor, define both __get__() and __set__() with the __set__() raising an AttributeError when called. Defining the __set__() method with an exception raising placeholder is enough to make it a data descriptor.
Invoking Descriptors

A descriptor can be called directly by its method name. For example, `d.__get__(obj)`.

Alternatively, it is more common for a descriptor to be invoked automatically upon attribute access. For example, `obj.d` looks up `d` in the dictionary of `obj`. If `d` defines the method `__get__()`, then `d.__get__(obj)` is invoked according to the precedence rules listed below.

The details of invocation depend on whether `obj` is an object or a class.

For objects, the machinery is in `object.__getattribute__()` which transforms `b.x` into `type(b).__dict__['x' ].__get__(b, type(b))`. The implementation works through a precedence chain that gives data descriptors priority over instance variables, instance variables priority over non-data descriptors, and assigns lowest priority to `__getattr__()` if provided. The full C implementation can be found in `PyObject_GenericGetAttr()` in `Objects/object.c`.

For classes, the machinery is in `type.__getattribute__()` which transforms `B.x` into `B.__dict__['x' ].__get__(None, B)`. In pure Python, it looks like:

```python
def __getattribute__(self, key):
    # Emulate type_getattro() in Objects/typeobject.c
    v = object.__getattribute__(self, key)
    if hasattr(v, '__get__ '):
        return v.__get__(None, self)
    return v
```
The important points to remember are:

- descriptors are invoked by the `__getattribute__()` method
- overriding `__getattribute__()` prevents automatic descriptor calls
- `object.__getattribute__()` and `type.__getattribute__()` make different calls to `__get__()`.  
- data descriptors always override instance dictionaries.
- non-data descriptors may be overridden by instance dictionaries.

The object returned by `super()` also has a custom `__getattribute__()` method for invoking descriptors. The call `super(B, obj).m()` searches `obj.__class__.__mro__` for the base class `A` immediately following `B` and then returns `A.__dict__['m'].__get__(obj, B)`. If not a descriptor, `m` is returned unchanged. If not in the dictionary, `m` reverts to a search using `object.__getattribute__()`.

The implementation details are in `super_getattro()` in `Objects/typeobject.c` and a pure Python equivalent can be found in Guido's Tutorial.

The details above show that the mechanism for descriptors is embedded in the `__getattribute__()` methods for `object`, `type`, and `super()`. Classes inherit this machinery when they derive from `object` or if they have a meta-class providing similar functionality. Likewise, classes can turn-off descriptor invocation by overriding `__getattribute__()`. 
Descriptor Example

The following code creates a class whose objects are data descriptors which print a message for each get or set. Overriding __getattribute__() is alternate approach that could do this for every attribute. However, this descriptor is useful for monitoring just a few chosen attributes:

```python
class RevealAccess(object):
    """A data descriptor that sets and returns values normally and prints a message logging their access. """

    def __init__(self, initval=None, name='var '):
        self.val = initval
        self.name = name

    def __get__(self, obj, objtype):
        print('Retrieving', self.name)
        return self.val

    def __set__(self, obj, val):
        print('Updating', self.name)
        self.val = val

>>> class MyClass(object):
...     x = RevealAccess(10, 'var "x"')
...     y = 5
...     
... >>> m = MyClass()
... >>> m.x
Retrieving var "x"
10
... >>> m.x = 20
Updating var "x"
```

"""
The protocol is simple and offers exciting possibilities. Several use cases are so common that they have been packaged into individual function calls. Properties, bound and unbound methods, static methods, and class methods are all based on the descriptor protocol.
Properties

Calling `property()` is a succinct way of building a data descriptor that triggers function calls upon access to an attribute. Its signature is:

```
property(fget=None, fset=None, fdel=None, doc=None)
```

The documentation shows a typical use to define a managed attribute `x`:

```
class C(object):
    def getx(self):
        return self.__x
    def setx(self, value):
        self.__x = value
    def delx(self):
        del self.__x
    x = property(getx, setx, delx, "I'm the 'x' property."
```

To see how `property()` is implemented in terms of the descriptor protocol, here is a pure Python equivalent:

```
class Property(object):
    "Emulate PyProperty_Type() in Objects/descrobject.c"
    def __init__(self, fget=None, fset=None, fdel=None, doc=None):
        self.fget = fget
        self.fset = fset
        self.fdel = fdel
        if doc is None and fget is not None:
            doc = fget.__doc__
        self.__doc__ = doc

    def __get__(self, obj, objtype=None):
        if obj is None:
            return self
```
The `property()` builtin helps whenever a user interface has granted attribute access and then subsequent changes require the intervention of a method.

For instance, a spreadsheet class may grant access to a cell value through `Cell('b10').value`. Subsequent improvements to the program require the cell to be recalculated on every access; however, the programmer does not want to affect existing client code accessing the attribute directly. The solution is to wrap access to the value attribute in a property data descriptor:
def getvalue(self):
    "Recalculate the cell before returning value"
    self.recalc()
    return self._value
value = property(getvalue)
Functions and Methods

Python’s object oriented features are built upon a function based environment. Using non-data descriptors, the two are merged seamlessly.

Class dictionaries store methods as functions. In a class definition, methods are written using `def` and `lambda`, the usual tools for creating functions. The only difference from regular functions is that the first argument is reserved for the object instance. By Python convention, the instance reference is called `self` but may be called `this` or any other variable name.

To support method calls, functions include the `__get__()` method for binding methods during attribute access. This means that all functions are non-data descriptors which return bound or unbound methods depending whether they are invoked from an object or a class. In pure python, it works like this:

```python
class Function(object):
    ...
    def __get__(self, obj, objtype=None):
        "Simulate func_descr_get() in Objects/funcobject.c"
        return types.MethodType(self, obj)
```

Running the interpreter shows how the function descriptor works in practice:

```python
>>> class D(object):
...     def f(self, x):
...         return x
...```
The output suggests that bound and unbound methods are two different types. While they could have been implemented that way, the actual C implementation of `PyMethod_Type` in `Objects/classobject.c` is a single object with two different representations depending on whether the `im_self` field is set or is `NULL` (the C equivalent of `None`).

Likewise, the effects of calling a method object depend on the `im_self` field. If set (meaning bound), the original function (stored in the `im_func` field) is called as expected with the first argument set to the instance. If unbound, all of the arguments are passed unchanged to the original function. The actual C implementation of `instancemethod_call()` is only slightly more complex in that it includes some type checking.
Static Methods and Class Methods

Non-data descriptors provide a simple mechanism for variations on the usual patterns of binding functions into methods.

To recap, functions have a `__get__()` method so that they can be converted to a method when accessed as attributes. The non-data descriptor transforms an `obj.f(*args)` call into `f(obj, *args)`. Calling `klass.f(*args)` becomes `f(*args)`.

This chart summarizes the binding and its two most useful variants:

<table>
<thead>
<tr>
<th>Transformation</th>
<th>Called from an Object</th>
<th>Called from a Class</th>
</tr>
</thead>
<tbody>
<tr>
<td>function</td>
<td><code>f(obj, *args)</code></td>
<td><code>f(*args)</code></td>
</tr>
<tr>
<td>staticmethod</td>
<td><code>f(*args)</code></td>
<td><code>f(*args)</code></td>
</tr>
<tr>
<td>classmethod</td>
<td><code>f(type(obj), *args)</code></td>
<td><code>f(klass, *args)</code></td>
</tr>
</tbody>
</table>

Static methods return the underlying function without changes. Calling either `c.f` or `C.f` is the equivalent of a direct lookup into `object.__getattribute__(c, "f")` or `object.__getattribute__(C, "f")`. As a result, the function becomes identically accessible from either an object or a class.

Good candidates for static methods are methods that do not reference the `self` variable.

For instance, a statistics package may include a container class for experimental data. The class provides normal methods for computing the average, mean, median, and other descriptive statistics that depend on the data. However, there may be useful functions which are
conceptually related but do not depend on the data. For instance, \texttt{erf(x)} is handy conversion routine that comes up in statistical work but does not directly depend on a particular dataset. It can be called either from an object or the class: \texttt{s.erf(1.5) \rightarrow .9332} or \texttt{Sample.erf(1.5) \rightarrow .9332}.

Since staticmethods return the underlying function with no changes, the example calls are unexciting:

```python
>> class E(object):
...     def f(x):
...         print(x)
...     f = staticmethod(f)
...
>> print(E.f(3))
3
>> print(E().f(3))
3
```

Using the non-data descriptor protocol, a pure Python version of \texttt{staticmethod()} would look like this:

```python
class StaticMethod(object):
    "Emulate PyStaticMethod_Type() in Objects/funcobject.c"
    def __init__(self, f):
        self.f = f

    def __get__(self, obj, objtype=\texttt{None}):  
        return self.f
```

Unlike static methods, class methods prepend the class reference to the argument list before calling the function. This format is the same for whether the caller is an object or a class:
>>> class E(object):
...     def f(klass, x):
...         return klass.__name__, x
...     f = classmethod(f)
... >>> print(E.f(3))
('E', 3)
>>> print(E().f(3))
('E', 3)

This behavior is useful whenever the function only needs to have a class reference and does not care about any underlying data. One use for classmethods is to create alternate class constructors. In Python 2.3, the classmethod `dict.fromkeys()` creates a new dictionary from a list of keys. The pure Python equivalent is:

```python
class Dict(object):
    ...    def fromkeys(klass, iterable, value=None):
        "Emulate dict_fromkeys() in Objects/dictobject.c"
        d = klass()
        for key in iterable:
            d[key] = value
        return d
    fromkeys = classmethod(fromkeys)
```

Now a new dictionary of unique keys can be constructed like this:

```python
>>> Dict.fromkeys('abracadabra')
{'a': None, 'r': None, 'b': None, 'c': None, 'd': None}
```

Using the non-data descriptor protocol, a pure Python version of `classmethod()` would look like this:
```python
class ClassMethod(object):
    "Emulate PyClassMethod_Type() in Objects/funcobject.c"

    def __init__(self, f):
        self.f = f

    def __get__(self, obj, klass=None):
        if klass is None:
            klass = type(obj)
        def newfunc(*args):
            return self.f(klass, *args)
        return newfunc
```

---

In this document, we'll take a tour of Python's features suitable for implementing programs in a functional style. After an introduction to the concepts of functional programming, we'll look at language features such as iterators and generators and relevant library modules such as itertools and functools.
Introduction

This section explains the basic concept of functional programming; if you're just interested in learning about Python language features, skip to the next section on Iterators.

Programming languages support decomposing problems in several different ways:

- Most programming languages are **procedural**: programs are lists of instructions that tell the computer what to do with the program's input. C, Pascal, and even Unix shells are procedural languages.
- In **declarative** languages, you write a specification that describes the problem to be solved, and the language implementation figures out how to perform the computation efficiently. SQL is the declarative language you're most likely to be familiar with; a SQL query describes the data set you want to retrieve, and the SQL engine decides whether to scan tables or use indexes, which subclauses should be performed first, etc.
- **Object-oriented** programs manipulate collections of objects. Objects have internal state and support methods that query or modify this internal state in some way. Smalltalk and Java are object-oriented languages. C++ and Python are languages that support object-oriented programming, but don’t force the use of object-oriented features.
- **Functional** programming decomposes a problem into a set of functions. Ideally, functions only take inputs and produce outputs, and don’t have any internal state that affects the output produced for a given input. Well-known functional languages include the ML family (Standard ML, OCaml, and other variants) and Haskell.

The designers of some computer languages choose to emphasize one particular approach to programming. This often makes it difficult to
write programs that use a different approach. Other languages are multi-paradigm languages that support several different approaches. Lisp, C++, and Python are multi-paradigm; you can write programs or libraries that are largely procedural, object-oriented, or functional in all of these languages. In a large program, different sections might be written using different approaches; the GUI might be object-oriented while the processing logic is procedural or functional, for example.

In a functional program, input flows through a set of functions. Each function operates on its input and produces some output. Functional style discourages functions with side effects that modify internal state or make other changes that aren’t visible in the function’s return value. Functions that have no side effects at all are called purely functional. Avoiding side effects means not using data structures that get updated as a program runs; every function’s output must only depend on its input.

Some languages are very strict about purity and don’t even have assignment statements such as a=3 or c = a + b, but it’s difficult to avoid all side effects. Printing to the screen or writing to a disk file are side effects, for example. For example, in Python a call to the print() or time.sleep() function both return no useful value; they’re only called for their side effects of sending some text to the screen or pausing execution for a second.

Python programs written in functional style usually won’t go to the extreme of avoiding all I/O or all assignments; instead, they’ll provide a functional-appearing interface but will use non-functional features internally. For example, the implementation of a function will still use assignments to local variables, but won’t modify global variables or have other side effects.

Functional programming can be considered the opposite of object-
oriented programming. Objects are little capsules containing some internal state along with a collection of method calls that let you modify this state, and programs consist of making the right set of state changes. Functional programming wants to avoid state changes as much as possible and works with data flowing between functions. In Python you might combine the two approaches by writing functions that take and return instances representing objects in your application (e-mail messages, transactions, etc.).

Functional design may seem like an odd constraint to work under. Why should you avoid objects and side effects? There are theoretical and practical advantages to the functional style:

- Formal provability.
- Modularity.
- Composability.
- Ease of debugging and testing.

**Formal provability**

A theoretical benefit is that it's easier to construct a mathematical proof that a functional program is correct.

For a long time researchers have been interested in finding ways to mathematically prove programs correct. This is different from testing a program on numerous inputs and concluding that its output is usually correct, or reading a program’s source code and concluding that the code looks right; the goal is instead a rigorous proof that a program produces the right result for all possible inputs.

The technique used to prove programs correct is to write down invariants, properties of the input data and of the program’s variables that are always true. For each line of code, you then show that if
invariants X and Y are true \textbf{before} the line is executed, the slightly different invariants X' and Y' are true \textbf{after} the line is executed. This continues until you reach the end of the program, at which point the invariants should match the desired conditions on the program’s output.

Functional programming’s avoidance of assignments arose because assignments are difficult to handle with this technique; assignments can break invariants that were true before the assignment without producing any new invariants that can be propagated onward.

Unfortunately, proving programs correct is largely impractical and not relevant to Python software. Even trivial programs require proofs that are several pages long; the proof of correctness for a moderately complicated program would be enormous, and few or none of the programs you use daily (the Python interpreter, your XML parser, your web browser) could be proven correct. Even if you wrote down or generated a proof, there would then be the question of verifying the proof; maybe there’s an error in it, and you wrongly believe you’ve proved the program correct.

**Modularity**

A more practical benefit of functional programming is that it forces you to break apart your problem into small pieces. Programs are more modular as a result. It’s easier to specify and write a small function that does one thing than a large function that performs a complicated transformation. Small functions are also easier to read and to check for errors.

**Ease of debugging and testing**
Testing and debugging a functional-style program is easier.

Debugging is simplified because functions are generally small and clearly specified. When a program doesn’t work, each function is an interface point where you can check that the data are correct. You can look at the intermediate inputs and outputs to quickly isolate the function that’s responsible for a bug.

Testing is easier because each function is a potential subject for a unit test. Functions don’t depend on system state that needs to be replicated before running a test; instead you only have to synthesize the right input and then check that the output matches expectations.

**Composability**

As you work on a functional-style program, you’ll write a number of functions with varying inputs and outputs. Some of these functions will be unavoidably specialized to a particular application, but others will be useful in a wide variety of programs. For example, a function that takes a directory path and returns all the XML files in the directory, or a function that takes a filename and returns its contents, can be applied to many different situations.

Over time you’ll form a personal library of utilities. Often you’ll assemble new programs by arranging existing functions in a new configuration and writing a few functions specialized for the current task.
Iterators

I’ll start by looking at a Python language feature that’s an important foundation for writing functional-style programs: iterators.

An iterator is an object representing a stream of data; this object returns the data one element at a time. A Python iterator must support a method called \texttt{\_\_next\_\_()} that takes no arguments and always returns the next element of the stream. If there are no more elements in the stream, \texttt{\_\_next\_\_()} must raise the \texttt{StopIteration} exception. Iterators don’t have to be finite, though; it’s perfectly reasonable to write an iterator that produces an infinite stream of data.

The built-in \texttt{iter()} function takes an arbitrary object and tries to return an iterator that will return the object’s contents or elements, raising \texttt{TypeError} if the object doesn’t support iteration. Several of Python’s built-in data types support iteration, the most common being lists and dictionaries. An object is called \texttt{iterable} if you can get an iterator for it.

You can experiment with the iteration interface manually:

\begin{verbatim}
>>> L = [1,2,3]
>>> it = iter(L)
>>> it
<...iterator object at ...>
>>> it.__next__()  # same as next(it)
1
>>> next(it)
2
>>> next(it)
3
>>> next(it)
\end{verbatim}
Python expects iterable objects in several different contexts, the most important being the `for` statement. In the statement `for X in Y`, `Y` must be an iterator or some object for which `iter()` can create an iterator. These two statements are equivalent:

```python
for i in iter(obj):
    print(i)
for i in obj:
    print(i)
```

Iterators can be materialized as lists or tuples by using the `list()` or `tuple()` constructor functions:

```python
>>> L = [1, 2, 3]
>>> iterator = iter(L)
>>> t = tuple(iterator)
>>> t
(1, 2, 3)
```

Sequence unpacking also supports iterators: if you know an iterator will return `N` elements, you can unpack them into an `N`-tuple:

```python
>>> L = [1, 2, 3]
>>> iterator = iter(L)
>>> a, b, c = iterator
>>> a, b, c
(1, 2, 3)
```

Built-in functions such as `max()` and `min()` can take a single iterator
argument and will return the largest or smallest element. The "in" and "not in" operators also support iterators: X in iterator is true if X is found in the stream returned by the iterator. You'll run into obvious problems if the iterator is infinite; \texttt{max()}, \texttt{min()} will never return, and if the element X never appears in the stream, the "in" and "not in" operators won't return either.

Note that you can only go forward in an iterator; there's no way to get the previous element, reset the iterator, or make a copy of it. Iterator objects can optionally provide these additional capabilities, but the iterator protocol only specifies the \texttt{\_\_next\_(\_\_)} method. Functions may therefore consume all of the iterator's output, and if you need to do something different with the same stream, you'll have to create a new iterator.

Data Types That Support Iterators

We've already seen how lists and tuples support iterators. In fact, any Python sequence type, such as strings, will automatically support creation of an iterator.

Calling \texttt{iter()} on a dictionary returns an iterator that will loop over the dictionary's keys:

```
>>> m = {'Jan': 1, 'Feb': 2, 'Mar': 3, 'Apr': 4, 'May': 5, ...
      'Jul': 7, 'Aug': 8, 'Sep': 9, 'Oct': 10, 'Nov': 11, ...
>>> for key in m:
...    print(key, m[key])
Mar 3
Feb 2
Aug 8
Sep 9
Apr 4
```
Note that the order is essentially random, because it's based on the hash ordering of the objects in the dictionary.

Applying `iter()` to a dictionary always loops over the keys, but dictionaries have methods that return other iterators. If you want to iterate over values or key/value pairs, you can explicitly call the `values()` or `items()` methods to get an appropriate iterator.

The `dict()` constructor can accept an iterator that returns a finite stream of (key, value) tuples:

```python
>>> L = [('Italy', 'Rome'), ('France', 'Paris'), ('US', 'Washington DC')]
>>> dict(iter(L))
{'Italy': 'Rome', 'US': 'Washington DC', 'France': 'Paris'}
```

Files also support iteration by calling the `readline()` method until there are no more lines in the file. This means you can read each line of a file like this:

```python
for line in file:
    # do something for each line
...
```

Sets can take their contents from an iterable and let you iterate over the set's elements:
S = \{2, 3, 5, 7, 11, 13\}
for i in S:
    print(i)
Generator expressions and list comprehensions

Two common operations on an iterator’s output are 1) performing some operation for every element, 2) selecting a subset of elements that meet some condition. For example, given a list of strings, you might want to strip off trailing whitespace from each line or extract all the strings containing a given substring.

List comprehensions and generator expressions (short form: “listcomps” and “genexps”) are a concise notation for such operations, borrowed from the functional programming language Haskell (https://www.haskell.org/). You can strip all the whitespace from a stream of strings with the following code:

```python
line_list = [' line 1
', 'line 2
', '...
#
# Generator expression -- returns iterator
stripped_iter = (line.strip() for line in line_list)
#
# List comprehension -- returns list
stripped_list = [line.strip() for line in line_list]
```

You can select only certain elements by adding an "if" condition:

```python
stripped_list = [line.strip() for line in line_list if line != '']
```

With a list comprehension, you get back a Python list; `stripped_list` is a list containing the resulting lines, not an iterator. Generator expressions return an iterator that computes the values as necessary, not needing to materialize all the values at once. This
means that list comprehensions aren’t useful if you’re working with iterators that return an infinite stream or a very large amount of data. Generator expressions are preferable in these situations.

Generator expressions are surrounded by parentheses (“()”) and list comprehensions are surrounded by square brackets (“[]”). Generator expressions have the form:

```
( expression for expr in sequence1
  if condition1
  for expr2 in sequence2
  if condition2
  for expr3 in sequence3 ...
  if condition3
  for exprN in sequenceN
  if conditionN )
```

Again, for a list comprehension only the outside brackets are different (square brackets instead of parentheses).

The elements of the generated output will be the successive values of expression. The if clauses are all optional; if present, expression is only evaluated and added to the result when condition is true.

Generator expressions always have to be written inside parentheses, but the parentheses signalling a function call also count. If you want to create an iterator that will be immediately passed to a function you can write:

```
obj_total = sum(obj.count for obj in list_all_objects)
```

The for...in clauses contain the sequences to be iterated over.
The sequences do not have to be the same length, because they are iterated over from left to right, not in parallel. For each element in sequence1, sequence2 is looped over from the beginning. sequence3 is then looped over for each resulting pair of elements from sequence1 and sequence2.

To put it another way, a list comprehension or generator expression is equivalent to the following Python code:

```python
for expr1 in sequence1:
    if not (condition1):
        continue  # Skip this element
for expr2 in sequence2:
    if not (condition2):
        continue  # Skip this element
...
for exprN in sequenceN:
    if not (conditionN):
        continue  # Skip this element

# Output the value of
# the expression.
```

This means that when there are multiple `for...in` clauses but no `if` clauses, the length of the resulting output will be equal to the product of the lengths of all the sequences. If you have two lists of length 3, the output list is 9 elements long:

```python
>>> seq1 = 'abc'
>>> seq2 = (1, 2, 3)
>>> [(x, y) for x in seq1 for y in seq2]
[('a', 1), ('a', 2), ('a', 3),
 ('b', 1), ('b', 2), ('b', 3),
 ('c', 1), ('c', 2), ('c', 3)]
```
To avoid introducing an ambiguity into Python’s grammar, if expression is creating a tuple, it must be surrounded with parentheses. The first list comprehension below is a syntax error, while the second one is correct:

```python
# Syntax error
[x, y for x in seq1 for y in seq2]
# Correct
[(x, y) for x in seq1 for y in seq2]
```
Generators

Generators are a special class of functions that simplify the task of writing iterators. Regular functions compute a value and return it, but generators return an iterator that returns a stream of values.

You’re doubtless familiar with how regular function calls work in Python or C. When you call a function, it gets a private namespace where its local variables are created. When the function reaches a `return` statement, the local variables are destroyed and the value is returned to the caller. A later call to the same function creates a new private namespace and a fresh set of local variables. But, what if the local variables weren’t thrown away on exiting a function? What if you could later resume the function where it left off? This is what generators provide; they can be thought of as resumable functions.

Here’s the simplest example of a generator function:

```python
>>> def generate_ints(N):
...     for i in range(N):
...         yield i
```

Any function containing a `yield` keyword is a generator function; this is detected by Python’s bytecode compiler which compiles the function specially as a result.

When you call a generator function, it doesn’t return a single value; instead it returns a generator object that supports the iterator protocol. On executing the `yield` expression, the generator outputs the value of `i`, similar to a `return` statement. The big difference between `yield` and a `return` statement is that on reaching a `yield` the generator’s state of execution is suspended and local variables are
preserved. On the next call to the generator’s `__next__()` method, the function will resume executing.

Here's a sample usage of the `generate_ints()` generator:

```python
>>> gen = generate_ints(3)
>>> gen
<generator object generate_ints at ...>
>>> next(gen)
0
>>> next(gen)
1
>>> next(gen)
2
>>> next(gen)
Traceback (most recent call last):
  File "stdin", line 1, in <module>
  File "stdin", line 2, in generate_ints
StopIteration
```

You could equally write `for i in generate_ints(5), or a,b,c = generate_ints(3).`  

Inside a generator function, `return value` causes `StopIteration(value)` to be raised from the `__next__()` method. Once this happens, or the bottom of the function is reached, the procession of values ends and the generator cannot yield any further values.

You could achieve the effect of generators manually by writing your own class and storing all the local variables of the generator as instance variables. For example, returning a list of integers could be done by setting `self.count` to 0, and having the `__next__()` method increment `self.count` and return it. However, for a
moderately complicated generator, writing a corresponding class can be much messier.

The test suite included with Python’s library, `Lib/test/test_generators.py`, contains a number of more interesting examples. Here’s one generator that implements an in-order traversal of a tree using generators recursively.

```python
# A recursive generator that generates Tree leaves in order.
def inorder(t):
    if t:
        for x in inorder(t.left):
            yield x

        yield t.label

    for x in inorder(t.right):
        yield x
```

Two other examples in `test_generators.py` produce solutions for the N-Queens problem (placing N queens on an NxN chess board so that no queen threatens another) and the Knight’s Tour (finding a route that takes a knight to every square of an NxN chessboard without visiting any square twice).

### Passing values into a generator

In Python 2.4 and earlier, generators only produced output. Once a generator’s code was invoked to create an iterator, there was no way to pass any new information into the function when its execution is resumed. You could hack together this ability by making the generator look at a global variable or by passing in some mutable object that callers then modify, but these approaches are messy.
In Python 2.5 there's a simple way to pass values into a generator. `yield` became an expression, returning a value that can be assigned to a variable or otherwise operated on:

```python
val = (yield i)
```

I recommend that you **always** put parentheses around a `yield` expression when you're doing something with the returned value, as in the above example. The parentheses aren't always necessary, but it's easier to always add them instead of having to remember when they're needed.

(PEP 342 explains the exact rules, which are that a `yield-expression` must always be parenthesized except when it occurs at the top-level expression on the right-hand side of an assignment. This means you can write `val = yield i` but have to use parentheses when there's an operation, as in `val = (yield i) + 12`.)

Values are sent into a generator by calling its `send(value)` method. This method resumes the generator's code and the `yield` expression returns the specified value. If the regular `__next__()` method is called, the `yield` returns `None`.

Here's a simple counter that increments by 1 and allows changing the value of the internal counter.

```python
def counter(maximum):
    i = 0
    while i < maximum:
        val = (yield i)
        # If value provided, change counter
        if val is not None:
            i = val
```
And here's an example of changing the counter:

```python
>>> it = counter(10)
>>> next(it)
0
>>> next(it)
1
>>> it.send(8)
8
>>> next(it)
9
>>> next(it)
Traceback (most recent call last):
  File "t.py", line 15, in <module>
    it.next()
StopIteration
```

Because `yield` will often be returning `None`, you should always check for this case. Don’t just use its value in expressions unless you’re sure that the `send()` method will be the only method used to resume your generator function.

In addition to `send()`, there are two other methods on generators:

- `throw(type, value=None, traceback=None)` is used to raise an exception inside the generator; the exception is raised by the `yield` expression where the generator’s execution is paused.

- `close()` raises a `GeneratorExit` exception inside the generator to terminate the iteration. On receiving this exception, the generator’s code must either raise `GeneratorExit` or
StopIteration; catching the exception and doing anything else is illegal and will trigger a `RuntimeError`. `close()` will also be called by Python's garbage collector when the generator is garbage-collected.

If you need to run cleanup code when a `GeneratorExit` occurs, I suggest using a `try: ... finally: suite` instead of catching `GeneratorExit`.

The cumulative effect of these changes is to turn generators from one-way producers of information into both producers and consumers.

Generators also become `coroutines`, a more generalized form of subroutines. Subroutines are entered at one point and exited at another point (the top of the function, and a `return` statement), but coroutines can be entered, exited, and resumed at many different points (the `yield` statements).
Built-in functions

Let's look in more detail at built-in functions often used with iterators.

Two of Python's built-in functions, \texttt{map()} and \texttt{filter()} duplicate the features of generator expressions:

\texttt{map(f, iterA, iterB, \ldots)} returns an iterator over the sequence
\[ f(\text{iterA}[0], \text{iterB}[0]), f(\text{iterA}[1], \text{iterB}[1]), f(\text{iterA}[2], \text{iterB}[2]), \ldots. \]

```python
>>> def upper(s):
    ...    return s.upper()
```

```python
>>> list(map(upper, ['sentence', 'fragment']))
['SENTENCE', 'FRAGMENT']
>>> list([upper(s) for s in ['sentence', 'fragment']])
['SENTENCE', 'FRAGMENT']
```

You can of course achieve the same effect with a list comprehension.

\texttt{filter(predicate, iter)} returns an iterator over all the sequence elements that meet a certain condition, and is similarly duplicated by list comprehensions. A \texttt{predicate} is a function that returns the truth value of some condition; for use with \texttt{filter()}, the predicate must take a single value.

```python
>>> def is_even(x):
    ...    return (x % 2) == 0
```

```python
>>> list(filter(is_even, range(10)))
[0, 2, 4, 6, 8]
```
This can also be written as a list comprehension:

```python
>>> list(x for x in range(10) if is_even(x))
[0, 2, 4, 6, 8]
```

`enumerate(iter, start=0)` counts off the elements in the iterable returning 2-tuples containing the count (from `start`) and each element.

```python
>>> for item in enumerate(['subject', 'verb', 'object', ...
  print(item)
(0, 'subject')
(1, 'verb')
(2, 'object')
```

`enumerate()` is often used when looping through a list and recording the indexes at which certain conditions are met:

```python
f = open('data.txt', 'r')
for i, line in enumerate(f):
    if line.strip() == '':
        print('Blank line at line #%i' % i)
```

`sorted(iterable, key=None, reverse=False)` collects all the elements of the iterable into a list, sorts the list, and returns the sorted result. The `key` and `reverse` arguments are passed through to the constructed list’s `sort()` method.

```python
>>> import random
>>> # Generate 8 random numbers between [0, 10000)
>>> rand_list = random.sample(range(10000), 8)
>>> rand_list
[769, 7953, 9828, 6431, 8442, 9878, 6213, 2207]
>>> sorted(rand_list)
[2207, 6213, 6431, 769, 7953, 8442, 9828, 9878]```
>>> sorted(rand_list, reverse=True)
[9878, 9828, 8442, 7953, 6431, 6213, 2207, 769]

(For a more detailed discussion of sorting, see the Sorting HOW TO.)

The any(iter) and all(iter) built-ins look at the truth values of an iterable's contents. any() returns True if any element in the iterable is a true value, and all() returns True if all of the elements are true values:

```python
>>> any([0,1,0])
True
>>> any([0,0,0])
False
>>> any([1,1,1])
True
>>> all([0,1,0])
False
>>> all([0,0,0])
False
>>> all([1,1,1])
True
```

zip(iterA, iterB, ...) takes one element from each iterable and returns them in a tuple:

```python
zip(['a', 'b', 'c'], (1, 2, 3)) =>
('a', 1), ('b', 2), ('c', 3)
```

It doesn’t construct an in-memory list and exhaust all the input iterators before returning; instead tuples are constructed and returned only if they’re requested. (The technical term for this behaviour is lazy evaluation.)
This iterator is intended to be used with iterables that are all of the same length. If the iterables are of different lengths, the resulting stream will be the same length as the shortest iterable.

```python
zip(['a', 'b'], (1, 2, 3)) =>
  ('a', 1), ('b', 2)
```

You should avoid doing this, though, because an element may be taken from the longer iterators and discarded. This means you can’t go on to use the iterators further because you risk skipping a discarded element.
The itertools module

The `itertools` module contains a number of commonly-used iterators as well as functions for combining several iterators. This section will introduce the module's contents by showing small examples.

The module's functions fall into a few broad classes:

- Functions that create a new iterator based on an existing iterator.
- Functions for treating an iterator’s elements as function arguments.
- Functions for selecting portions of an iterator’s output.
- A function for grouping an iterator’s output.

Creating new iterators

`itertools.count(start, step)` returns an infinite stream of evenly spaced values. You can optionally supply the starting number, which defaults to 0, and the interval between numbers, which defaults to 1:

```
    itertools.count() =>
    0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
    itertools.count(10) =>
    10, 11, 12, 13, 14, 15, 16, 17, 18, 19, ...
    itertools.count(10, 5) =>
    10, 15, 20, 25, 30, 35, 40, 45, 50, 55, ...
```

`itertools.cycle(iter)` saves a copy of the contents of a provided iterable and returns a new iterator that returns its elements from first to last. The new iterator will repeat these elements infinitely.
```python
import itertools

cycle = itertools.cycle([1, 2, 3, 4, 5])
1, 2, 3, 4, 5, 1, 2, 3, 4, 5, ...

repeat = itertools.repeat('abc')
abc, abc, abc, abc, abc, abc, abc, abc, abc,
repeat('abc', 5)
abc, abc, abc, abc, abc

chain = itertools.chain([a, b, c], (1, 2, 3))
a, b, c, 1, 2, 3

islice = itertools.islice(range(10), 8)
0, 1, 2, 3, 4, 5, 6, 7
islice(range(10), 2, 8)
2, 3, 4, 5, 6, 7
islice(range(10), 2, 8, 2)
2, 4, 6
```

`itertools.cycle([1, 2, 3, 4, 5])` returns the provided element \( n \) times, or returns the element endlessly if \( n \) is not provided.

`itertools.repeat('abc')`:
abc, abc, abc, abc, abc, abc, abc, abc, abc,
`itertools.repeat('abc', 5)`:
abc, abc, abc, abc, abc

`itertools.chain([a, 'b', 'c'], (1, 2, 3))`:
a, b, c, 1, 2, 3

`itertools.islice(range(10), 8)`:
0, 1, 2, 3, 4, 5, 6, 7
`itertools.islice(range(10), 2, 8)`:
2, 3, 4, 5, 6, 7
`itertools.islice(range(10), 2, 8, 2)`:
2, 4, 6
**itertools.tee(iter, [n])** replicates an iterator; it returns \( n \) independent iterators that will all return the contents of the source iterator. If you don’t supply a value for \( n \), the default is 2. Replicating iterators requires saving some of the contents of the source iterator, so this can consume significant memory if the iterator is large and one of the new iterators is consumed more than the others.

```python
itertools.tee( itertools.count() ) =>
    iterA, iterB

where iterA ->
    0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...

and iterB ->
    0, 1, 2, 3, 4, 5, 6, 7, 8, 9, ...
```

### Calling functions on elements

The **operator** module contains a set of functions corresponding to Python’s operators. Some examples are `operator.add(a, b)` (adds two values), `operator.ne(a, b)` (same as \( a \neq b \)), and `operator.attrgetter('id')` (returns a callable that fetches the `.id` attribute).

**itertools.starmap(func, iter)** assumes that the iterable will return a stream of tuples, and calls `func` using these tuples as the arguments:

```python
itertools.starmap(os.path.join,
    [('/bin', 'python'), ('/usr', 'bin', 'perl'), ('/usr',
      =>
        '/bin/python, /usr/bin/java, /usr/bin/perl, /usr/bin/python, /usr/bin/perl, /usr/bin/java')
```
Selecting elements

Another group of functions chooses a subset of an iterator’s elements based on a predicate.

`itertools.filterfalse(predicate, iter)` is the opposite of `filter()`, returning all elements for which the predicate returns false:

```
itertools.filterfalse(is_even, itertools.count()) =>
   1, 3, 5, 7, 9, 11, 13, 15, ...
```

`itertools.takewhile(predicate, iter)` returns elements for as long as the predicate returns true. Once the predicate returns false, the iterator will signal the end of its results.

```
def less_than_10(x):
    return x < 10

itertools.takewhile(less_than_10, itertools.count()) =>
   0, 1, 2, 3, 4, 5, 6, 7, 8, 9

itertools.takewhile(is_even, itertools.count()) =>
   0
```

`itertools.dropwhile(predicate, iter)` discards elements while the predicate returns true, and then returns the rest of the iterable’s results.

```
itertools.dropwhile(less_than_10, itertools.count()) =>
   10, 11, 12, 13, 14, 15, 16, 17, 18, 19, ...
```
\[
\text{itertools.dropwhile(is\_even, itertools.count())} => 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, \ldots
\]

\text{itertools.compress(data, selectors)} takes two iterators and returns only those elements of \text{data} for which the corresponding element of \text{selectors} is true, stopping whenever either one is exhausted:

\[
\text{itertools.compress([1, 2, 3, 4, 5], [True, True, False, 1, 2, 5])}
\]

\section*{Combinatoric functions}

The \text{itertools.combinations(iterable, r)} returns an iterator giving all possible \(r\)-tuple combinations of the elements contained in \text{iterable}.

\[
\text{itertools.combinations([1, 2, 3, 4, 5], 2)} => \\
(1, 2), (1, 3), (1, 4), (1, 5), \\
(2, 3), (2, 4), (2, 5), \\
(3, 4), (3, 5), \\
(4, 5)
\]

\[
\text{itertools.combinations([1, 2, 3, 4, 5], 3)} => \\
(1, 2, 3), (1, 2, 4), (1, 2, 5), (1, 3, 4), (1, 3, 5), \\
(2, 3, 4), (2, 3, 5), (2, 4, 5), \\
(3, 4, 5)
\]

The elements within each tuple remain in the same order as \text{iterable} returned them. For example, the number 1 is always before 2, 3, 4, or 5 in the examples above. A similar function,
**itertools.permutations(iterable, r=None)**, removes this constraint on the order, returning all possible arrangements of length r:

```python
itertools.permutations([1, 2, 3, 4, 5], 2) =>
(1, 2), (1, 3), (1, 4), (1, 5),
(2, 1), (2, 3), (2, 4), (2, 5),
(3, 1), (3, 2), (3, 4), (3, 5),
(4, 1), (4, 2), (4, 3), (4, 5),
(5, 1), (5, 2), (5, 3), (5, 4)
```

```python
itertools.permutations([1, 2, 3, 4, 5]) =>
(1, 2, 3, 4, 5), (1, 2, 3, 5, 4), (1, 2, 4, 3, 5),
... (5, 4, 3, 2, 1)
```

If you don’t supply a value for r the length of the iterable is used, meaning that all the elements are permuted.

Note that these functions produce all of the possible combinations by position and don’t require that the contents of iterable are unique:

```python
itertools.permutations('aba', 3) =>
('a', 'b', 'a'), ('a', 'a', 'b'), ('b', 'a', 'a'),
('b', 'a', 'a'), ('a', 'a', 'b'), ('a', 'b', 'a')
```

The identical tuple ('a', 'a', 'b') occurs twice, but the two ‘a’ strings came from different positions.

The **itertools.combinations_with_replacement(iterable, r)** function relaxes a different constraint: elements can be repeated within a single tuple. Conceptually an element is selected for the first position of each tuple and then is replaced before the second element is
selected.

```python
itertools.combinations_with_replacement([1, 2, 3, 4, (1, 1), (1, 2), (1, 3), (1, 4), (1, 5), (2, 2), (2, 3), (2, 4), (2, 5), (3, 3), (3, 4), (3, 5), (4, 4), (4, 5), (5, 5)]
```

**Grouping elements**

The last function I'll discuss, `itertools.groupby(iter, key_func=None)`, is the most complicated. `key_func(elem)` is a function that can compute a key value for each element returned by the iterable. If you don't supply a key function, the key is simply each element itself.

`groupby()` collects all the consecutive elements from the underlying iterable that have the same key value, and returns a stream of 2-tuples containing a key value and an iterator for the elements with that key.

```python
city_list = [('Decatur', 'AL'), ('Huntsville', 'AL'), ('Anchorage', 'AK'), ('Nome', 'AK'), ('Flagstaff', 'AZ'), ('Phoenix', 'AZ'), ...

def get_state(city_state):
    return city_state[1]

itertools.groupby(city_list, get_state) =>
('AL', iterator-1),
('AK', iterator-2),
('AZ', iterator-3), ...
```
where
iterator-1 =>
    ('Decatur', 'AL'), ('Huntsville', 'AL'), ('Selma',
iterator-2 =>
    ('Anchorage', 'AK'), ('Nome', 'AK')
iterator-3 =>
    ('Flagstaff', 'AZ'), ('Phoenix', 'AZ'), ('Tucson',

`groupby()` assumes that the underlying iterable’s contents will already be sorted based on the key. Note that the returned iterators also use the underlying iterable, so you have to consume the results of iterator-1 before requesting iterator-2 and its corresponding key.
The **functools** module in Python 2.5 contains some higher-order functions. A **higher-order function** takes one or more functions as input and returns a new function. The most useful tool in this module is the **functools.partial()** function.

For programs written in a functional style, you'll sometimes want to construct variants of existing functions that have some of the parameters filled in. Consider a Python function \( f(a, b, c) \); you may wish to create a new function \( g(b, c) \) that's equivalent to \( f(1, b, c) \); you're filling in a value for one of \( f() \)'s parameters. This is called "partial function application".

The constructor for **partial()** takes the arguments \((\text{function}, \text{arg1}, \text{arg2}, \ldots, \text{kwarg1}=\text{value1}, \text{kwarg2}=\text{value2})\). The resulting object is callable, so you can just call it to invoke \( \text{function} \) with the filled-in arguments.

Here's a small but realistic example:

```python
import functools

def log(message, subsystem):
    '''Write the contents of 'message' to the specified subsystem.'
    print('%s: %s' % (subsystem, message))
...

server_log = functools.partial(log, subsystem='server')
server_log('Unable to open socket')
```

```python
functools.reduce(func, iter, [initial_value])
```
cumulatively performs an operation on all the iterable's elements and, therefore, can't be applied to infinite iterables. *func* must be a function that takes two elements and returns a single value. *functools.reduce()* takes the first two elements A and B returned by the iterator and calculates *func(A, B)*. It then requests the third element, C, calculates *func(func(A, B), C)*, combines this result with the fourth element returned, and continues until the iterable is exhausted. If the iterable returns no values at all, a *TypeError* exception is raised. If the initial value is supplied, it's used as a starting point and *func(initial_value, A)* is the first calculation.

```
>>> import operator, functools
>>> functools.reduce(operator.concat, ['A', 'BB', 'C', 'ABBC'])
>>> functools.reduce(operator.concat, []
Traceback (most recent call last):
... ValueError: reduce() of empty sequence with no initial value
>>> functools.reduce(operator.mul, [1,2,3], 1)
6
>>> functools.reduce(operator.mul, [], 1)
1
```

If you use *operator.add()* with *functools.reduce()*, you'll add up all the elements of the iterable. This case is so common that there's a special built-in called *sum()* to compute it:

```
>>> import functools, operator
>>> functools.reduce(operator.add, [1,2,3,4], 0)
10
>>> sum([1,2,3,4])
10
>>> sum([])
0
```
For many uses of `functools.reduce()`, though, it can be clearer to just write the obvious `for` loop:

```python
import functools
#
# Instead of:
# product = functools.reduce(operator.mul, [1,2,3], 1)
#
# You can write:
product = 1
for i in [1,2,3]:
    product *= i
```

A related function is `itertools.accumulate(iterable, func=operator.add)`. It performs the same calculation, but instead of returning only the final result, `accumulate()` returns an iterator that also yields each partial result:

```python
itertools.accumulate([1,2,3,4,5]) =>
  1, 3, 6, 10, 15

itertools.accumulate([1,2,3,4,5], operator.mul) =>
  1, 2, 6, 24, 120
```

### The operator module

The `operator` module was mentioned earlier. It contains a set of functions corresponding to Python's operators. These functions are often useful in functional-style code because they save you from writing trivial functions that perform a single operation.

Some of the functions in this module are:
- Math operations: `add()`, `sub()`, `mul()`, `floordiv()`, `abs()`, ...
- Logical operations: `not_()`, `truth()`.
- Bitwise operations: `and_()`, `or_()`, `invert()`.
- Comparisons: `eq()`, `ne()`, `lt()`, `le()`, `gt()`, and `ge()`.
- Object identity: `is_()`, `is_not()`.

Consult the operator module’s documentation for a complete list.
Small functions and the lambda expression

When writing functional-style programs, you'll often need little functions that act as predicates or that combine elements in some way.

If there's a Python built-in or a module function that's suitable, you don't need to define a new function at all:

```python
stripped_lines = [line.strip() for line in lines]
existing_files = filter(os.path.exists, file_list)
```

If the function you need doesn't exist, you need to write it. One way to write small functions is to use the `lambda` statement. `lambda` takes a number of parameters and an expression combining these parameters, and creates an anonymous function that returns the value of the expression:

```python
adder = lambda x, y: x+y
print_assign = lambda name, value: name + '=' + str(value)
```

An alternative is to just use the `def` statement and define a function in the usual way:

```python
def adder(x, y):
    return x + y

def print_assign(name, value):
    return name + '=' + str(value)
```

Which alternative is preferable? That's a style question; my usual
course is to avoid using `lambda`.

One reason for my preference is that `lambda` is quite limited in the functions it can define. The result has to be computable as a single expression, which means you can't have multiway `if... elif... else` comparisons or `try... except` statements. If you try to do too much in a `lambda` statement, you'll end up with an overly complicated expression that's hard to read. Quick, what's the following code doing?

```python
import functools
total = functools.reduce(lambda a, b: (0, a[1] + b[1]), )
```

You can figure it out, but it takes time to disentangle the expression to figure out what's going on. Using a short nested `def` statements makes things a little bit better:

```python
import functools
def combine(a, b):
    return 0, a[1] + b[1]
total = functools.reduce(combine, items)[1]
```

But it would be best of all if I had simply used a `for` loop:

```python
total = 0
for a, b in items:
    total += b
```

Or the `sum()` built-in and a generator expression:

```python
total = sum(b for a, b in items)
```
Many uses of `functools.reduce()` are clearer when written as for loops.

Fredrik Lundh once suggested the following set of rules for refactoring uses of lambda:

1. Write a lambda function.
2. Write a comment explaining what the heck that lambda does.
3. Study the comment for a while, and think of a name that captures the essence of the comment.
4. Convert the lambda to a def statement, using that name.
5. Remove the comment.

I really like these rules, but you’re free to disagree about whether this lambda-free style is better.
Revision History and Acknowledgements

The author would like to thank the following people for offering suggestions, corrections and assistance with various drafts of this article: Ian Bicking, Nick Coghlan, Nick Efford, Raymond Hettinger, Jim Jewett, Mike Krell, Leandro Lameiro, Jussi Salmela, Collin Winter, Blake Winton.

Version 0.1: posted June 30 2006.

Version 0.11: posted July 1 2006. Typo fixes.

Version 0.2: posted July 10 2006. Merged genexp and listcomp sections into one. Typo fixes.

Version 0.21: Added more references suggested on the tutor mailing list.

Version 0.30: Adds a section on the functional module written by Collin Winter; adds short section on the operator module; a few other edits.

Logging HOWTO

Author: Vinay Sajip <vinay_sajip at red-dove dot com>
Basic Logging Tutorial

Logging is a means of tracking events that happen when some software runs. The software’s developer adds logging calls to their code to indicate that certain events have occurred. An event is described by a descriptive message which can optionally contain variable data (i.e. data that is potentially different for each occurrence of the event). Events also have an importance which the developer ascribes to the event; the importance can also be called the level or severity.

When to use logging

Logging provides a set of convenience functions for simple logging usage. These are `debug()`, `info()`, `warning()`, `error()` and `critical()`. To determine when to use logging, see the table below, which states, for each of a set of common tasks, the best tool to use for it.

<table>
<thead>
<tr>
<th>Task you want to perform</th>
<th>The best tool for the task</th>
</tr>
</thead>
<tbody>
<tr>
<td>Display console output for ordinary usage of a command line script or program</td>
<td><code>print()</code></td>
</tr>
<tr>
<td>Report events that occur during normal operation of a program (e.g. for status monitoring or fault investigation)</td>
<td><code>logging.info()</code> (or <code>logging.debug()</code> for very detailed output for diagnostic purposes)</td>
</tr>
<tr>
<td></td>
<td><code>warnings.warn()</code> in library code if the issue is avoidable and the client application should be</td>
</tr>
</tbody>
</table>
Issue a warning regarding a particular runtime event

<table>
<thead>
<tr>
<th>Level</th>
<th>When it’s used</th>
</tr>
</thead>
<tbody>
<tr>
<td>DEBUG</td>
<td>Detailed information, typically of interest only when diagnosing problems.</td>
</tr>
<tr>
<td>INFO</td>
<td>Confirmation that things are working as expected.</td>
</tr>
<tr>
<td>WARNING</td>
<td>An indication that something unexpected happened, or indicative of some problem in the near future (e.g. ‘disk space low’). The software is still working as expected.</td>
</tr>
<tr>
<td>ERROR</td>
<td>Due to a more serious problem, the software has not been able to perform some function.</td>
</tr>
<tr>
<td>CRITICAL</td>
<td>A serious error, indicating that the program itself may be unable to continue running.</td>
</tr>
</tbody>
</table>
The default level is **WARNING**, which means that only events of this level and above will be tracked, unless the logging package is configured to do otherwise.

Events that are tracked can be handled in different ways. The simplest way of handling tracked events is to print them to the console. Another common way is to write them to a disk file.

**A simple example**

A very simple example is:

```python
import logging
logging.warning('Watch out!')  # will print a message
logging.info('I told you so')  # will not print anything
```

If you type these lines into a script and run it, you’ll see:

```
WARNING:root:Watch out!
```

printed out on the console. The **INFO** message doesn’t appear because the default level is **WARNING**. The printed message includes the indication of the level and the description of the event provided in the logging call, i.e. ‘Watch out!’. Don’t worry about the ‘root’ part for now: it will be explained later. The actual output can be formatted quite flexibly if you need that; formatting options will also be explained later.

**Logging to a file**

A very common situation is that of recording logging events in a file, so let’s look at that next. Be sure to try the following in a newly-started Python interpreter, and don’t just continue from the session described
above:

```python
import logging
logging.basicConfig(filename='example.log', level=logging.DEBUG)
logging.debug('This message should go to the log file')
logging.info('So should this')
logging.warning('And this, too')
```

And now if we open the file and look at what we have, we should find the log messages:

```
DEBUG:root:This message should go to the log file
INFO:root:So should this
WARNING:root:And this, too
```

This example also shows how you can set the logging level which acts as the threshold for tracking. In this case, because we set the threshold to DEBUG, all of the messages were printed.

If you want to set the logging level from a command-line option such as:

```
--log=INFO
```

and you have the value of the parameter passed for `--log` in some variable `loglevel`, you can use:

```python
getattr(logging, loglevel.upper())
```

to get the value which you’ll pass to `basicConfig()` via the `level` argument. You may want to error check any user input value, perhaps as in the following example:
# assuming loglevel is bound to the string value obtained from the command line argument. Convert to upper case to allow the user to specify --log=DEBUG or --log=debug

numeric_level = getattr(logging, loglevel.upper(), None)
if not isinstance(numeric_level, int):
    raise ValueError('Invalid log level: %s' % loglevel)

logging.basicConfig(level=numeric_level, ...)

The call to basicConfig() should come before any calls to debug(), info() etc. As it's intended as a one-off simple configuration facility, only the first call will actually do anything: subsequent calls are effectively no-ops.

If you run the above script several times, the messages from successive runs are appended to the file example.log. If you want each run to start afresh, not remembering the messages from earlier runs, you can specify the filemode argument, by changing the call in the above example to:

```
logging.basicConfig(filename='example.log', filemode=
```

The output will be the same as before, but the log file is no longer appended to, so the messages from earlier runs are lost.

Logging from multiple modules

If your program consists of multiple modules, here's an example of how you could organize logging in it:

```
# myapp.py
import logging
import mylib
```

def main():
    logging.basicConfig(filename='myapp.log', level=logging.info('Started'))
    mylib.do_something()
    logging.info('Finished')

if __name__ == '__main__':
    main()

# mylib.py
import logging
def do_something():
    logging.info('Doing something')

If you run myapp.py, you should see this in myapp.log:

INFO:root:Started
INFO:root:Doing something
INFO:root:Finished

which is hopefully what you were expecting to see. You can generalize this to multiple modules, using the pattern in mylib.py. Note that for this simple usage pattern, you won’t know, by looking in the log file, *where* in your application your messages came from, apart from looking at the event description. If you want to track the location of your messages, you’ll need to refer to the documentation beyond the tutorial level – see Advanced Logging Tutorial.

Logging variable data

To log variable data, use a format string for the event description
message and append the variable data as arguments. For example:

```python
import logging/logging.
logging.warning('%s before you %s', 'Look', 'leap!')
```

will display:

```
WARNING:root:Look before you leap!
```

As you can see, merging of variable data into the event description message uses the old, %-style of string formatting. This is for backwards compatibility: the logging package pre-dates newer formatting options such as `str.format()` and `string.Template`. These newer formatting options are supported, but exploring them is outside the scope of this tutorial: see Using particular formatting styles throughout your application for more information.

**Changing the format of displayed messages**

To change the format which is used to display messages, you need to specify the format you want to use:

```python
import logging
logging.basicConfig(format='%s%(levelname)s:%s%(message)s')
logging.debug('This message should appear on the console')
logging.info('So should this')
logging.warning('And this, too')
```

which would print:

```
DEBUG:This message should appear on the console
INFO:So should this
```
Notice that the ‘root’ which appeared in earlier examples has disappeared. For a full set of things that can appear in format strings, you can refer to the documentation for LogRecord attributes, but for simple usage, you just need thelevelname (severity), message (event description, including variable data) and perhaps to display when the event occurred. This is described in the next section.

Displaying the date/time in messages

To display the date and time of an event, you would place ‘% (asctime)s’ in your format string:

```python
import logging
logging.basicConfig(format='%(asctime)s %%(message)s'
logging.warning('is when this event was logged.')
```

which should print something like this:

```
2010-12-12 11:41:42,612 is when this event was logged.
```

The default format for date/time display (shown above) is ISO8601. If you need more control over the formatting of the date/time, provide a datefmt argument to basicConfig, as in this example:

```python
import logging
logging.basicConfig(format='%(asctime)s %%(message)s'
logging.warning('is when this event was logged.')
```

which would display something like this:
The format of the `datefmt` argument is the same as supported by `time.strftime()`.

**Next Steps**

That concludes the basic tutorial. It should be enough to get you up and running with logging. There's a lot more that the logging package offers, but to get the best out of it, you'll need to invest a little more of your time in reading the following sections. If you're ready for that, grab some of your favourite beverage and carry on.

If your logging needs are simple, then use the above examples to incorporate logging into your own scripts, and if you run into problems or don't understand something, please post a question on the comp.lang.python Usenet group (available at https://groups.google.com/group/comp.lang.python) and you should receive help before too long.

Still here? You can carry on reading the next few sections, which provide a slightly more advanced/in-depth tutorial than the basic one above. After that, you can take a look at the Logging Cookbook.
The logging library takes a modular approach and offers several categories of components: loggers, handlers, filters, and formatters.

- Loggers expose the interface that application code directly uses.
- Handlers send the log records (created by loggers) to the appropriate destination.
- Filters provide a finer grained facility for determining which log records to output.
- Formatters specify the layout of log records in the final output.

Log event information is passed between loggers, handlers, filters and formatters in a `LogRecord` instance.

Logging is performed by calling methods on instances of the `Logger` class (hereafter called `loggers`). Each instance has a name, and they are conceptually arranged in a namespace hierarchy using dots (periods) as separators. For example, a logger named ‘scan’ is the parent of loggers ‘scan.text’, ‘scan.html’ and ‘scan.pdf’. Logger names can be anything you want, and indicate the area of an application in which a logged message originates.

A good convention to use when naming loggers is to use a module-level logger, in each module which uses logging, named as follows:

```python
logger = logging.getLogger(__name__)
```

This means that logger names track the package/module hierarchy, and it’s intuitively obvious where events are logged just from the logger name.

The root of the hierarchy of loggers is called the root logger. That’s the
logger used by the functions `debug()`, `info()`, `warning()`, `error()` and `critical()`, which just call the same-named method of the root logger. The functions and the methods have the same signatures. The root logger’s name is printed as ‘root’ in the logged output.

It is, of course, possible to log messages to different destinations. Support is included in the package for writing log messages to files, HTTP GET/POST locations, email via SMTP, generic sockets, queues, or OS-specific logging mechanisms such as syslog or the Windows NT event log. Destinations are served by `handler` classes. You can create your own log destination class if you have special requirements not met by any of the built-in handler classes.

By default, no destination is set for any logging messages. You can specify a destination (such as console or file) by using `basicConfig()` as in the tutorial examples. If you call the functions `debug()`, `info()`, `warning()`, `error()` and `critical()`, they will check to see if no destination is set; and if one is not set, they will set a destination of the console (`sys.stderr`) and a default format for the displayed message before delegating to the root logger to do the actual message output.

The default format set by `basicConfig()` for messages is:

```
severity:logger name:message
```

You can change this by passing a format string to `basicConfig()` with the `format` keyword argument. For all options regarding how a format string is constructed, see `Formatter Objects`.

**Logging Flow**
The flow of log event information in loggers and handlers is illustrated in the following diagram.

**Loggers**

Logger objects have a threefold job. First, they expose several methods to application code so that applications can log messages at runtime. Second, logger objects determine which log messages to act upon based upon severity (the default filtering facility) or filter objects. Third, logger objects pass along relevant log messages to all interested log handlers.

The most widely used methods on logger objects fall into two categories: configuration and message sending.
These are the most common configuration methods:

- **Logger.setLevel()** specifies the lowest-severity log message a logger will handle, where debug is the lowest built-in severity level and critical is the highest built-in severity. For example, if the severity level is INFO, the logger will handle only INFO, WARNING, ERROR, and CRITICAL messages and will ignore DEBUG messages.
- **Logger.addHandler()** and **Logger.removeHandler()** add and remove handler objects from the logger object. Handlers are covered in more detail in Handlers.
- **Logger.addFilter()** and **Logger.removeFilter()** add and remove filter objects from the logger object. Filters are covered in more detail in Filter Objects.

You don’t need to always call these methods on every logger you create. See the last two paragraphs in this section.

With the logger object configured, the following methods create log messages:

- **Logger.debug(), Logger.info(), Logger.warning(), Logger.error(), and Logger.critical()** all create log records with a message and a level that corresponds to their respective method names. The message is actually a format string, which may contain the standard string substitution syntax of %s, %d, %f, and so on. The rest of their arguments is a list of objects that correspond with the substitution fields in the message. With regard to **kwargs, the logging methods care only about a keyword of exc_info and use it to determine whether to log exception information.
- **Logger.exception()** creates a log message similar to Logger.error(). The difference is that Logger.exception() dumps a stack trace along with it. Call
this method only from an exception handler.

- **Logger.log()** takes a log level as an explicit argument. This is a little more verbose for logging messages than using the log level convenience methods listed above, but this is how to log at custom log levels.

**getLogger()** returns a reference to a logger instance with the specified name if it is provided, or root if not. The names are period-separated hierarchical structures. Multiple calls to **getLogger()** with the same name will return a reference to the same logger object. Loggers that are further down in the hierarchical list are children of loggers higher up in the list. For example, given a logger with a name of foo, loggers with names of foo.bar, foo.bar.baz, and foo.bam are all descendants of foo.

Loggers have a concept of *effective level*. If a level is not explicitly set on a logger, the level of its parent is used instead as its effective level. If the parent has no explicit level set, its parent is examined, and so on - all ancestors are searched until an explicitly set level is found. The root logger always has an explicit level set (**WARNING** by default). When deciding whether to process an event, the effective level of the logger is used to determine whether the event is passed to the logger’s handlers.

Child loggers propagate messages up to the handlers associated with their ancestor loggers. Because of this, it is unnecessary to define and configure handlers for all the loggers an application uses. It is sufficient to configure handlers for a top-level logger and create child loggers as needed. (You can, however, turn off propagation by setting the **propagate** attribute of a logger to False.)

**Handlers**
Handler objects are responsible for dispatching the appropriate log messages (based on the log messages' severity) to the handler's specified destination. Logger objects can add zero or more handler objects to themselves with an addHandler() method. As an example scenario, an application may want to send all log messages to a log file, all log messages of error or higher to stdout, and all messages of critical to an email address. This scenario requires three individual handlers where each handler is responsible for sending messages of a specific severity to a specific location.

The standard library includes quite a few handler types (see Useful Handlers); the tutorials use mainly StreamHandler and FileHandler in its examples.

There are very few methods in a handler for application developers to concern themselves with. The only handler methods that seem relevant for application developers who are using the built-in handler objects (that is, not creating custom handlers) are the following configuration methods:

- The setLevel() method, just as in logger objects, specifies the lowest severity that will be dispatched to the appropriate destination. Why are there two setLevel() methods? The level set in the logger determines which severity of messages it will pass to its handlers. The level set in each handler determines which messages that handler will send on.
- setFormatter() selects a Formatter object for this handler to use.
- addFilter() and removeFilter() respectively configure and deconfigure filter objects on handlers.

Application code should not directly instantiate and use instances of Handler. Instead, the Handler class is a base class that defines the
interface that all handlers should have and establishes some default behavior that child classes can use (or override).

Formatters

Formatter objects configure the final order, structure, and contents of the log message. Unlike the base logging.Handler class, application code may instantiate formatter classes, although you could likely subclass the formatter if your application needs special behavior. The constructor takes three optional arguments – a message format string, a date format string and a style indicator.

logging.Formatter.__init__(fmt=None, datefmt=None, style='%')

If there is no message format string, the default is to use the raw message. If there is no date format string, the default date format is:

```
%Y-%m-%d %H:%M:%S
```

with the milliseconds tacked on at the end. The style is one of %, '{' or '$'. If one of these is not specified, then '%' will be used.

If the style is ‘%’, the message format string uses %(<dictionary key>)s styled string substitution; the possible keys are documented in LogRecord attributes. If the style is ‘{’, the message format string is assumed to be compatible with str.format() (using keyword arguments), while if the style is ‘$’ then the message format string should conform to what is expected by string.Template.substitute().

*Changed in version 3.2:* Added the style parameter.
The following message format string will log the time in a human-readable format, the severity of the message, and the contents of the message, in that order:

```
%(asctime)s - %(levelname)s - %(message)s
```

Formatters use a user-configurable function to convert the creation time of a record to a tuple. By default, `time.localtime()` is used; to change this for a particular formatter instance, set the `converter` attribute of the instance to a function with the same signature as `time.localtime()` or `time.gmtime()`. To change it for all formatters, for example if you want all logging times to be shown in GMT, set the `converter` attribute in the Formatter class (to `time.gmtime` for GMT display).

## Configuring Logging

Programmers can configure logging in three ways:

1. Creating loggers, handlers, and formatters explicitly using Python code that calls the configuration methods listed above.
2. Creating a logging config file and reading it using the `fileConfig()` function.
3. Creating a dictionary of configuration information and passing it to the `dictConfig()` function.

For the reference documentation on the last two options, see [Configuration functions](#). The following example configures a very simple logger, a console handler, and a simple formatter using Python code:

```python
import logging
```
# create logger
logger = logging.getLogger('simple_example')
logger.setLevel(logging.DEBUG)

# create console handler and set level to debug
ch = logging.StreamHandler()
ch.setLevel(logging.DEBUG)

# create formatter
formatter = logging.Formatter('%(asctime)s - %(name)s - %(levelname)s - %(message)s')

# add formatter to ch
ch.setFormatter(formatter)

# add ch to logger
logger.addHandler(ch)

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warn('warn message')
logger.error('error message')
logger.critical('critical message')

Running this module from the command line produces the following output:

$ python simple_logging_module.py
2005-03-19 15:10:26,618 - simple_example - DEBUG - debug message
2005-03-19 15:10:26,620 - simple_example - INFO - info message
2005-03-19 15:10:26,695 - simple_example - WARNING - warn message
2005-03-19 15:10:26,697 - simple_example - ERROR - error message
2005-03-19 15:10:26,773 - simple_example - CRITICAL - critical message

The following Python module creates a logger, handler, and formatter
nearly identical to those in the example listed above, with the only
difference being the names of the objects:

```python
import logging
import logging.config

logging.config.fileConfig('logging.conf')

# create logger
logger = logging.getLogger('simpleExample')

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warn('warn message')
logger.error('error message')
logger.critical('critical message')
```

Here is the logging.conf file:

```plaintext
[loggers]
keys=root,simpleExample

[handlers]
keys=consoleHandler

[formatters]
keys=simpleFormatter

[logger_root]
level=DEBUG
handlers=consoleHandler

[logger_simpleExample]
level=DEBUG
handlers=consoleHandler
```
The output is nearly identical to that of the non-config-file-based example:

```bash
$ python simple_logging_config.py
2005-03-19 15:38:55,977 - simpleExample - DEBUG - debug message
2005-03-19 15:38:55,979 - simpleExample - INFO - info message
2005-03-19 15:38:56,054 - simpleExample - WARNING - warn message
2005-03-19 15:38:56,055 - simpleExample - ERROR - error message
2005-03-19 15:38:56,130 - simpleExample - CRITICAL - critical message
```

You can see that the config file approach has a few advantages over the Python code approach, mainly separation of configuration and code and the ability of noncoders to easily modify the logging properties.

**Warning:** The `fileConfig()` function takes a default parameter, `disable_existing_loggers`, which defaults to `True` for reasons of backward compatibility. This may or may not be what you want, since it will cause any loggers existing before the `fileConfig()` call to be disabled unless they (or an ancestor) are
explicitly named in the configuration. Please refer to the reference documentation for more information, and specify False for this parameter if you wish.

The dictionary passed to dictConfig() can also specify a Boolean value with key disable_existing_loggers, which if not specified explicitly in the dictionary also defaults to being interpreted as True. This leads to the logger-disabling behaviour described above, which may not be what you want - in which case, provide the key explicitly with a value of False.

Note that the class names referenced in config files need to be either relative to the logging module, or absolute values which can be resolved using normal import mechanisms. Thus, you could use either WatchedFileHandler (relative to the logging module) or mypackage.mymodule.MyHandler (for a class defined in package mypackage and module mymodule, where mypackage is available on the Python import path).

In Python 3.2, a new means of configuring logging has been introduced, using dictionaries to hold configuration information. This provides a superset of the functionality of the config-file-based approach outlined above, and is the recommended configuration method for new applications and deployments. Because a Python dictionary is used to hold configuration information, and since you can populate that dictionary using different means, you have more options for configuration. For example, you can use a configuration file in JSON format, or, if you have access to YAML processing functionality, a file in YAML format, to populate the configuration dictionary. Or, of course, you can construct the dictionary in Python code, receive it in pickled form over a socket, or use whatever approach makes sense.
for your application.

Here's an example of the same configuration as above, in YAML format for the new dictionary-based approach:

```yaml
version: 1
formatters:
    simple:
        format: '%(asctime)s - %(name)s - %(levelname)s
handlers:
    console:
        class: logging.StreamHandler
        level: DEBUG
        formatter: simple
        stream: ext://sys.stdout
loggers:
    simpleExample:
        level: DEBUG
        handlers: [console]
        propagate: no
root:
    level: DEBUG
    handlers: [console]
```

For more information about logging using a dictionary, see Configuration functions.

What happens if no configuration is provided

If no logging configuration is provided, it is possible to have a situation where a logging event needs to be output, but no handlers can be found to output the event. The behaviour of the logging package in these circumstances is dependent on the Python version.
For versions of Python prior to 3.2, the behaviour is as follows:

- If `logging.raiseExceptions` is `False` (production mode), the event is silently dropped.
- If `logging.raiseExceptions` is `True` (development mode), a message ‘No handlers could be found for logger X.Y.Z’ is printed once.

In Python 3.2 and later, the behaviour is as follows:

- The event is output using a ‘handler of last resort’, stored in `logging.lastResort`. This internal handler is not associated with any logger, and acts like a `StreamHandler` which writes the event description message to the current value of `sys.stderr` (therefore respecting any redirections which may be in effect). No formatting is done on the message - just the bare event description message is printed. The handler’s level is set to `WARNING`, so all events at this and greater severities will be output.

To obtain the pre-3.2 behaviour, `logging.lastResort` can be set to `None`.

Configuring Logging for a Library

When developing a library which uses logging, you should take care to document how the library uses logging - for example, the names of loggers used. Some consideration also needs to be given to its logging configuration. If the using application does not use logging, and library code makes logging calls, then (as described in the previous section) events of severity `WARNING` and greater will be printed to `sys.stderr`. This is regarded as the best default behaviour.
If for some reason you don’t want these messages printed in the absence of any logging configuration, you can attach a do-nothing handler to the top-level logger for your library. This avoids the message being printed, since a handler will be always be found for the library’s events: it just doesn’t produce any output. If the library user configures logging for application use, presumably that configuration will add some handlers, and if levels are suitably configured then logging calls made in library code will send output to those handlers, as normal.

A do-nothing handler is included in the logging package: NullHandler (since Python 3.1). An instance of this handler could be added to the top-level logger of the logging namespace used by the library (if you want to prevent your library’s logged events being output to sys.stderr in the absence of logging configuration). If all logging by a library foo is done using loggers with names matching ‘foo.x’, ‘foo.x.y’, etc. then the code:

```python
import logging
logging.getLogger('foo').addHandler(logging.NullHandler())
```

should have the desired effect. If an organisation produces a number of libraries, then the logger name specified can be ‘orgname.foo’ rather than just ‘foo’.

**Note:** It is strongly advised that you do not add any handlers other than NullHandler to your library’s loggers. This is because the configuration of handlers is the prerogative of the application developer who uses your library. The application developer knows their target audience and what handlers are most appropriate for their application: if you add handlers ‘under the hood’, you might well interfere with their ability to carry out unit tests and deliver logs which
suit their requirements.
Logging Levels

The numeric values of logging levels are given in the following table. These are primarily of interest if you want to define your own levels, and need them to have specific values relative to the predefined levels. If you define a level with the same numeric value, it overwrites the predefined value; the predefined name is lost.

<table>
<thead>
<tr>
<th>Level</th>
<th>Numeric value</th>
</tr>
</thead>

Levels can also be associated with loggers, being set either by the developer or through loading a saved logging configuration. When a logging method is called on a logger, the logger compares its own level with the level associated with the method call. If the logger’s level is higher than the method call’s, no logging message is actually generated. This is the basic mechanism controlling the verbosity of logging output.

Logging messages are encoded as instances of the LogRecord class. When a logger decides to actually log an event, a LogRecord instance is created from the logging message.

Logging messages are subjected to a dispatch mechanism through
the use of *handlers*, which are instances of subclasses of the Handler class. Handlers are responsible for ensuring that a logged message (in the form of a LogRecord) ends up in a particular location (or set of locations) which is useful for the target audience for that message (such as end users, support desk staff, system administrators, developers). Handlers are passed LogRecord instances intended for particular destinations. Each logger can have zero, one or more handlers associated with it (via the `addHandler()` method of Logger). In addition to any handlers directly associated with a logger, *all handlers associated with all ancestors of the logger* are called to dispatch the message (unless the `propagate` flag for a logger is set to a false value, at which point the passing to ancestor handlers stops).

Just as for loggers, handlers can have levels associated with them. A handler’s level acts as a filter in the same way as a logger’s level does. If a handler decides to actually dispatch an event, the `emit()` method is used to send the message to its destination. Most user-defined subclasses of Handler will need to override this `emit()`.

**Custom Levels**

Defining your own levels is possible, but should not be necessary, as the existing levels have been chosen on the basis of practical experience. However, if you are convinced that you need custom levels, great care should be exercised when doing this, and it is possibly a very bad idea to define custom levels if you are developing a library. That’s because if multiple library authors all define their own custom levels, there is a chance that the logging output from such multiple libraries used together will be difficult for the using developer to control and/or interpret, because a given numeric value might mean
different things for different libraries.
Useful Handlers

In addition to the base Handler class, many useful subclasses are provided:

1. StreamHandler instances send messages to streams (file-like objects).
2. FileHandler instances send messages to disk files.
3. BaseRotatingHandler is the base class for handlers that rotate log files at a certain point. It is not meant to be instantiated directly. Instead, use RotatingFileHandler or TimedRotatingFileHandler.
4. RotatingFileHandler instances send messages to disk files, with support for maximum log file sizes and log file rotation.
5. TimedRotatingFileHandler instances send messages to disk files, rotating the log file at certain timed intervals.
6. SocketHandler instances send messages to TCP/IP sockets. Since 3.4, Unix domain sockets are also supported.
7. DatagramHandler instances send messages to UDP sockets. Since 3.4, Unix domain sockets are also supported.
8. SMTPHandler instances send messages to a designated email address.
9. SysLogHandler instances send messages to a Unix syslog daemon, possibly on a remote machine.
10. NTEventLogHandler instances send messages to a Windows NT/2000/XP event log.
11. MemoryHandler instances send messages to a buffer in memory, which is flushed whenever specific criteria are met.
12. HTTPHandler instances send messages to an HTTP server using either GET or POST semantics.
13. WatchedFileHandler instances watch the file they are logging to. If the file changes, it is closed and reopened using the file
name. This handler is only useful on Unix-like systems; Windows does not support the underlying mechanism used.

14. QueueHandler instances send messages to a queue, such as those implemented in the queue or multiprocessing modules.

15. NullHandler instances do nothing with error messages. They are used by library developers who want to use logging, but want to avoid the ‘No handlers could be found for logger XXX’ message which can be displayed if the library user has not configured logging. See Configuring Logging for a Library for more information.

New in version 3.1: The NullHandler class.

New in version 3.2: The QueueHandler class.

The NullHandler, StreamHandler and FileHandler classes are defined in the core logging package. The other handlers are defined in a sub-module, logging.handlers. (There is also another sub-module, logging.config, for configuration functionality.)

Logged messages are formatted for presentation through instances of the Formatter class. They are initialized with a format string suitable for use with the % operator and a dictionary.

For formatting multiple messages in a batch, instances of BufferingFormatter can be used. In addition to the format string (which is applied to each message in the batch), there is provision for header and trailer format strings.

When filtering based on logger level and/or handler level is not enough, instances of Filter can be added to both Logger and
Handler instances (through their `addFilter()` method). Before deciding to process a message further, both loggers and handlers consult all their filters for permission. If any filter returns a false value, the message is not processed further.

The basic **Filter** functionality allows filtering by specific logger name. If this feature is used, messages sent to the named logger and its children are allowed through the filter, and all others dropped.
Exceptions raised during logging

The logging package is designed to swallow exceptions which occur while logging in production. This is so that errors which occur while handling logging events - such as logging misconfiguration, network or other similar errors - do not cause the application using logging to terminate prematurely.

_SystemExit_ and _KeyboardInterrupt_ exceptions are never swallowed. Other exceptions which occur during the _emit()_ method of a Handler subclass are passed to its _handleError()_ method.

The default implementation of _handleError()_ in Handler checks to see if a module-level variable, _raiseExceptions_, is set. If set, a traceback is printed to _sys.stderr_. If not set, the exception is swallowed.

**Note:** The default value of _raiseExceptions_ is True. This is because during development, you typically want to be notified of any exceptions that occur. It's advised that you set _raiseExceptions_ to False for production usage.
Using arbitrary objects as messages

In the preceding sections and examples, it has been assumed that the message passed when logging the event is a string. However, this is not the only possibility. You can pass an arbitrary object as a message, and its `__str__()` method will be called when the logging system needs to convert it to a string representation. In fact, if you want to, you can avoid computing a string representation altogether - for example, the `SocketHandler` emits an event by pickling it and sending it over the wire.
Optimization

Formatting of message arguments is deferred until it cannot be avoided. However, computing the arguments passed to the logging method can also be expensive, and you may want to avoid doing it if the logger will just throw away your event. To decide what to do, you can call the `isEnabledFor()` method which takes a level argument and returns true if the event would be created by the Logger for that level of call. You can write code like this:

```python
if logger.isEnabledFor(logging.DEBUG):
    logger.debug('Message with %s, %s', expensive_func1, expensive_func2)
```

so that if the logger's threshold is set above DEBUG, the calls to `expensive_func1()` and `expensive_func2()` are never made.

**Note:** In some cases, `isEnabledFor()` can itself be more expensive than you'd like (e.g. for deeply nested loggers where an explicit level is only set high up in the logger hierarchy). In such cases (or if you want to avoid calling a method in tight loops), you can cache the result of a call to `isEnabledFor()` in a local or instance variable, and use that instead of calling the method each time. Such a cached value would only need to be recomputed when the logging configuration changes dynamically while the application is running (which is not all that common).

There are other optimizations which can be made for specific applications which need more precise control over what logging information is collected. Here’s a list of things you can do to avoid
processing during logging which you don’t need:

<table>
<thead>
<tr>
<th>What you don’t want to collect</th>
<th>How to avoid collecting it</th>
</tr>
</thead>
<tbody>
<tr>
<td>Information about where calls were made from.</td>
<td>Set logging._srcfile to None. This avoids calling sys._getframe(), which may help to speed up your code in environments like PyPy (which can't speed up code that uses sys._getframe()), if and when PyPy supports Python 3.x.</td>
</tr>
<tr>
<td>Threading information.</td>
<td>Set logging.logThreads to 0.</td>
</tr>
<tr>
<td>Process information.</td>
<td>Set logging.logProcesses to 0.</td>
</tr>
</tbody>
</table>

Also note that the core logging module only includes the basic handlers. If you don’t import logging.handlers and logging.config, they won’t take up any memory.

Logging Cookbook

Author: Vinay Sajip <vinay_sajip at red-dove dot com>

This page contains a number of recipes related to logging, which have been found useful in the past.
Using logging in multiple modules

Multiple calls to `logging.getLogger('someLogger')` return a reference to the same logger object. This is true not only within the same module, but also across modules as long as it is in the same Python interpreter process. It is true for references to the same object; additionally, application code can define and configure a parent logger in one module and create (but not configure) a child logger in a separate module, and all logger calls to the child will pass up to the parent. Here is a main module:

```python
import logging
import auxiliary_module

# create logger with 'spam_application'
logger = logging.getLogger('spam_application')
logger.setLevel(logging.DEBUG)
# create file handler which logs even debug messages
fh = logging.FileHandler('spam.log')
fh.setLevel(logging.DEBUG)
# create console handler with a higher log level
ch = logging.StreamHandler()
ch.setLevel(logging.ERROR)
# create formatter and add it to the handlers
formatter = logging.Formatter('%(asctime)s - %(name)s
fh.setFormatter(formatter)
ch.setFormatter(formatter)
# add the handlers to the logger
logger.addHandler(fh)
logger.addHandler(ch)

logger.info('creating an instance of auxiliary_module.Auxiliary')
a = auxiliary_module.Auxiliary()
logger.info('created an instance of auxiliary_module.Auxiliary')
```
Here is the auxiliary module:

```python
import logging

# create logger
module_logger = logging.getLogger('spam_application.auxiliary')

class Auxiliary:
    def __init__(self):
        self.logger = logging.getLogger('spam_application.auxiliary.Auxiliary')
        self.logger.info('creating an instance of Auxiliary')

    def do_something(self):
        a = 1 + 1
        self.logger.info('done doing something')

    def some_function():
        module_logger.info('received a call to "some_function"')
```

The output looks like this:

```
2005-03-23 23:47:11,664 - spam_application.auxiliary - INFO - creating an instance of Auxiliary
```
2005-03-23 23:47:11,668 - spam_application.auxiliary doing something
2005-03-23 23:47:11,669 - spam_application.auxiliary done doing something
2005-03-23 23:47:11,671 - spam_application - INFO - calling auxiliary_module.some_function()
2005-03-23 23:47:11,672 - spam_application.auxiliary received a call to 'some_function'
2005-03-23 23:47:11,673 - spam_application - INFO - done with auxiliary_module.some_function()
Logging from multiple threads

Logging from multiple threads requires no special effort. The following example shows logging from the main (initial) thread and another thread:

```python
import logging
import threading
import time

def worker(arg):
    while not arg['stop']:
        logging.debug('Hi from myfunc')
        time.sleep(0.5)

def main():
    logging.basicConfig(level=logging.DEBUG, format='%(asctime)s - %(levelname)s - %(message)s',
                        datefmt='%Y-%m-%d %H:%M:%S',
                        handlers=[logging.StreamHandler()])
    info = {'stop': False}
    thread = threading.Thread(target=worker, args=(info,))
    thread.start()
    while True:
        try:
            logging.debug('Hello from main')
            time.sleep(0.75)
        except KeyboardInterrupt:
            info['stop'] = True
            break
    thread.join()

if __name__ == '__main__':
    main()
```

When run, the script should print something like the following:
This shows the logging output interspersed as one might expect. This approach works for more threads than shown here, of course.
Multiple handlers and formatters

Loggers are plain Python objects. The `addHandler()` method has no minimum or maximum quota for the number of handlers you may add. Sometimes it will be beneficial for an application to log all messages of all severities to a text file while simultaneously logging errors or above to the console. To set this up, simply configure the appropriate handlers. The logging calls in the application code will remain unchanged. Here is a slight modification to the previous simple module-based configuration example:

```python
import logging

logger = logging.getLogger('simple_example')
logger.setLevel(logging.DEBUG)
# create file handler which logs even debug messages
fh = logging.FileHandler('spam.log')
fh.setLevel(logging.DEBUG)
# create console handler with a higher log level
ch = logging.StreamHandler()
ch.setLevel(logging.ERROR)
# create formatter and add it to the handlers
formatter = logging.Formatter('%(asctime)s - %(name)s - %(levelname)s - %(message)s')
ch.setFormatter(formatter)
fh.setFormatter(formatter)
# add the handlers to logger
logger.addHandler(ch)
logger.addHandler(fh)

# 'application' code
logger.debug('debug message')
logger.info('info message')
logger.warn('warn message')
logger.error('error message')
```
Notice that the ‘application’ code does not care about multiple handlers. All that changed was the addition and configuration of a new handler named `fh`.

The ability to create new handlers with higher- or lower-severity filters can be very helpful when writing and testing an application. Instead of using many `print` statements for debugging, use `logger.debug`:

Unlike the print statements, which you will have to delete or comment out later, the `logger.debug` statements can remain intact in the source code and remain dormant until you need them again. At that time, the only change that needs to happen is to modify the severity level of the logger and/or handler to debug.
Logging to multiple destinations

Let's say you want to log to console and file with different message formats and in differing circumstances. Say you want to log messages with levels of DEBUG and higher to file, and those messages at level INFO and higher to the console. Let's also assume that the file should contain timestamps, but the console messages should not. Here's how you can achieve this:

```python
import logging

# set up logging to file - see previous section for
logging.basicConfig(level=logging.DEBUG,
    format='%(asctime)s %(name)-12s',
    datefmt='%m-%d %H:%M',
    filename='/temp/myapp.log',
    filemode='w')

# define a Handler which writes INFO messages or higher
console = logging.StreamHandler()
console.setLevel(logging.INFO)

# set a format which is simpler for console use
formatter = logging.Formatter('%(name)-12s: %(levelname)-8s

# tell the handler to use this format
console.setFormatter(formatter)

# add the handler to the root logger
logging.getLogger('').addHandler(console)

# Now, we can log to the root logger, or any other logger
logging.info('Jackdaws love my big sphinx of quartz.

# Now, define a couple of other loggers which might be
logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')
```
When you run this, on the console you will see

```
root  : INFO   Jackdaws love my big sphinx of myapp.
myapp.area1: INFO   How quickly daft jumping zebras vex.
myapp.area2: WARNING  Jail zesty vixen who grabbed myapp.
myapp.area2: ERROR    The five boxing wizards jump quickly.
```

and in the file you will see something like

```
10-22 22:19 root  INFO   Jackdaws love my big sphinx of myapp.
10-22 22:19 myapp.area1 DEBUG  Quick zephyrs blow.
10-22 22:19 myapp.area1 INFO   How quickly daft jumping zebras vex.
10-22 22:19 myapp.area2 WARNING  Jail zesty vixen who grabbed myapp.
10-22 22:19 myapp.area2 ERROR    The five boxing wizards jump quickly.
```

As you can see, the DEBUG message only shows up in the file. The other messages are sent to both destinations.

This example uses console and file handlers, but you can use any number and combination of handlers you choose.
Configuration server example

Here is an example of a module using the logging configuration server:

```python
import logging
import logging.config
import time
import os

# read initial config file
logging.config.fileConfig('logging.conf')

# create and start listener on port 9999
_t = logging.config.listen(9999)
t.start()

logger = logging.getLogger('simpleExample')

try:
    # loop through logging calls to see the different
    # new configurations make, until Ctrl+C is pressed
    while True:
        logger.debug('debug message')
        logger.info('info message')
        logger.warn('warn message')
        logger.error('error message')
        logger.critical('critical message')
        time.sleep(5)

except KeyboardInterrupt:
    # cleanup
    logging.config.stopListening()
t.join()
```

And here is a script that takes a filename and sends that file to the
server, properly preceded with the binary-encoded length, as the new logging configuration:

```python
#!/usr/bin/env python
import socket, sys, struct

with open(sys.argv[1], 'rb') as f:
    data_to_send = f.read()

HOST = 'localhost'
PORT = 9999
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
print('connecting...')
s.connect((HOST, PORT))
print('sending config...')
s.send(struct.pack('>L', len(data_to_send)))
s.send(data_to_send)
s.close()
print('complete')
```
Dealing with handlers that block

Sometimes you have to get your logging handlers to do their work without blocking the thread you're logging from. This is common in Web applications, though of course it also occurs in other scenarios.

A common culprit which demonstrates sluggish behaviour is the SMTPHandler: sending emails can take a long time, for a number of reasons outside the developer's control (for example, a poorly performing mail or network infrastructure). But almost any network-based handler can block: Even a SocketHandler operation may do a DNS query under the hood which is too slow (and this query can be deep in the socket library code, below the Python layer, and outside your control).

One solution is to use a two-part approach. For the first part, attach only a QueueHandler to those loggers which are accessed from performance-critical threads. They simply write to their queue, which can be sized to a large enough capacity or initialized with no upper bound to their size. The write to the queue will typically be accepted quickly, though you will probably need to catch the queue.Full exception as a precaution in your code. If you are a library developer who has performance-critical threads in their code, be sure to document this (together with a suggestion to attach only QueueHandlers to your loggers) for the benefit of other developers who will use your code.

The second part of the solution is QueueListener, which has been designed as the counterpart to QueueHandler. A QueueListener is very simple: it's passed a queue and some handlers, and it fires up an internal thread which listens to its queue for LogRecords sent from
QueueHandlers (or any other source of LogRecords, for that matter). The LogRecords are removed from the queue and passed to the handlers for processing.

The advantage of having a separate QueueListener class is that you can use the same instance to service multiple QueueHandlers. This is more resource-friendly than, say, having threaded versions of the existing handler classes, which would eat up one thread per handler for no particular benefit.

An example of using these two classes follows (imports omitted):

```python
que = queue.Queue(-1)  # no limit on size
queue_handler = QueueHandler(que)
handler = logging.StreamHandler()
listener = QueueListener(que, handler)
root = logging.getLogger()
root.addHandler(queue_handler)
formatter = logging.Formatter('%(threadName)s: %(message)s')
handler.setFormatter(formatter)
listener.start()  # The log output will display the thread which generated the event (the main thread) rather than the internal thread which monitors the internal queue. This is what you want to happen.
root.warning('Look out!')
listener.stop()
```

which, when run, will produce:

```
MainThread: Look out!
```

*Changed in version 3.5:* Prior to Python 3.5, the QueueListener always passed every message received from the queue to every
handler it was initialized with. (This was because it was assumed that level filtering was all done on the other side, where the queue is filled.) From 3.5 onwards, this behaviour can be changed by passing a keyword argument `respect_handler_level=True` to the listener’s constructor. When this is done, the listener compares the level of each message with the handler’s level, and only passes a message to a handler if it’s appropriate to do so.
Sending and receiving logging events across a network

Let's say you want to send logging events across a network, and handle them at the receiving end. A simple way of doing this is attaching a `SocketHandler` instance to the root logger at the sending end:

```python
import logging, logging.handlers

rootLogger = logging.getLogger('')
rootLogger.setLevel(logging.DEBUG)
socketHandler = logging.handlers.SocketHandler('localhost', logging.handlers.DEFAULT_TCP_LOGGING_PORT)

# don't bother with a formatter, since a socket handler
# an unformatted pickle
rootLogger.addHandler(socketHandler)

# Now, we can log to the root logger, or any other logger:
logging.info('Jackdaws love my big sphinx of quartz.'

# Now, define a couple of other loggers which might
# application:

logger1 = logging.getLogger('myapp.area1')
logger2 = logging.getLogger('myapp.area2')

logger1.debug('Quick zephyrs blow, vexing daft Jim.
logger1.info('How quickly daft jumping zebras vex.
logger2.warning('Jail zesty vixen who grabbed pay from quack.
logger2.error('The five boxing wizards jump quickly.
```

At the receiving end, you can set up a receiver using the
socketserver module. Here is a basic working example:

```python
import pickle
import logging
import logging.handlers
import socketserver
import struct

class LogRecordStreamHandler(socketserver.StreamRequestHandler):
    """Handler for a streaming logging request."

    This basically logs the record using whatever log configured locally.
    """

def handle(self):
    """
    Handle multiple requests - each expected to followed by the LogRecord in pickle format. according to whatever policy is configured locally.
    """
    while True:
        chunk = self.connection.recv(4)
        if len(chunk) < 4:
            break
        slen = struct.unpack('>L', chunk)[0]
        chunk = self.connection.recv(slen)
        while len(chunk) < slen:
            chunk = chunk + self.connection.recv(slen - len(chunk))
        obj = self.unPickle(chunk)
        record = logging.makeLogRecord(obj)
        self.handleLogRecord(record)

def unPickle(self, data):
    return pickle.loads(data)
```
def handleLogRecord(self, record):
    # if a name is specified, we use the named logger rather than the one implied by the record.
    if self.server.logname is not None:
        name = self.server.logname
    else:
        name = record.name
    logger = logging.getLogger(name)
    # N.B. EVERY record gets logged. This is because
    # is normally called AFTER logger-level filtering.
    # to do filtering, do it at the client end to
    # cycles and network bandwidth!
    logger.handle(record)

class LogRecordSocketReceiver(socketserver.ThreadingTCPServer):
    """
    Simple TCP socket-based logging receiver suitable for testing.
    """
    allow_reuse_address = True

    def __init__(self, host='localhost', port=logging.handlers.DEFAULT_TCP_LOGGING_PORT, handler=LogRecordStreamHandler):
        socketserver.ThreadingTCPServer.__init__(self, host, port, handler)
        self.abort = 0
        self.timeout = 1
        self.logname = None

    def serve_until_stopped(self):
        import select
        abort = 0
        while not abort:
            rd, wr, ex = select.select([self.socket.fileno()], [], [], self.timeout)
            if rd:
```python
    self.handle_request()
    abort = self.abort

def main():
    logging.basicConfig(
        format='%(relativeCreated)5d %(name)-15s %(levelname)-8s
    )
tcpserver = LogRecordSocketReceiver()
print('About to start TCP server...')
tcpserver.serve_until_stopped()

if __name__ == '__main__':
    main()
```

First run the server, and then the client. On the client side, nothing is printed on the console; on the server side, you should see something like:

```
About to start TCP server...

59 root INFO   Jackdaws love my big
59 myapp.area1 DEBUG Quick zephyrs blow, v
69 myapp.area1 INFO   How quickly daft jump
69 myapp.area2 WARNING Jail zesty vixen who
69 myapp.area2 ERROR  The five boxing wizards
```

Note that there are some security issues with pickle in some scenarios. If these affect you, you can use an alternative serialization scheme by overriding the makePickle() method and implementing your alternative there, as well as adapting the above script to use your alternative serialization.
Adding contextual information to your logging output

Sometimes you want logging output to contain contextual information in addition to the parameters passed to the logging call. For example, in a networked application, it may be desirable to log client-specific information in the log (e.g. remote client’s username, or IP address). Although you could use the `extra` parameter to achieve this, it’s not always convenient to pass the information in this way. While it might be tempting to create Logger instances on a per-connection basis, this is not a good idea because these instances are not garbage collected. While this is not a problem in practice, when the number of Logger instances is dependent on the level of granularity you want to use in logging an application, it could be hard to manage if the number of Logger instances becomes effectively unbounded.

Using LoggerAdapters to impart contextual information

An easy way in which you can pass contextual information to be output along with logging event information is to use the LoggerAdapter class. This class is designed to look like a Logger, so that you can call `debug()`, `info()`, `warning()`, `error()`, `exception()`, `critical()` and `log()`. These methods have the same signatures as their counterparts in Logger, so you can use the two types of instances interchangeably.

When you create an instance of LoggerAdapter, you pass it a Logger instance and a dict-like object which contains your contextual information. When you call one of the logging methods on an instance
of LoggerAdapter, it delegates the call to the underlying instance of Logger passed to its constructor, and arranges to pass the contextual information in the delegated call. Here’s a snippet from the code of LoggerAdapter:

```python
def debug(self, msg, *args, **kwargs):
    
    Delegate a debug call to the underlying logger, contextual information from this adapter instance
    
    msg, kwargs = self.process(msg, kwargs)
    self.logger.debug(msg, *args, **kwargs)
```

The process() method of LoggerAdapter is where the contextual information is added to the logging output. It's passed the message and keyword arguments of the logging call, and it passes back (potentially) modified versions of these to use in the call to the underlying logger. The default implementation of this method leaves the message alone, but inserts an ‘extra’ key in the keyword argument whose value is the dict-like object passed to the constructor. Of course, if you had passed an ‘extra’ keyword argument in the call to the adapter, it will be silently overwritten.

The advantage of using ‘extra’ is that the values in the dict-like object are merged into the LogRecord instance's __dict__, allowing you to use customized strings with your Formatter instances which know about the keys of the dict-like object. If you need a different method, e.g. if you want to prepend or append the contextual information to the message string, you just need to subclass LoggerAdapter and override process() to do what you need. Here is a simple example:

```python
class CustomAdapter(logging.LoggerAdapter):
```
This example adapter expects the passed in dict-like object to have a 'connid' key, whose value in brackets is prepended to the log message.

```python
def process(self, msg, kwargs):
    return '[%s] %s' % (self.extra['connid'], msg)
```

which you can use like this:

```python
logger = logging.getLogger(__name__)
adapte = CustomAdapter(logger, {'connid': some_conn_id})
```

Then any events that you log to the adapter will have the value of `some_conn_id` prepended to the log messages.

Using objects other than dicts to pass contextual information

You don’t need to pass an actual dict to a LoggerAdapter - you could pass an instance of a class which implements `__getitem__` and `__iter__` so that it looks like a dict to logging. This would be useful if you want to generate values dynamically (whereas the values in a dict would be constant).

Using Filters to impart contextual information

You can also add contextual information to log output using a user-defined Filter. Filter instances are allowed to modify the LogRecords passed to them, including adding additional attributes which can then be output using a suitable format string, or if needed a custom Formatter.

For example in a web application, the request being processed (or at
least, the interesting parts of it) can be stored in a threadlocal (``threading.local``) variable, and then accessed from a Filter to add, say, information from the request - say, the remote IP address and remote user's username - to the LogRecord, using the attribute names ‘ip’ and ‘user’ as in the LoggerAdapter example above. In that case, the same format string can be used to get similar output to that shown above. Here's an example script:

```python
import logging
from random import choice

class ContextFilter(logging.Filter):
    """
    This is a filter which injects contextual information into the log.

    Rather than use actual contextual information, we just use random data in this demo.
    """

    USERS = ['jim', 'fred', 'sheila']
    IPS = ['123.231.231.123', '127.0.0.1', '192.168.0.1']

    def filter(self, record):
        record.ip = choice(ContextFilter.IPS)
        record.user = choice(ContextFilter.USERS)
        return True

if __name__ == '__main__':
    levels = (logging.DEBUG, logging.INFO, logging.WARNING)
    logging.basicConfig(level=logging.DEBUG, format='%asctime)-15s %name
    a1 = logging.getLogger('a.b.c')
    a2 = logging.getLogger('d.e.f')

    f = ContextFilter()
```
a1.addFilter(f)
a2.addFilter(f)
a1.debug('A debug message')
a1.info('An info message with %s', 'some parameters')
for x in range(10):
    lvl = choice(levels)
    lvlname = logging.getLoggerName(lvl)
    a2.log(lvl, 'A message at %s level with %d %s which, when run, produces something like:

```

Logging to a single file from multiple processes

Although logging is thread-safe, and logging to a single file from multiple threads in a single process is supported, logging to a single file from multiple processes is not supported, because there is no standard way to serialize access to a single file across multiple processes in Python. If you need to log to a single file from multiple processes, one way of doing this is to have all the processes log to a SocketHandler, and have a separate process which implements a socket server which reads from the socket and logs to file. (If you prefer, you can dedicate one thread in one of the existing processes to perform this function.) This section documents this approach in more detail and includes a working socket receiver which can be used as a starting point for you to adapt in your own applications.

If you are using a recent version of Python which includes the multiprocessing module, you could write your own handler which uses the Lock class from this module to serialize access to the file from your processes. The existing FileHandler and subclasses do not make use of multiprocessing at present, though they may do so in the future. Note that at present, the multiprocessing module does not provide working lock functionality on all platforms (see https://bugs.python.org/issue3770).

Alternatively, you can use a Queue and a QueueHandler to send all logging events to one of the processes in your multi-process application. The following example script demonstrates how you can do this; in the example a separate listener process listens for events sent by other processes and logs them according to its own logging configuration. Although the example only demonstrates one way of
doing it (for example, you may want to use a listener thread rather than a separate listener process – the implementation would be analogous) it does allow for completely different logging configurations for the listener and the other processes in your application, and can be used as the basis for code meeting your own specific requirements:

```python
# You'll need these imports in your own code
import logging
import logging.handlers
import multiprocessing

# Next two import lines for this demo only
from random import choice, random
import time

# Because you'll want to define the logging configurations for the listener and worker process functions take a configurer parameter which they use for communication.
#
# In practice, you can configure the listener however you want, but in this simple example, the listener does not apply level or filter logic to the received events.
# In practice, you would probably want to do this logic in the worker processes to avoid sending events which would be filtered out between processes.
#
# The size of the rotated files is made small so you can see the results easily.

def listenerConfigurer():
    root = logging.getLogger()
    h = logging.handlers.RotatingFileHandler('mptest.log')
    f = logging.Formatter('%(asctime)s %(levelname)-10s
    h.setFormatter(f)
    root.addHandler(h)

    # This is the listener process top-level loop: wait for (LogRecords) on the queue and handle them, quit when...
# LogRecord.

def listener_process(queue, configurer):
    configurer()
    while True:
        try:
            record = queue.get()
            if record is None:  # We send this as a sentinel to tell the listener to quit.
                break
            logger = logging.getLogger(record.name)
            logger.handle(record)  # No level or filter logic applied - just do it!
        except Exception:
            import sys, traceback
            print('Whoops! Problem:', file=sys.stderr)
            traceback.print_exc(file=sys.stderr)

    # Arrays used for random selections in this demo

LEVELS = [logging.DEBUG, logging.INFO, logging.WARN, logging.ERROR, logging.CRITICAL]

LOGGERS = ['a.b.c', 'd.e.f']

MESSAGES = [
    'Random message #1',
    'Random message #2',
    'Random message #3',
]

# The worker configuration is done at the start of the worker process run.
# Note that on Windows you can't rely on fork semantics, so each process
# will run the logging configuration code when it starts.

def worker_configurer(queue):
    h = logging.handlers.QueueHandler(queue)  # Just need one handler
    root = logging.getLogger()
    root.addHandler(h)
    # send all messages, for demo; no other level or filter logic applied
    root.setLevel(logging.DEBUG)
# This is the worker process top-level loop, which just logs ten events with random intervening delays before terminating.  
# The print messages are just so you know it's doing something!

def worker_process(queue, configurer):
    configurer(queue)
    name = multiprocessing.current_process().name
    print('Worker started: %s' % name)
    for i in range(10):
        time.sleep(random())
        logger = logging.getLogger(choice(LOGGERS))
        level = choice(LEVELS)
        message = choice(MESSAGES)
        logger.log(level, message)
    print('Worker finished: %s' % name)

# Here's where the demo gets orchestrated.  Create the listener, create ten workers and start them, wait for them to finish, then send a None to the queue to tell the listener to finish.

def main():
    queue = multiprocessing.Queue(-1)
    listener = multiprocessing.Process(target=listener_process, args=(queue, ))
    listener.start()
    workers = []
    for i in range(10):
        worker = multiprocessing.Process(target=worker_process, args=(queue, ))
        workers.append(worker)
        worker.start()
    for w in workers:
        w.join()
    queue.put_nowait(None)
    listener.join()

if __name__ == '__main__':
    main()
import logging
import logging.config
import logging.handlers
from multiprocessing import Process, Queue
import random
import threading
import time

def logger_thread(q):
    while True:
        record = q.get()
        if record is None:
            break
        logger = logging.getLogger(record.name)
        logger.handle(record)

def worker_process(q):
    qh = logging.handlers.QueueHandler(q)
    root = logging.getLogger()
    root.setLevel(logging.DEBUG)
    root.addHandler(qh)
    levels = [logging.DEBUG, logging.INFO, logging.WARNING, logging.CRITICAL]
    loggers = ['foo', 'foo.bar', 'foo.bar.baz', 'spam', 'spam.ham', 'spam.ham.eggs']
    for i in range(100):
        lvl = random.choice(levels)
        logger = logging.getLogger(random.choice(loggers))
        logger.log(lvl, 'Message no. %d', i)

if __name__ == '__main__':

A variant of the above script keeps the logging in the main process, in a separate thread:
q = Queue()
d = {
    'version': 1,
    'formatters': {
        'detailed': {
            'class': 'logging.Formatter',
            'format': '%(asctime)s %(name)-15s %(levelname)-8s '
        }
    },
    'handlers': {
        'console': {
            'class': 'logging.StreamHandler',
            'level': 'INFO',
        },
        'file': {
            'class': 'logging.FileHandler',
            'filename': 'mplog.log',
            'mode': 'w',
            'formatter': 'detailed',
        },
        'foofile': {
            'class': 'logging.FileHandler',
            'filename': 'mplog-foo.log',
            'mode': 'w',
            'formatter': 'detailed',
        },
        'errors': {
            'class': 'logging.FileHandler',
            'filename': 'mplog-errors.log',
            'mode': 'w',
            'level': 'ERROR',
            'formatter': 'detailed',
        },
    },
    'loggers': {
        'foo': {
            'handlers': ['foofile']
        }
    }
}

This variant shows how you can e.g. apply configuration for particular loggers - e.g. the foo logger has a special handler which stores all events in the foo subsystem in a file mplog-foo.log. This will be used by the logging machinery in the main process (even though the logging events are generated in the worker processes) to direct the messages to the appropriate destinations.
Using file rotation

Sometimes you want to let a log file grow to a certain size, then open a new file and log to that. You may want to keep a certain number of these files, and when that many files have been created, rotate the files so that the number of files and the size of the files both remain bounded. For this usage pattern, the logging package provides a RotatingFileHandler:

```python
import glob
import logging
import logging.handlers

LOG_FILENAME = 'logging_rotatingfile_example.out'

# Set up a specific logger with our desired output level
my_logger = logging.getLogger('MyLogger')
my_logger.setLevel(logging.DEBUG)

# Add the log message handler to the logger
handler = logging.handlers.RotatingFileHandler(
    LOG_FILENAME, maxBytes=20, backupCount
)
my_logger.addHandler(handler)

# Log some messages
for i in range(20):
    my_logger.debug('i = %d' % i)

# See what files are created
logfiles = glob.glob('%s*' % LOG_FILENAME)

for filename in logfiles:
    print(filename)
```
The result should be 6 separate files, each with part of the log history for the application:

logging_rotatingfile_example.out
logging_rotatingfile_example.out.1
logging_rotatingfile_example.out.2
logging_rotatingfile_example.out.3
logging_rotatingfile_example.out.4
logging_rotatingfile_example.out.5

The most current file is always logging_rotatingfile_example.out, and each time it reaches the size limit it is renamed with the suffix .1. Each of the existing backup files is renamed to increment the suffix (.1 becomes .2, etc.) and the .6 file is erased.

Obviously this example sets the log length much too small as an extreme example. You would want to set maxBytes to an appropriate value.
Use of alternative formatting styles

When logging was added to the Python standard library, the only way of formatting messages with variable content was to use the %-formatting method. Since then, Python has gained two new formatting approaches: \texttt{string.Template} (added in Python 2.4) and \texttt{str.format()} (added in Python 2.6).

Logging (as of 3.2) provides improved support for these two additional formatting styles. The \texttt{Formatter} class been enhanced to take an additional, optional keyword parameter named \texttt{style}. This defaults to '%', but other possible values are '{' and '$', which correspond to the other two formatting styles. Backwards compatibility is maintained by default (as you would expect), but by explicitly specifying a style parameter, you get the ability to specify format strings which work with \texttt{str.format()} or \texttt{string.Template}. Here's an example console session to show the possibilities:

```
>>> import logging
>>> root = logging.getLogger()
>>> root.setLevel(logging.DEBUG)
>>> handler = logging.StreamHandler()
...       style='{'}
>>> handler.setFormatter(bf)
>>> root.addHandler(handler)
>>> logger = logging.getLogger('foo.bar')
>>> logger.debug('This is a DEBUG message')
2010-10-28 15:11:55,341 foo.bar DEBUG  This is a DEBUG message
>>> logger.critical('This is a CRITICAL message')
2010-10-28 15:12:11,526 foo.bar CRITICAL This is a CRITICAL message
>>> df = logging.Formatter('{asctime} $name $levelname:0s $message')
...       style='$')
```
>>> handler.setFormatter(df)

>>> logger.debug('This is a DEBUG message')
2010-10-28 15:13:06,924 foo.bar DEBUG This is a DEBUG message

>>> logger.critical('This is a CRITICAL message')
2010-10-28 15:13:11,494 foo.bar CRITICAL This is a CRITICAL message

Note that the formatting of logging messages for final output to logs is completely independent of how an individual logging message is constructed. That can still use %-formatting, as shown here:

```python
>>> logger.error('This is an%s %s %s', 'other,', 'ERROR,
2010-10-28 15:19:29,833 foo.bar ERROR This is another
```

Logging calls (logger.debug(), logger.info() etc.) only take positional parameters for the actual logging message itself, with keyword parameters used only for determining options for how to handle the actual logging call (e.g. the exc_info keyword parameter to indicate that traceback information should be logged, or the extra keyword parameter to indicate additional contextual information to be added to the log). So you cannot directly make logging calls using `str.format()` or `string.Template` syntax, because internally the logging package uses %-formatting to merge the format string and the variable arguments. There would no changing this while preserving backward compatibility, since all logging calls which are out there in existing code will be using %-format strings.

There is, however, a way that you can use {}- and $- formatting to construct your individual log messages. Recall that for a message you can use an arbitrary object as a message format string, and that the logging package will call `str()` on that object to get the actual format
string. Consider the following two classes:

```python
class BraceMessage:
    def __init__(self, fmt, *args, **kwargs):
        self.fmt = fmt
        self.args = args
        self.kwargs = kwargs

    def __str__(self):
        return self.fmt.format(*self.args, **self.kwargs)

class DollarMessage:
    def __init__(self, fmt, **kwargs):
        self.fmt = fmt
        self.kwargs = kwargs

    def __str__(self):
        from string import Template
        return Template(self.fmt).substitute(**self.kwargs)
```

Either of these can be used in place of a format string, to allow {}- or $-formatting to be used to build the actual “message” part which appears in the formatted log output in place of “%(message)s” or “{message}” or “$message”. It’s a little unwieldy to use the class names whenever you want to log something, but it’s quite palatable if you use an alias such as __ (double underscore — not to be confused with _, the single underscore used as a synonym/alias for gettext.gettext() or its brethren).

The above classes are not included in Python, though they’re easy enough to copy and paste into your own code. They can be used as follows (assuming that they’re declared in a module called wherever):
>>> from wherever import BraceMessage as __
>>> print(__('Message with {0} {name}', 2, name='placeholders'))
Message with 2 placeholders
>>> class Point: pass
...    __
>>> p = Point()
>>> p.x = 0.5
>>> p.y = 0.5
>>> print(__('Message with coordinates: ({point.x:.2f}, {point.y:.2f})', point=p))
Message with coordinates: (0.50, 0.50)
>>> from wherever import DollarMessage as __
>>> print(__('Message with $num $what', num=2, what='placeholders'))
Message with 2 placeholders

While the above examples use print() to show how the formatting works, you would of course use logger.debug() or similar to actually log using this approach.

One thing to note is that you pay no significant performance penalty with this approach: the actual formatting happens not when you make the logging call, but when (and if) the logged message is actually about to be output to a log by a handler. So the only slightly unusual thing which might trip you up is that the parentheses go around the format string and the arguments, not just the format string. That’s because the __ notation is just syntax sugar for a constructor call to one of the XXXMessage classes.

If you prefer, you can use a LoggerAdapter to achieve a similar effect to the above, as in the following example:

```python
import logging
```
class Message(object):
    def __init__(self, fmt, args):
        self.fmt = fmt
        self.args = args

    def __str__(self):
        return self.fmt.format(*self.args)

class StyleAdapter(logging.LoggerAdapter):
    def __init__(self, logger, extra=None):
        super(StyleAdapter, self).__init__(logger, extra)

        def log(self, level, msg, *args, **kwargs):
            if self.isEnabledFor(level):
                msg, kwargs = self.process(msg, kwargs)
                self.logger._log(level, Message(msg, args)

logger = StyleAdapter(logging.getLogger(__name__))

def main():
    logger.debug('Hello, {}', 'world!')

if __name__ == '__main__':
    logging.basicConfig(level=logging.DEBUG)
    main()

The above script should log the message Hello, world! when run with Python 3.2 or later.
Customizing LogRecord

Every logging event is represented by a LogRecord instance. When an event is logged and not filtered out by a logger's level, a LogRecord is created, populated with information about the event and then passed to the handlers for that logger (and its ancestors, up to and including the logger where further propagation up the hierarchy is disabled). Before Python 3.2, there were only two places where this creation was done:

- Logger.makeRecord(), which is called in the normal process of logging an event. This invoked LogRecord directly to create an instance.
- makeLogRecord(), which is called with a dictionary containing attributes to be added to the LogRecord. This is typically invoked when a suitable dictionary has been received over the network (e.g. in pickle form via a SocketHandler, or in JSON form via an HTTPHandler).

This has usually meant that if you need to do anything special with a LogRecord, you've had to do one of the following.

- Create your own Logger subclass, which overrides Logger.makeRecord(), and set it using setLoggerClass() before any loggers that you care about are instantiated.
- Add a Filter to a logger or handler, which does the necessary special manipulation you need when its filter() method is called.

The first approach would be a little unwieldy in the scenario where (say) several different libraries wanted to do different things. Each would attempt to set its own Logger subclass, and the one which did
this last would win.

The second approach works reasonably well for many cases, but does not allow you to e.g. use a specialized subclass of `LogRecord`. Library developers can set a suitable filter on their loggers, but they would have to remember to do this every time they introduced a new logger (which they would do simply by adding new packages or modules and doing

```python
logger = logging.getLogger(__name__)
```

at module level). It's probably one too many things to think about. Developers could also add the filter to a `NullHandler` attached to their top-level logger, but this would not be invoked if an application developer attached a handler to a lower-level library logger — so output from that handler would not reflect the intentions of the library developer.

In Python 3.2 and later, `LogRecord` creation is done through a factory, which you can specify. The factory is just a callable you can set with `setLogRecordFactory()`, and interrogate with `getLogRecordFactory()`. The factory is invoked with the same signature as the `LogRecord` constructor, as `LogRecord` is the default setting for the factory.

This approach allows a custom factory to control all aspects of LogRecord creation. For example, you could return a subclass, or just add some additional attributes to the record once created, using a pattern similar to this:

```python
old_factory = logging.getLogRecordFactory()

def record_factory(*args, **kwargs):
```
```python
record = old_factory(*args, **kwargs)
record.custom_attribute = 0xDECAFBAD
return record

logging.setLogRecordFactory(record_factory)
```

This pattern allows different libraries to chain factories together, and as long as they don’t overwrite each other’s attributes or unintentionally overwrite the attributes provided as standard, there should be no surprises. However, it should be borne in mind that each link in the chain adds run-time overhead to all logging operations, and the technique should only be used when the use of a Filter does not provide the desired result.
Subclassing QueueHandler - a ZeroMQ example

You can use a QueueHandler subclass to send messages to other kinds of queues, for example a ZeroMQ ‘publish’ socket. In the example below, the socket is created separately and passed to the handler (as its ‘queue’):

```python
import zmq  # using pyzmq, the Python binding for ZeroMQ
import json  # for serializing records portably

ctx = zmq.Context()
sock = zmq.Socket(ctx, zmq.PUB)  # or zmq.PUSH, or whatever
sock.bind('tcp://*:5556')  # or wherever

class ZeroMQSocketHandler(QueueHandler):
    def enqueue(self, record):
        self.queue.send_json(record.__dict__)

handler = ZeroMQSocketHandler(sock)
```

Of course there are other ways of organizing this, for example passing in the data needed by the handler to create the socket:

```python
class ZeroMQSocketHandler(QueueHandler):
    def __init__(self, uri, socktype=zmq.PUB, ctx=None):
        self.ctx = ctx or zmq.Context()
        socket = zmq.Socket(self.ctx, socktype)
        socket.bind(uri)
        super().__init__(socket)

    def enqueue(self, record):
```
self.queue.send_json(record.__dict__)

def close(self):
    self.queue.close()
Subclassing QueueListener - a ZeroMQ example

You can also subclass QueueListener to get messages from other kinds of queues, for example a ZeroMQ ‘subscribe’ socket. Here’s an example:

```python
class ZeroMQSocketListener(QueueListener):
    def __init__(self, uri, *handlers, **kwargs):
        self.ctx = kwargs.get('ctx') or zmq.Context()
        socket = zmq.Socket(self.ctx, zmq.SUB)
        socket.setsockopt_string(zmq.SUBSCRIBE, '')
        socket.connect(uri)
        super().__init__(socket, *handlers, **kwargs)

    def dequeue(self):
        msg = self.queue.recv_json()
        return logging.makeLogRecord(msg)
```

An example dictionary-based configuration

Below is an example of a logging configuration dictionary - it’s taken from the documentation on the Django project. This dictionary is passed to `dictConfig()` to put the configuration into effect:

```python
LOGGING = {
    'version': 1,
    'disable_existing_loggers': True,
    'formatters': {
        'verbose': {
            'format': '%(levelname)s %(asctime)s %(module)s
        },
        'simple': {
            'format': '%(levelname)s %(message)s'
        },
    },
    'filters': {
        'special': {
            '()': 'project.logging.SpecialFilter',
            'foo': 'bar',
        }
    },
    'handlers': {
        'null': {
            'level': 'DEBUG',
            'class': 'django.utils.log.NullHandler',
        },
        'console':{
            'level': 'DEBUG',
            'class': 'logging.StreamHandler',
            'formatter': 'simple'
        },
        'mail_admins': {
            'level': 'ERROR',
        }
    }
}
```
For more information about this configuration, you can see the relevant section of the Django documentation.
Using a rotator and namer to customize log rotation processing

An example of how you can define a namer and rotator is given in the following snippet, which shows zlib-based compression of the log file:

```python
def namer(name):
    return name + "\.gz"

def rotator(source, dest):
    with open(source, "rb") as sf:
        data = sf.read()
        compressed = zlib.compress(data, 9)
    with open(dest, "wb") as df:
        df.write(compressed)
    os.remove(source)

rh = logging.handlers.RotatingFileHandler(...)
rh.rotator = rotator
rh.namer = namer
```

These are not “true” .gz files, as they are bare compressed data, with no “container” such as you’d find in an actual gzip file. This snippet is just for illustration purposes.
A more elaborate multiprocessing example

The following working example shows how logging can be used with multiprocessing using configuration files. The configurations are fairly simple, but serve to illustrate how more complex ones could be implemented in a real multiprocessing scenario.

In the example, the main process spawns a listener process and some worker processes. Each of the main process, the listener and the workers have three separate configurations (the workers all share the same configuration). We can see logging in the main process, how the workers log to a QueueHandler and how the listener implements a QueueListener and a more complex logging configuration, and arranges to dispatch events received via the queue to the handlers specified in the configuration. Note that these configurations are purely illustrative, but you should be able to adapt this example to your own scenario.

Here's the script - the docstrings and the comments hopefully explain how it works:

```python
import logging
import logging.config
import logging.handlers
from multiprocessing import Process, Queue, Event, current_process
import os
import random
import time

class MyHandler:
    """
    A simple handler for logging events. It runs in
    dispatches events to loggers based on the name in
```
which then get dispatched, by the logging system configured for those loggers.

```python
def handle(self, record):
    logger = logging.getLogger(record.name)
    # The process name is transformed just to show that it's the listener doing the logging to files and console
    record.processName = '%s (for %s)' % (current_process, record.processName)
    return logger.handle(record)

def listener_process(q, stop_event, config):
    """
    This could be done in the main process, but is just done in a separate process for illustrative purposes.

    This initialises logging according to the specified configuration, starts the listener and waits for the main process to signal completion via the event. The listener is then stopped, and the process exits.
    """
    logging.config.dictConfig(config)
    listener = logging.handlers.QueueListener(q, MyHandler)
    listener.start()
    if os.name == 'posix':
        # On POSIX, the setup logger will have been parent process, but should have been disabled by dictConfig call.
        # On Windows, since fork isn't used, the setup logger, if it exist in the child, so it would be created and
        # would appear - hence the "if posix" clause
        logger = logging.getLogger('setup')
        logger.critical('Should not appear, because')
    stop_event.wait()
    listener.stop()

def worker_process(config):
    """
    A number of these are spawned for the purpose of
    """
```
practice, they could be a heterogeneous bunch of ones which are identical to each other.

This initialises logging according to the specified configuration, and logs a hundred messages with random levels to randomly selected loggers.

A small sleep is added to allow other processes to run. This is not strictly needed, but it mixes the output from the different processes a bit more than if it's left out.

```
logging.config.dictConfig(config)
levels = [logging.DEBUG, logging.INFO, logging.WARNING, logging.CRITICAL]
loggers = ['foo', 'foo.bar', 'foo.bar.baz', 'spam', 'spam.ham', 'spam.ham.eggs']
if os.name == 'posix':
    # On POSIX, the setup logger will have been
    # parent process, but should have been disabled
    # dictConfig call.
    # On Windows, since fork isn't used, the setup loggers will
    # exist in the child, so it would be created and
    # would appear - hence the "if posix" clause.
    logger = logging.getLogger('setup')
    logger.critical('Should not appear, because...

for i in range(100):
    lvl = random.choice(levels)
    logger = logging.getLogger(random.choice(loggers))
    logger.log(lvl, 'Message no. %d', i)
    time.sleep(0.01)
```

def main():
    q = Queue()
    # The main process gets a simple configuration with
    config_initial = {
        'version': 1,
        'formatters': {
The worker process configuration is just a Queue root logger, which allows all messages to be sent to the queue. We disable existing loggers to disable the "setup" logger used in the parent process. This is needed on POSIX because the logger will be there in the child following a fork().

```python
cfg_worker = {
    'version': 1,
    'disable_existing_loggers': True,
    'handlers': {
        'queue': {
            'class': 'logging.handlers.QueueHandler',
            'queue': q,
        },
    },
    'root': {
        'level': 'DEBUG',
        'handlers': ['queue'],
    },
}
```

The listener process configuration shows that the full flexibility of logging configuration is available to dispatch events to handlers however
# you want.
# We disable existing loggers to disable the "setup" logger used in the
# parent process. This is needed on POSIX because the logger will
# be there in the child following a fork().

cfg = {
    'version': 1,
    'disable_existing_loggers': True,
    'formatters': {
        'detailed': {
            'class': 'logging.Formatter',
            'format': '%(asctime)s %(name)-15s %(levelname)-8s
        },
        'simple': {
            'class': 'logging.Formatter',
            'format': '%(name)-15s %(levelname)-8s
        }
    },
    'handlers': {

        args=(q, stop_event, config_listener

)
lp.start()
logger.info('Started listener')
# We now hang around for the workers to finish their work.
for wp in workers:
    wp.join()
# Workers all done, listening can now stop.
# Logging in the parent still works normally.
logger.info('Telling listener to stop ...')
stop_event.set()
lp.join()
logger.info('All done. ')

if __name__ == '__main__':
    main()
Inserting a BOM into messages sent to a SysLogHandler

RFC 5424 requires that a Unicode message be sent to a syslog daemon as a set of bytes which have the following structure: an optional pure-ASCII component, followed by a UTF-8 Byte Order Mark (BOM), followed by Unicode encoded using UTF-8. (See the relevant section of the specification.)

In Python 3.1, code was added to SysLogHandler to insert a BOM into the message, but unfortunately, it was implemented incorrectly, with the BOM appearing at the beginning of the message and hence not allowing any pure-ASCII component to appear before it.

As this behaviour is broken, the incorrect BOM insertion code is being removed from Python 3.2.4 and later. However, it is not being replaced, and if you want to produce RFC 5424-compliant messages which include a BOM, an optional pure-ASCII sequence before it and arbitrary Unicode after it, encoded using UTF-8, then you need to do the following:

1. Attach a Formatter instance to your SysLogHandler instance, with a format string such as:

   `'ASCII section\ufeffUnicode section'`

   The Unicode code point U+FEFF, when encoded using UTF-8, will be encoded as a UTF-8 BOM – the byte-string `b'\xef\xbb\xbf'`.

2. Replace the ASCII section with whatever placeholders you like, but make sure that the data that appears in there after substitution
is always ASCII (that way, it will remain unchanged after UTF-8 encoding).

3. Replace the Unicode section with whatever placeholders you like; if the data which appears there after substitution contains characters outside the ASCII range, that’s fine – it will be encoded using UTF-8.

The formatted message will be encoded using UTF-8 encoding by SysLogHandler. If you follow the above rules, you should be able to produce RFC 5424-compliant messages. If you don’t, logging may not complain, but your messages will not be RFC 5424-compliant, and your syslog daemon may complain.
Implementing structured logging

Although most logging messages are intended for reading by humans, and thus not readily machine-parseable, there might be circumstances where you want to output messages in a structured format which is capable of being parsed by a program (without needing complex regular expressions to parse the log message). This is straightforward to achieve using the logging package. There are a number of ways in which this could be achieved, but the following is a simple approach which uses JSON to serialise the event in a machine-parseable manner:

```python
import json
import logging

class StructuredMessage(object):
    def __init__(self, message, **kwargs):
        self.message = message
        self.kwargs = kwargs

    def __str__(self):
        return '%s >>> %s' % (self.message, json.dumps(self.kwargs))

_ = StructuredMessage  # optional, to improve readability
logging.basicConfig(level=logging.INFO, format='%(message)s')
logging.info(_('message 1', foo='bar', bar='baz', num=123))
```

If the above script is run, it prints:

```
message 1 >>> {"fnum": 123.456, "num": 123, "bar": "baz", num: 123}
```
Note that the order of items might be different according to the version of Python used.

If you need more specialised processing, you can use a custom JSON encoder, as in the following complete example:

```python
from __future__ import unicode_literals
import json
import logging

# This next bit is to ensure the script runs unchanged
try:
    unicode
except NameError:
    unicode = str

class Encoder(json.JSONEncoder):
    def default(self, o):
        if isinstance(o, set):
            return tuple(o)
        elif isinstance(o, unicode):
            return o.encode('unicode_escape').decode
        return super(Encoder, self).default(o)

class StructuredMessage(object):
    def __init__(self, message, **kwargs):
        self.message = message
        self.kwargs = kwargs

    def __str__(self):
        s = Encoder().encode(self.kwargs)
        return '%s >>> %s' % (self.message, s)

_ = StructuredMessage  # optional, to improve readability
```
def main():
    logging.basicConfig(level=logging.INFO, format='logging.info(_('message 1', set_value={1, 2, 3},
    if __name__ == '__main__':
        main()

When the above script is run, it prints:

message 1 >>> {'snowman': '\u2603', 'set_value': [1,

Note that the order of items might be different according to the version of Python used.
Customizing handlers with `dictConfig()`

There are times when you want to customize logging handlers in particular ways, and if you use `dictConfig()` you may be able to do this without subclassing. As an example, consider that you may want to set the ownership of a log file. On POSIX, this is easily done using `shutil.chown()`, but the file handlers in the stdlib don't offer built-in support. You can customize handler creation using a plain function such as:

```python
def owned_file_handler(filename, mode='a', encoding='utf-8', owner=None):
    if owner:
        if not os.path.exists(filename):
            open(filename, 'a').close()
        shutil.chown(filename, *owner)
    return logging.FileHandler(filename, mode, encoding)
```

You can then specify, in a logging configuration passed to `dictConfig()`, that a logging handler be created by calling this function:

```python
LOGGING = {
    'version': 1,
    'disable_existing_loggers': False,
    'formatters': {
        'default': {
            'format': '%(asctime)s %(levelname)s %(name)s
        }
    },
    'handlers': {
        'file': {
```

```python
```
```
In this example I am setting the ownership using the pulse user and group, just for the purposes of illustration. Putting it together into a working script, chowntest.py:

```python
import logging, logging.config, os, shutil

def owned_file_handler(filename, mode='a', encoding='utf-8', owner=[
    'pulse', 'pulse'],
    **kwargs):
    if owner:
        if not os.path.exists(filename):
            open(filename, 'a').close()
            shutil.chown(filename, *owner)
        return logging.FileHandler(filename, mode, encoding, **kwargs)

LOGGING = {
    'version': 1,
    'disable_existing_loggers': False,
    }:
```
'formatters': {
    'default': {
        'format': '%(asctime)s %(levelname)s %(name)s',
    },
},
'handlers': {
    'file':{
        # The values below are popped from this
dict to create the handler, set the handler's
# level and its formatter.
        '()': owned_file_handler,
        'level':'DEBUG',
        'formatter': 'default',
        # The values below are passed to the handler
        # as keyword arguments.
        'owner': ['pulse', 'pulse'],
        'filename': 'chowntest.log',
        'mode': 'w',
        'encoding': 'utf-8',
    },
},
'root': { 
    'handlers': ['file'],
    'level': 'DEBUG',
},
}

logging.config.dictConfig(LOGGING)
logger = logging.getLogger('mylogger')
logger.debug('A debug message')

To run this, you will probably need to run as root:

$ sudo python3.3 chowntest.py
$ cat chowntest.log
2013-11-05 09:34:51,128 DEBUG mylogger A debug message
Note that this example uses Python 3.3 because that’s where `shutil.chown()` makes an appearance. This approach should work with any Python version that supports `dictConfig()` - namely, Python 2.7, 3.2 or later. With pre-3.3 versions, you would need to implement the actual ownership change using e.g. `os.chown()`.

In practice, the handler-creating function may be in a utility module somewhere in your project. Instead of the line in the configuration:

```
'()': owned_file_handler,
```

you could use e.g.:

```
'()': 'ext://project.util.owned_file_handler',
```

where `project.util` can be replaced with the actual name of the package where the function resides. In the above working script, using

```
'ext://__main__.owned_file_handler'
```

should work. Here, the actual callable is resolved by `dictConfig()` from the `ext://` specification.

This example hopefully also points the way to how you could implement other types of file change - e.g. setting specific POSIX permission bits - in the same way, using `os.chmod()`.

Of course, the approach could also be extended to types of handler other than a `FileHandler` - for example, one of the rotating file handlers, or a different type of handler altogether.
Using particular formatting styles throughout your application

In Python 3.2, the `Formatter` gained a `style` keyword parameter which, while defaulting to `%` for backward compatibility, allowed the specification of `{` or `$` to support the formatting approaches supported by `str.format()` and `string.Template`. Note that this governs the formatting of logging messages for final output to logs, and is completely orthogonal to how an individual logging message is constructed.

Logging calls (debug(), info() etc.) only take positional parameters for the actual logging message itself, with keyword parameters used only for determining options for how to handle the logging call (e.g. the `exc_info` keyword parameter to indicate that traceback information should be logged, or the `extra` keyword parameter to indicate additional contextual information to be added to the log). So you cannot directly make logging calls using `str.format()` or `string.Template` syntax, because internally the logging package uses %-formatting to merge the format string and the variable arguments. There would no changing this while preserving backward compatibility, since all logging calls which are out there in existing code will be using %-format strings.

There have been suggestions to associate format styles with specific loggers, but that approach also runs into backward compatibility problems because any existing code could be using a given logger name and using %-formatting.

For logging to work interoperably between any third-party libraries and your code, decisions about formatting need to be made at the level of
the individual logging call. This opens up a couple of ways in which alternative formatting styles can be accommodated.

**Using LogRecord factories**

In Python 3.2, along with the *Formatter* changes mentioned above, the logging package gained the ability to allow users to set their own *LogRecord* subclasses, using the `setLogRecordFactory()` function. You can use this to set your own subclass of *LogRecord*, which does the Right Thing by overriding the `getMessage()` method. The base class implementation of this method is where the `msg % args` formatting happens, and where you can substitute your alternate formatting; however, you should be careful to support all formatting styles and allow `%`-formatting as the default, to ensure interoperability with other code. Care should also be taken to call `str(self.msg)`, just as the base implementation does.

Refer to the reference documentation on `setLogRecordFactory()` and *LogRecord* for more information.

**Using custom message objects**

There is another, perhaps simpler way that you can use {}- and $-formatting to construct your individual log messages. You may recall (from *Using arbitrary objects as messages*) that when logging you can use an arbitrary object as a message format string, and that the logging package will call `str()` on that object to get the actual format string. Consider the following two classes:

```python
class BraceMessage(object):
    def __init__(self, fmt, *args, **kwargs):
```
Either of these can be used in place of a format string, to allow \{\}- or \$-formatting to be used to build the actual "message" part which appears in the formatted log output in place of "%(message)s" or "{message}" or "$message". If you find it a little unwieldy to use the class names whenever you want to log something, you can make it more palatable if you use an alias such as \\_M or \\_\_ for the message (or perhaps \\_\_\_, if you are using \\_ for localization).

Examples of this approach are given below. Firstly, formatting with \texttt{str.format}():

```python
g1 = BraceMessage
>>> print(g1('Message with \{0\} \{1\}', 2, 'placeholders'))
Message with 2 placeholders
```
Secondly, formatting with `string.Template`:

```
>>> __ = DollarMessage
>>> print(__('Message with $num $what', num=2, what='what'),
       'Message with 2 placeholders'
```

One thing to note is that you pay no significant performance penalty with this approach: the actual formatting happens not when you make the logging call, but when (and if) the logged message is actually about to be output to a log by a handler. So the only slightly unusual thing which might trip you up is that the parentheses go around the format string and the arguments, not just the format string. That's because the `__` notation is just syntax sugar for a constructor call to one of the `XXXMessage` classes shown above.
Configuring filters with `dictConfig()`

You can configure filters using `dictConfig()`, though it might not be obvious at first glance how to do it (hence this recipe). Since `Filter` is the only filter class included in the standard library, and it is unlikely to cater to many requirements (it’s only there as a base class), you will typically need to define your own `Filter` subclass with an overridden `filter()` method. To do this, specify the `()` key in the configuration dictionary for the filter, specifying a callable which will be used to create the filter (a class is the most obvious, but you can provide any callable which returns a `Filter` instance). Here is a complete example:

```python
import logging
import logging.config
import sys

class MyFilter(logging.Filter):
    def __init__(self, param=None):
        self.param = param

    def filter(self, record):
        if self.param is None:
            allow = True
        else:
            allow = self.param not in record.msg
        if allow:
            record.msg = 'changed: ' + record.msg
        return allow

LOGGING = {
    'version': 1,
    'filters': {
```
This example shows how you can pass configuration data to the callable which constructs the instance, in the form of keyword parameters. When run, the above script will print:

```python
changed: hello
```

which shows that the filter is working as configured.

A couple of extra points to note:

- If you can't refer to the callable directly in the configuration (e.g. if it lives in a different module, and you can't import it directly where the configuration dictionary is), you can use the form `ext://...` as described in Access to external objects. For example, you
could have used the text `ext://__main__.MyFilter` instead of `MyFilter` in the above example.

- As well as for filters, this technique can also be used to configure custom handlers and formatters. See User-defined objects for more information on how logging supports using user-defined objects in its configuration, and see the other cookbook recipe Customizing handlers with dictConfig() above.
Customized exception formatting

There might be times when you want to do customized exception formatting - for argument's sake, let's say you want exactly one line per logged event, even when exception information is present. You can do this with a custom formatter class, as shown in the following example:

```python
import logging

class OneLineExceptionFormatter(logging.Formatter):
    def formatException(self, exc_info):
        """
        Format an exception so that it prints on a single line.
        """
        result = super(OneLineExceptionFormatter, self).formatException(exc_info)
        return repr(result)  # or format into one line however you want to

    def format(self, self, record):
        s = super(OneLineExceptionFormatter, self).format(record)
        if record.exc_text:
            s = s.replace('
', '') + ' |
        return s

    def configure_logging():
        fh = logging.FileHandler('output.txt', 'w')
        f = OneLineExceptionFormatter('%(asctime)s|%(levelname)s|%(name)s|%(funcName)s|%(message)s')
        fh.setFormatter(f)
        root = logging.getLogger()
        root.setLevel(logging.DEBUG)
        root.addHandler(fh)

    def main():
        configure_logging()
```

This code snippet defines a class `OneLineExceptionFormatter` that inherits from the `logging.Formatter` class. The `formatException` method is overridden to format exceptions into a single line. The `format` method is also overridden to handle the format of log records, including exception information. Finally, the `configure_logging` function sets up the logging configuration, including a file handler and a formatter, and the `main` function calls `configure_logging` to apply the custom formatting.
logging.info('Sample message')
try:
    x = 1 / 0
except ZeroDivisionError as e:
    logging.exception('ZeroDivisionError: %s', e)

if __name__ == '__main__':
    main()

When run, this produces a file with exactly two lines:

28/01/2015 07:21:23|INFO|Sample message|
28/01/2015 07:21:23|ERROR|ZeroDivisionError: integer

While the above treatment is simplistic, it points the way to how exception information can be formatted to your liking. The traceback module may be helpful for more specialized needs.
Speaking logging messages

There might be situations when it is desirable to have logging messages rendered in an audible rather than a visible format. This is easy to do if you have text-to-speech (TTS) functionality available in your system, even if it doesn’t have a Python binding. Most TTS systems have a command line program you can run, and this can be invoked from a handler using `subprocess`. It’s assumed here that TTS command line programs won’t expect to interact with users or take a long time to complete, and that the frequency of logged messages will be not so high as to swamp the user with messages, and that it’s acceptable to have the messages spoken one at a time rather than concurrently. The example implementation below waits for one message to be spoken before the next is processed, and this might cause other handlers to be kept waiting. Here is a short example showing the approach, which assumes that the `espeak` TTS package is available:

```python
import logging
import subprocess
import sys

class TTSHandler(logging.Handler):
    def emit(self, record):
        msg = self.format(record)
        # Speak slowly in a female English voice
        cmd = ['espeak', '-s150', '-ven+f3', msg]
        p = subprocess.Popen(cmd, stdout=subprocess.STDOUT, stderr=subprocess.STDOUT)
        # wait for the program to finish
        p.communicate()

    def configure_logging():
```

When run, this script should say “Hello” and then “Goodbye” in a female voice.

The above approach can, of course, be adapted to other TTS systems and even other systems altogether which can process messages via external programs run from a command line.
Buffering logging messages and outputting them conditionally

There might be situations where you want to log messages in a temporary area and only output them if a certain condition occurs. For example, you may want to start logging debug events in a function, and if the function completes without errors, you don’t want to clutter the log with the collected debug information, but if there is an error, you want all the debug information to be output as well as the error.

Here is an example which shows how you could do this using a decorator for your functions where you want logging to behave this way. It makes use of the `logging.handlers.MemoryHandler`, which allows buffering of logged events until some condition occurs, at which point the buffered events are flushed - passed to another handler (the target handler) for processing. By default, the MemoryHandler flushed when its buffer gets filled up or an event whose level is greater than or equal to a specified threshold is seen. You can use this recipe with a more specialised subclass of MemoryHandler if you want custom flushing behavior.

The example script has a simple function, `foo`, which just cycles through all the logging levels, writing to `sys.stderr` to say what level it’s about to log at, and then actually logging a message at that level. You can pass a parameter to `foo` which, if true, will log at ERROR and CRITICAL levels - otherwise, it only logs at DEBUG, INFO and WARNING levels.

The script just arranges to decorate `foo` with a decorator which will do the conditional logging that’s required. The decorator takes a logger as a parameter and attaches a memory handler for the duration of the call
to the decorated function. The decorator can be additionally parameterised using a target handler, a level at which flushing should occur, and a capacity for the buffer. These default to a \texttt{StreamHandler} which writes to \texttt{sys.stderr}, \texttt{logging.ERROR} and 100 respectively.

Here's the script:

```python
import logging
from logging.handlers import MemoryHandler
import sys

logger = logging.getLogger(__name__)
logger.addHandler(logging.NullHandler())

def log_if_errors(logger, target_handler=None, flush_level=None, capacity=None):
    if target_handler is None:
        target_handler = logging.StreamHandler()
    if flush_level is None:
        flush_level = logging.ERROR
    if capacity is None:
        capacity = 100
    handler = MemoryHandler(capacity, flushLevel=flush_level)

    def decorator(fn):
        def wrapper(*args, **kwargs):
            logger.addHandler(handler)
            try:
                return fn(*args, **kwargs)
            except Exception:
                logger.exception('call failed')
            raise
        finally:
            super(MemoryHandler, handler).flush()
            logger.removeHandler(handler)
        return wrapper
```
```

return decorator

def write_line(s):
    sys.stderr.write('%s\n' % s)

def foo(fail=False):
    write_line('about to log at DEBUG ...')
    logger.debug('Actually logged at DEBUG')
    write_line('about to log at INFO ...')
    logger.info('Actually logged at INFO')
    write_line('about to log at WARNING ...')
    logger.warning('Actually logged at WARNING')
    if fail:
        write_line('about to log at ERROR ...')
        logger.error('Actually logged at ERROR')
        write_line('about to log at CRITICAL ...')
        logger.critical('Actually logged at CRITICAL')
    return fail

decorated_foo = log_if_errors(logger)(foo)

if __name__ == '__main__':
    logger.setLevel(logging.DEBUG)
    write_line('Calling undecorated foo with False')
    assert not foo(False)
    write_line('Calling undecorated foo with True')
    assert foo(True)
    write_line('Calling decorated foo with False')
    assert not decorated_foo(False)
    write_line('Calling decorated foo with True')
    assert decorated_foo(True)
```

When this script is run, the following output should be observed:

Calling undecorated foo with False
As you can see, actual logging output only occurs when an event is logged whose severity is ERROR or greater, but in that case, any previous events at lower severities are also logged.

You can of course use the conventional means of decoration:

```python
@log_if_errors(logger)
def foo(fail=False):
    ...
```
Formatting times using UTC (GMT) via configuration

Sometimes you want to format times using UTC, which can be done using a class such as `UTCFormatter`, shown below:

```python
import logging
import time

class UTCFormatter(logging.Formatter):
    converter = time.gmtime
```

and you can then use the `UTCFormatter` in your code instead of `Formatter`. If you want to do that via configuration, you can use the `dictConfig()` API with an approach illustrated by the following complete example:

```python
import logging
import logging.config
import time

class UTCFormatter(logging.Formatter):
    converter = time.gmtime

LOGGING = {
    'version': 1,
    'disable_existing_loggers': False,
    'formatters': {
        'utc': {
            '()': UTCFormatter,
            'format': '%(asctime)s %(message)s',
        },
        'local': {
            'format': '%(asctime)s %(message)s',
        },
    },
    'handlers': {
        'console': {
            '()': logging.StreamHandler,
            'formatter': 'local',
        },
    },
    'loggers': {
        '': {
            'handlers': ['console'],
            'level': 'INFO',
        },
    },
}
logging.config.dictConfig(LOGGING)
```
```python
if __name__ == '__main__':
    logging.config.dictConfig(LOGGING)
    logging.warning('The local time is %s', time.asctime())
```

When this script is run, it should print something like:

```
```

showing how the time is formatted both as local time and UTC, one for each handler.
Using a context manager for selective logging

There are times when it would be useful to temporarily change the logging configuration and revert it back after doing something. For this, a context manager is the most obvious way of saving and restoring the logging context. Here is a simple example of such a context manager, which allows you to optionally change the logging level and add a logging handler purely in the scope of the context manager:

```python
import logging
import sys

class LoggingContext(object):
    def __init__(self, logger, level=None, handler=None):
        self.logger = logger
        self.level = level
        self.handler = handler
        self.close = close

    def __enter__(self):
        if self.level is not None:
            self.old_level = self.logger.level
            self.logger.setLevel(self.level)
        if self.handler:
            self.logger.addHandler(self.handler)

    def __exit__(self, et, ev, tb):
        if self.level is not None:
            self.logger.setLevel(self.old_level)
        if self.handler:
            self.logger.removeHandler(self.handler)
        if self.handler and self.close:
            self.handler.close()
```
If you specify a level value, the logger's level is set to that value in the scope of the with block covered by the context manager. If you specify a handler, it is added to the logger on entry to the block and removed on exit from the block. You can also ask the manager to close the handler for you on block exit - you could do this if you don't need the handler any more.

To illustrate how it works, we can add the following block of code to the above:

```python
if __name__ == '__main__':
    logger = logging.getLogger('foo')
    logger.addHandler(logging.StreamHandler())
    logger.setLevel(logging.INFO)
    logger.info('1. This should appear just once on stderr.')
    with LoggingContext(logger, level=logging.DEBUG):
        logger.debug('3. This should appear once on stdout.')
        logger.debug('4. This should not appear.')
    h = logging.StreamHandler(sys.stdout)
    with LoggingContext(logger, level=logging.DEBUG, handler=h):
        logger.debug('5. This should appear twice - once on stderr and once on stdout.')
    logger.info('6. This should appear just once on stdout.')
    logger.debug('7. This should not appear.')
```

We initially set the logger's level to `INFO`, so message #1 appears and message #2 doesn't. We then change the level to `DEBUG` temporarily in the following with block, and so message #3 appears. After the block exits, the logger's level is restored to `INFO` and so message #4 doesn't appear. In the next with block, we set the level to `DEBUG` again but also add a handler writing to `sys.stdout`. Thus, message
#5 appears twice on the console (once via stderr and once via stdout). After the with statement's completion, the status is as it was before so message #6 appears (like message #1) whereas message #7 doesn't (just like message #2).

If we run the resulting script, the result is as follows:

```bash
$ python logctx.py
1. This should appear just once on stderr.
3. This should appear once on stderr.
5. This should appear twice - once on stderr and once on stdout.
5. This should appear twice - once on stderr and once on stdout.
6. This should appear just once on stderr.
```

If we run it again, but pipe stderr to `/dev/null`, we see the following, which is the only message written to stdout:

```bash
$ python logctx.py 2>/dev/null
5. This should appear twice - once on stderr and once on stdout.
```

Once again, but piping stdout to `/dev/null`, we get:

```bash
$ python logctx.py >/dev/null
1. This should appear just once on stderr.
3. This should appear once on stderr.
5. This should appear twice - once on stderr and once on stdout.
6. This should appear just once on stderr.
```

In this case, the message #5 printed to stdout doesn't appear, as expected.

Of course, the approach described here can be generalised, for
example to attach logging filters temporarily. Note that the above code works in Python 2 as well as Python 3.
Regular Expression HOWTO

Author: A.M. Kuchling <amk@amk.ca>

Abstract

This document is an introductory tutorial to using regular expressions in Python with the `re` module. It provides a gentler introduction than the corresponding section in the Library Reference.
Introduction

Regular expressions (called REs, or regexes, or regex patterns) are essentially a tiny, highly specialized programming language embedded inside Python and made available through the `re` module. Using this little language, you specify the rules for the set of possible strings that you want to match; this set might contain English sentences, or e-mail addresses, or TeX commands, or anything you like. You can then ask questions such as “Does this string match the pattern?”, or “Is there a match for the pattern anywhere in this string?”. You can also use REs to modify a string or to split it apart in various ways.

Regular expression patterns are compiled into a series of bytecodes which are then executed by a matching engine written in C. For advanced use, it may be necessary to pay careful attention to how the engine will execute a given RE, and write the RE in a certain way in order to produce bytecode that runs faster. Optimization isn’t covered in this document, because it requires that you have a good understanding of the matching engine’s internals.

The regular expression language is relatively small and restricted, so not all possible string processing tasks can be done using regular expressions. There are also tasks that can be done with regular expressions, but the expressions turn out to be very complicated. In these cases, you may be better off writing Python code to do the processing; while Python code will be slower than an elaborate regular expression, it will also probably be more understandable.
Simple Patterns

We'll start by learning about the simplest possible regular expressions. Since regular expressions are used to operate on strings, we'll begin with the most common task: matching characters.

For a detailed explanation of the computer science underlying regular expressions (deterministic and non-deterministic finite automata), you can refer to almost any textbook on writing compilers.

Matching Characters

Most letters and characters will simply match themselves. For example, the regular expression `test` will match the string `test` exactly. (You can enable a case-insensitive mode that would let this RE match `Test` or `TEST` as well; more about this later.)

There are exceptions to this rule; some characters are special *metacharacters*, and don’t match themselves. Instead, they signal that some out-of-the-ordinary thing should be matched, or they affect other portions of the RE by repeating them or changing their meaning. Much of this document is devoted to discussing various metacharacters and what they do.

Here's a complete list of the metacharacters; their meanings will be discussed in the rest of this HOWTO.

```
. ^ $ * + ? { } [ ] \ | ( )
```

The first metacharacters we'll look at are `[` and `]`. They're used for specifying a character class, which is a set of characters that you wish to match. Characters can be listed individually, or a range of
characters can be indicated by giving two characters and separating them by a ' - '. For example, [abc] will match any of the characters a, b, or c; this is the same as [a-c], which uses a range to express the same set of characters. If you wanted to match only lowercase letters, your RE would be [a-z].

Metacharacters are not active inside classes. For example, [akm$] will match any of the characters 'a', 'k', 'm', or '$'; '$' is usually a metacharacter, but inside a character class it's stripped of its special nature.

You can match the characters not listed within the class by complementing the set. This is indicated by including a '^' as the first character of the class; '^' outside a character class will simply match the '^' character. For example, [^5] will match any character except '5'.

Perhaps the most important metacharacter is the backslash, \. As in Python string literals, the backslash can be followed by various characters to signal various special sequences. It's also used to escape all the metacharacters so you can still match them in patterns; for example, if you need to match a [ or \, you can precede them with a backslash to remove their special meaning: \[ or \\.

Some of the special sequences beginning with '\' represent predefined sets of characters that are often useful, such as the set of digits, the set of letters, or the set of anything that isn't whitespace.

Let's take an example: \w matches any alphanumerical character. If the regex pattern is expressed in bytes, this is equivalent to the class [a-zA-Z0-9_]. If the regex pattern is a string, \w will match all the characters marked as letters in the Unicode database provided by the
\texttt{unicodedata} module. You can use the more restricted definition of \texttt{\textbackslash w} in a string pattern by supplying the \texttt{re.ASCII} flag when compiling the regular expression.

The following list of special sequences isn’t complete. For a complete list of sequences and expanded class definitions for Unicode string patterns, see the last part of \texttt{Regular Expression Syntax} in the Standard Library reference. In general, the Unicode versions match any character that’s in the appropriate category in the Unicode database.

\texttt{\textbackslash d}

Matches any decimal digit; this is equivalent to the class \texttt{[0-9]}

\texttt{\textbackslash D}

Matches any non-digit character; this is equivalent to the class \texttt{[^0-9]}

\texttt{\textbackslash s}

Matches any whitespace character; this is equivalent to the class \texttt{[\t\n\r\f\v]}

\texttt{\textbackslash S}

Matches any non-whitespace character; this is equivalent to the class \texttt{[^\t\n\r\f\v]}

\texttt{\textbackslash w}

Matches any alphanumerical character; this is equivalent to the class \texttt{[a-zA-Z0-9_]}

\texttt{\textbackslash W}

Matches any non-alphanumerical character; this is equivalent to the class \texttt{[^a-zA-Z0-9_]}

These sequences can be included inside a character class. For example, \texttt{[\s,\.]} is a character class that will match any whitespace
character, or , or "."

The final metacharacter in this section is . It matches anything except a newline character, and there’s an alternate mode (re.DOTALL) where it will match even a newline. "." is often used where you want to match “any character”.

Repeating Things

Being able to match varying sets of characters is the first thing regular expressions can do that isn’t already possible with the methods available on strings. However, if that was the only additional capability of regexes, they wouldn’t be much of an advance. Another capability is that you can specify that portions of the RE must be repeated a certain number of times.

The first metacharacter for repeating things that we’ll look at is *. * doesn’t match the literal character *; instead, it specifies that the previous character can be matched zero or more times, instead of exactly once.

For example, ca*t will match ct (0 a characters), cat (1 a), caaat (3 a characters), and so forth. The RE engine has various internal limitations stemming from the size of C’s int type that will prevent it from matching over 2 billion a characters; patterns are usually not written to match that much data.

Repetitions such as * are greedy; when repeating a RE, the matching engine will try to repeat it as many times as possible. If later portions of the pattern don’t match, the matching engine will then back up and try again with fewer repetitions.
A step-by-step example will make this more obvious. Let’s consider the expression \( a[bcd]^*b \). This matches the letter 'a', zero or more letters from the class \( [bcd] \), and finally ends with a 'b'. Now imagine matching this RE against the string \( abcbd \).

<table>
<thead>
<tr>
<th>Step</th>
<th>Matched</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>a</td>
<td>The ( a ) in the RE matches.</td>
</tr>
<tr>
<td>2</td>
<td>abcbd</td>
<td>The engine matches ( [bcd]^* ), going as far as it can, which is to the end of the string.</td>
</tr>
<tr>
<td>3</td>
<td>Failure</td>
<td>The engine tries to match ( b ), but the current position is at the end of the string, so it fails.</td>
</tr>
<tr>
<td>4</td>
<td>abcb</td>
<td>Back up, so that ( [bcd]^* ) matches one less character.</td>
</tr>
<tr>
<td>5</td>
<td>Failure</td>
<td>Try ( b ) again, but the current position is at the last character, which is a 'd'.</td>
</tr>
<tr>
<td>6</td>
<td>abc</td>
<td>Back up again, so that ( [bcd]^* ) is only matching bc.</td>
</tr>
<tr>
<td>6</td>
<td>abcb</td>
<td>Try ( b ) again. This time the character at the current position is 'b', so it succeeds.</td>
</tr>
</tbody>
</table>

The end of the RE has now been reached, and it has matched \( abcb \). This demonstrates how the matching engine goes as far as it can at first, and if no match is found it will then progressively back up and retry the rest of the RE again and again. It will back up until it has tried zero matches for \( [bcd]^* \), and if that subsequently fails, the engine will conclude that the string doesn't match the RE at all.

Another repeating metacharacter is \( + \), which matches one or more times. Pay careful attention to the difference between \( * \) and \( + \); \( * \) matches zero or more times, so whatever’s being repeated may not be
present at all, while + requires at least one occurrence. To use a similar example, ca+t will match cat (1 a), caaat (3 a’s), but won’t match ct.

There are two more repeating qualifiers. The question mark character, ?, matches either once or zero times; you can think of it as marking something as being optional. For example, home-?brew matches either homebrew or home-brew.

The most complicated repeated qualifier is \{m,n\}, where m and n are decimal integers. This qualifier means there must be at least m repetitions, and at most n. For example, a/\{1,3\}b will match a/b, a/\//b, and a/////b. It won’t match ab, which has no slashes, or a//////b, which has four.

You can omit either m or n; in that case, a reasonable value is assumed for the missing value. Omitting m is interpreted as a lower limit of 0, while omitting n results in an upper bound of infinity — actually, the upper bound is the 2-billion limit mentioned earlier, but that might as well be infinity.

Readers of a reductionist bent may notice that the three other qualifiers can all be expressed using this notation. \{0,\} is the same as *, \{1,\} is equivalent to +, and \{0,1\} is the same as ?. It’s better to use *, +, or ? when you can, simply because they’re shorter and easier to read.
Using Regular Expressions

Now that we’ve looked at some simple regular expressions, how do we actually use them in Python? The `re` module provides an interface to the regular expression engine, allowing you to compile REs into objects and then perform matches with them.

Compiling Regular Expressions

Regular expressions are compiled into pattern objects, which have methods for various operations such as searching for pattern matches or performing string substitutions.

```python
>>> import re
>>> p = re.compile('ab*')
>>> p
re.compile('ab*')
```

`re.compile()` also accepts an optional `flags` argument, used to enable various special features and syntax variations. We’ll go over the available settings later, but for now a single example will do:

```python
>>> p = re.compile('ab*', re.IGNORECASE)
```

The RE is passed to `re.compile()` as a string. REs are handled as strings because regular expressions aren’t part of the core Python language, and no special syntax was created for expressing them. (There are applications that don’t need REs at all, so there’s no need to bloat the language specification by including them.) Instead, the `re` module is simply a C extension module included with Python, just like the `socket` or `zlib` modules.
Putting REs in strings keeps the Python language simpler, but has one disadvantage which is the topic of the next section.

**The Backslash Plague**

As stated earlier, regular expressions use the backslash character (\'\') to indicate special forms or to allow special characters to be used without invoking their special meaning. This conflicts with Python’s usage of the same character for the same purpose in string literals.

Let’s say you want to write a RE that matches the string \section, which might be found in a LaTeX file. To figure out what to write in the program code, start with the desired string to be matched. Next, you must escape any backslashes and other metacharacters by preceding them with a backslash, resulting in the string \\section. The resulting string that must be passed to `re.compile()` must be \\section. However, to express this as a Python string literal, both backslashes must be escaped again.

<table>
<thead>
<tr>
<th>Characters</th>
<th>Stage</th>
</tr>
</thead>
<tbody>
<tr>
<td>\section</td>
<td>Text string to be matched</td>
</tr>
<tr>
<td>\section</td>
<td>Escaped backslash for <code>re.compile()</code></td>
</tr>
<tr>
<td>&quot;\\section&quot;</td>
<td>Escaped backslashes for a string literal</td>
</tr>
</tbody>
</table>

In short, to match a literal backslash, one has to write `\\\\` as the RE string, because the regular expression must be `\\`, and each backslash must be expressed as `\\` inside a regular Python string literal. In REs that feature backslashes repeatedly, this leads to lots of repeated backslashes and makes the resulting strings difficult to understand.
The solution is to use Python's raw string notation for regular expressions; backslashes are not handled in any special way in a string literal prefixed with 'r', so r"\n" is a two-character string containing '\n' and 'n', while "\n" is a one-character string containing a newline. Regular expressions will often be written in Python code using this raw string notation.

<table>
<thead>
<tr>
<th>Regular String</th>
<th>Raw string</th>
</tr>
</thead>
<tbody>
<tr>
<td>&quot;ab*&quot;</td>
<td>r&quot;ab*&quot;</td>
</tr>
<tr>
<td>&quot;\section&quot;</td>
<td>r&quot;\section&quot;</td>
</tr>
<tr>
<td>&quot;\w+\s+\1&quot;</td>
<td>r&quot;\w+\s+\1&quot;</td>
</tr>
</tbody>
</table>

Performing Matches

Once you have an object representing a compiled regular expression, what do you do with it? Pattern objects have several methods and attributes. Only the most significant ones will be covered here; consult the re docs for a complete listing.

<table>
<thead>
<tr>
<th>Method/Attribute</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td>match()</td>
<td>Determine if the RE matches at the beginning of the string.</td>
</tr>
<tr>
<td>search()</td>
<td>Scan through a string, looking for any location where this RE matches.</td>
</tr>
<tr>
<td>findall()</td>
<td>Find all substrings where the RE matches, and returns them as a list.</td>
</tr>
<tr>
<td>finditer()</td>
<td>Find all substrings where the RE matches, and returns them as an iterator.</td>
</tr>
</tbody>
</table>

match() and search() return None if no match can be found. If
they're successful, a match object instance is returned, containing information about the match: where it starts and ends, the substring it matched, and more.

You can learn about this by interactively experimenting with the re module. If you have tkinter available, you may also want to look at Tools/demo/redemo.py, a demonstration program included with the Python distribution. It allows you to enter REs and strings, and displays whether the RE matches or fails. redemo.py can be quite useful when trying to debug a complicated RE.

This HOWTO uses the standard Python interpreter for its examples. First, run the Python interpreter, import the re module, and compile a RE:

```python
>>> import re
>>> p = re.compile('[a-z]+')
>>> p
re.compile('[a-z]+')
```

Now, you can try matching various strings against the RE [a-z]+. An empty string shouldn't match at all, since + means 'one or more repetitions'. match() should return None in this case, which will cause the interpreter to print no output. You can explicitly print the result of match() to make this clear.

```python
>>> p.match('')
>>> print(p.match(''))
None
```

Now, let's try it on a string that it should match, such as tempo. In this case, match() will return a match object, so you should store the result in a variable for later use.
Now you can query the `match object` for information about the matching string. `match object` instances also have several methods and attributes; the most important ones are:

<table>
<thead>
<tr>
<th>Method/Attribute</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>group()</code></td>
<td>Return the string matched by the RE</td>
</tr>
<tr>
<td><code>start()</code></td>
<td>Return the starting position of the match</td>
</tr>
<tr>
<td><code>end()</code></td>
<td>Return the ending position of the match</td>
</tr>
<tr>
<td><code>span()</code></td>
<td>Return a tuple containing the (start, end) positions of the match</td>
</tr>
</tbody>
</table>

Trying these methods will soon clarify their meaning:

```python
>>> m = p.match('tempo')
>>> m
<_sre.SRE_Match object; span=(0, 5), match='tempo'>
```

```
>>> m.group()
'tempo'
>>> m.start(), m.end()
(0, 5)
>>> m.span()
(0, 5)
```

group() returns the substring that was matched by the RE. start() and end() return the starting and ending index of the match. span() returns both start and end indexes in a single tuple. Since the match() method only checks if the RE matches at the start of a string, start() will always be zero. However, the search() method of patterns scans through the string, so the match may not start at zero in that case.
In actual programs, the most common style is to store the match object in a variable, and then check if it was None. This usually looks like:

```python
p = re.compile( ... )
m = p.match( 'string goes here' )
if m:
    print('Match found: ', m.group())
else:
    print('No match')
```

Two pattern methods return all of the matches for a pattern. `findall()` returns a list of matching strings:

```python
>>> p = re.compile('\d+')
>>> p.findall('12 drummers drumming, 11 pipers piping, 10 lords a-leaping')
['12', '11', '10']
```

`findall()` has to create the entire list before it can be returned as the result. The `finditer()` method returns a sequence of match object instances as an iterator:

```python
>>> iterator = p.finditer('12 drummers drumming, 11 pipers piping, 10 lords a-leaping')
```
Module-Level Functions

You don't have to create a pattern object and call its methods; the `re` module also provides top-level functions called `match()`, `search()`, `findall()`, `sub()`, and so forth. These functions take the same arguments as the corresponding pattern method with the RE string added as the first argument, and still return either `None` or a `match` object instance.

```python
>>> print(re.match(r'From\s+', 'Fromage amk'))
None
>>> re.match(r'From\s+', 'From amk Thu May 14 19:12:10 1998')
<_sre.SRE_Match object; span=(0, 5), match='From '>
```

Under the hood, these functions simply create a pattern object for you and call the appropriate method on it. They also store the compiled object in a cache, so future calls using the same RE won't need to parse the pattern again and again.

Should you use these module-level functions, or should you get the pattern and call its methods yourself? If you're accessing a regex within a loop, pre-compiling it will save a few function calls. Outside of loops, there's not much difference thanks to the internal cache.
Compilation Flags

Compilation flags let you modify some aspects of how regular expressions work. Flags are available in the `re` module under two names, a long name such as `IGNORECASE` and a short, one-letter form such as `I`. (If you’re familiar with Perl’s pattern modifiers, the one-letter forms use the same letters; the short form of `re.VERBOSE` is `re.X`, for example.) Multiple flags can be specified by bitwise OR-ing them; `re.I | re.M` sets both the `I` and `M` flags, for example.

Here’s a table of the available flags, followed by a more detailed explanation of each one.

<table>
<thead>
<tr>
<th>Flag</th>
<th>Meaning</th>
</tr>
</thead>
<tbody>
<tr>
<td>ASCII, A</td>
<td>Makes several escapes like <code>\w</code>, <code>\b</code>, <code>\s</code> and <code>\d</code> match only on ASCII characters with the respective property.</td>
</tr>
<tr>
<td>DOTALL, S</td>
<td>Make . match any character, including newlines</td>
</tr>
<tr>
<td>IGNORECASE, I</td>
<td>Do case-insensitive matches</td>
</tr>
<tr>
<td>LOCALE, L</td>
<td>Do a locale-aware match</td>
</tr>
<tr>
<td>MULTILINE, M</td>
<td>Multi-line matching, affecting <code>^</code> and <code>$</code></td>
</tr>
<tr>
<td>VERBOSE, X (for ‘extended’)</td>
<td>Enable verbose REs, which can be organized more cleanly and understandably.</td>
</tr>
</tbody>
</table>

**I**

**IGNORECASE**

Perform case-insensitive matching; character class and literal
strings will match letters by ignoring case. For example, \[A-Z\] will match lowercase letters, too, and \texttt{Spam} will match \texttt{Spam}, \texttt{spam}, or \texttt{spAM}. This lowercasing doesn’t take the current locale into account; it will if you also set the \texttt{LOCALE} flag.

L

\textbf{LOCALE}

Make \texttt{\w, \W, \b,} and \texttt{\B}, dependent on the current locale instead of the Unicode database.

Locales are a feature of the C library intended to help in writing programs that take account of language differences. For example, if you’re processing French text, you’d want to be able to write \texttt{\w+} to match words, but \texttt{\w} only matches the character class \texttt{[A-Za-z]}; it won’t match ‘é’ or ‘ç’. If your system is configured properly and a French locale is selected, certain C functions will tell the program that ‘é’ should also be considered a letter. Setting the \texttt{LOCALE} flag when compiling a regular expression will cause the resulting compiled object to use these C functions for \texttt{\w}; this is slower, but also enables \texttt{\w+} to match French words as you’d expect.

M

\textbf{MULTILINE}

(\wedge \texttt{and} \$ haven’t been explained yet; they’ll be introduced in section \texttt{More Metacharacters}.)

Usually \texttt{\wedge} matches only at the beginning of the string, and \texttt{\$} matches only at the end of the string and immediately before the newline (if any) at the end of the string. When this flag is specified, \texttt{\wedge} matches at the beginning of the string and at the beginning of each line within the string, immediately following each newline.
Similarly, the $ metacharacter matches either at the end of the string and at the end of each line (immediately preceding each newline).

**S**

**DOTALL**

Makes the '.' special character match any character at all, including a newline; without this flag, '.' will match anything except a newline.

**A**

**ASCII**

Make \w, \W, \b, \B, \s and \S perform ASCII-only matching instead of full Unicode matching. This is only meaningful for Unicode patterns, and is ignored for byte patterns.

**X**

**VERBOSE**

This flag allows you to write regular expressions that are more readable by granting you more flexibility in how you can format them. When this flag has been specified, whitespace within the RE string is ignored, except when the whitespace is in a character class or preceded by an unescaped backslash; this lets you organize and indent the RE more clearly. This flag also lets you put comments within a RE that will be ignored by the engine; comments are marked by a '!' that's neither in a character class or preceded by an unescaped backslash.

For example, here's a RE that uses `re.VERBOSE`; see how much easier it is to read?

```python
charref = re.compile(r""
&[#]                       # Start of a numeric entity
""")
```
Without the verbose setting, the RE would look like this:

```
charref = re.compile("&(\0[0-7]+" "|([0-9]+" "|x[0-9a-fA-F]+);")
```

In the above example, Python's automatic concatenation of string literals has been used to break up the RE into smaller pieces, but it's still more difficult to understand than the version using `re.VERBOSE`. 
More Pattern Power

So far we’ve only covered a part of the features of regular expressions. In this section, we’ll cover some new metacharacters, and how to use groups to retrieve portions of the text that was matched.

More Metacharacters

There are some metacharacters that we haven’t covered yet. Most of them will be covered in this section.

Some of the remaining metacharacters to be discussed are zero-width assertions. They don’t cause the engine to advance through the string; instead, they consume no characters at all, and simply succeed or fail. For example, \b is an assertion that the current position is located at a word boundary; the position isn’t changed by the \b at all. This means that zero-width assertions should never be repeated, because if they match once at a given location, they can obviously be matched an infinite number of times.

| Alternation, or the “or” operator. If A and B are regular expressions, A|B will match any string that matches either A or B. | has very low precedence in order to make it work reasonably when you’re alternating multi-character strings. Crow|Servo will match either Crow or Servo, not Cro, a 'w', or an 'S', and ervo.

To match a literal '||', use \|, or enclose it inside a character class, as in [\|].
Matches at the beginning of lines. Unless the MULTILINE flag has been set, this will only match at the beginning of the string. In MULTILINE mode, this also matches immediately after each newline within the string.

For example, if you wish to match the word From only at the beginning of a line, the RE to use is ^From.

```python
>>> print(re.search('^From', 'From Here to Eternity'))
<_sre.SRE_Match object; span=(0, 4), match='From'>
>>> print(re.search('^From', 'Reciting From Memory'))
None
```

Matches at the end of a line, which is defined as either the end of the string, or any location followed by a newline character.

```python
>>> print(re.search('}$', '{block}'))
<_sre.SRE_Match object; span=(6, 7), match='}'>
>>> print(re.search('}$', '{block} '))
None
>>> print(re.search('}$', '{block}\n'))
<_sre.SRE_Match object; span=(6, 7), match='}'>
```

To match a literal \$, use \$ or enclose it inside a character class, as in [$].

\A

Matches only at the start of the string. When not in MULTILINE mode, \A and ^ are effectively the same. In MULTILINE mode, they’re different: \A still matches only at the beginning of the string, but ^ may match at any location inside the string that follows a newline character.
Z
Matches only at the end of the string.

b
Word boundary. This is a zero-width assertion that matches only at the beginning or end of a word. A word is defined as a sequence of alphanumeric characters, so the end of a word is indicated by whitespace or a non-alphanumeric character.

The following example matches `class` only when it's a complete word; it won't match when it's contained inside another word.

```python
>>> p = re.compile(r'^\bclass\b$')
>>> print(p.search('no class at all'))
<_sre.SRE_Match object; span=(3, 8), match='class'>
>>> print(p.search('the declassified algorithm'))
None
>>> print(p.search('one subclass is'))
None
```

There are two subtleties you should remember when using this special sequence. First, this is the worst collision between Python's string literals and regular expression sequences. In Python's string literals, `\b` is the backspace character, ASCII value 8. If you're not using raw strings, then Python will convert the `\b` to a backspace, and your RE won't match as you expect it to. The following example looks the same as our previous RE, but omits the `r` in front of the RE string.

```python
>>> p = re.compile('\bclass\b')
>>> print(p.search('no class at all'))
None
>>> print(p.search('\b' + 'class' + '\b'))
<_sre.SRE_Match object; span=(0, 7), match='\x08class'>
```
Second, inside a character class, where there’s no use for this assertion, \b represents the backspace character, for compatibility with Python’s string literals.

\B

Another zero-width assertion, this is the opposite of \b, only matching when the current position is not at a word boundary.

Grouping

Frequently you need to obtain more information than just whether the RE matched or not. Regular expressions are often used to dissect strings by writing a RE divided into several subgroups which match different components of interest. For example, an RFC-822 header line is divided into a header name and a value, separated by a ':', like this:

From: author@example.com
User-Agent: Thunderbird 1.5.0.9 (X11/20061227)
MIME-Version: 1.0
To: editor@example.com

This can be handled by writing a regular expression which matches an entire header line, and has one group which matches the header name, and another group which matches the header’s value.

Groups are marked by the '(', ')' metacharacters. '(' and ')' have much the same meaning as they do in mathematical expressions; they group together the expressions contained inside them, and you can repeat the contents of a group with a repeating qualifier, such as *, +, ?, or {m,n}. For example, (ab)* will match zero or more repetitions of ab.
Groups indicated with `'(', ')'` also capture the starting and ending index of the text that they match; this can be retrieved by passing an argument to `group()`, `start()`, `end()`, and `span()`. Groups are numbered starting with 0. Group 0 is always present; it's the whole RE, so `match object` methods all have group 0 as their default argument. Later we'll see how to express groups that don't capture the span of text that they match.

```python
>>> p = re.compile('(ab)*')
>>> print(p.match('ababababab').span())
(0, 10)
```

Subgroups are numbered from left to right, from 1 upward. Groups can be nested; to determine the number, just count the opening parenthesis characters, going from left to right.

```python
>>> p = re.compile('(a)(b)c\d')
>>> m = p.match('abcd')
>>> m.group()  # 'abcd'
>>> m.group(0)  # 'ab'
>>> m.group(1)  # 'abc'
>>> m.group(2)  # 'b'
```

`group()` can be passed multiple group numbers at a time, in which case it will return a tuple containing the corresponding values for those
groups.

```python
>>> m.group(2,1,2)
('b', 'abc', 'b')
```

The `groups()` method returns a tuple containing the strings for all the subgroups, from 1 up to however many there are.

```python
>>> m.groups()
('abc', 'b')
```

Backreferences in a pattern allow you to specify that the contents of an earlier capturing group must also be found at the current location in the string. For example, `\1` will succeed if the exact contents of group 1 can be found at the current position, and fails otherwise. Remember that Python’s string literals also use a backslash followed by numbers to allow including arbitrary characters in a string, so be sure to use a raw string when incorporating backreferences in a RE.

For example, the following RE detects doubled words in a string.

```python
>>> p = re.compile(r'\b\w+\s+\1')
>>> p.search('Paris in the the spring').group()
'the the'
```

Backreferences like this aren’t often useful for just searching through a string — there are few text formats which repeat data in this way — but you’ll soon find out that they’re very useful when performing string substitutions.

**Non-capturing and Named Groups**

Elaborate REs may use many groups, both to capture substrings of
interest, and to group and structure the RE itself. In complex REs, it becomes difficult to keep track of the group numbers. There are two features which help with this problem. Both of them use a common syntax for regular expression extensions, so we'll look at that first.

Perl 5 is well known for its powerful additions to standard regular expressions. For these new features the Perl developers couldn't choose new single-keystroke metacharacters or new special sequences beginning with \ without making Perl's regular expressions confusingly different from standard REs. If they chose & as a new metacharacter, for example, old expressions would be assuming that & was a regular character and wouldn’t have escaped it by writing \& or [&].

The solution chosen by the Perl developers was to use (?...) as the extension syntax. ? immediately after a parenthesis was a syntax error because the ? would have nothing to repeat, so this didn’t introduce any compatibility problems. The characters immediately after the ? indicate what extension is being used, so (?=foo) is one thing (a positive lookahead assertion) and (?:foo) is something else (a non-capturing group containing the subexpression foo).

Python supports several of Perl's extensions and adds an extension syntax to Perl's extension syntax. If the first character after the question mark is a P, you know that it's an extension that's specific to Python.

Now that we've looked at the general extension syntax, we can return to the features that simplify working with groups in complex REs.

Sometimes you'll want to use a group to denote a part of a regular expression, but aren't interested in retrieving the group's contents. You
can make this fact explicit by using a non-capturing group: (?::....), where you can replace the ... with any other regular expression.

```python
>>> m = re.match("([abc])+", "abc")
>>> m.groups()
('c',)
>>> m = re.match("(?:[abc])+", "abc")
>>> m.groups()
()
```

Except for the fact that you can't retrieve the contents of what the group matched, a non-capturing group behaves exactly the same as a capturing group; you can put anything inside it, repeat it with a repetition metacharacter such as *, and nest it within other groups (capturing or non-capturing). (?::....) is particularly useful when modifying an existing pattern, since you can add new groups without changing how all the other groups are numbered. It should be mentioned that there's no performance difference in searching between capturing and non-capturing groups; neither form is any faster than the other.

A more significant feature is named groups: instead of referring to them by numbers, groups can be referenced by a name.

The syntax for a named group is one of the Python-specific extensions: (?P<name>...). name is, obviously, the name of the group. Named groups behave exactly like capturing groups, and additionally associate a name with a group. The match object methods that deal with capturing groups all accept either integers that refer to the group by number or strings that contain the desired group's name. Named groups are still given numbers, so you can retrieve information about a group in two ways:
Named groups are handy because they let you use easily-remembered names, instead of having to remember numbers. Here's an example RE from the `imaplib` module:

```python
InternalDate = re.compile(r'INTERNALDATE "' +
    r'(?P<day>\d{1,2})-(?P<mon>\w{3})-(?P<year>\d{4})' +
    r'(?P<hour>\d{2}):(?P<min>\d{2}):(?P<sec>\d{2})' +
    r'(\+\d{4})(?P<zoneh>\d{2})(?P<zonem>\d{2})' +
    r'"')
```

It's obviously much easier to retrieve `m.group('zonem')`, instead of having to remember to retrieve group 9.

The syntax for backreferences in an expression such as `(\d+)\1` refers to the number of the group. There's naturally a variant that uses the group name instead of the number. This is another Python extension: `(?P=name)` indicates that the contents of the group called `name` should again be matched at the current point. The regular expression for finding doubled words, `(\b\w+)\s+(\b\w+)\1` can also be written as `(\b\w+)\s+(?P=word)`:

```python
>>> p = re.compile(r'(\b\w+)\s+(?P=word)')
>>> p.search('Paris in the the spring').group()
'the the'
```
Lookahead Assertions

Another zero-width assertion is the lookahead assertion. Lookahead assertions are available in both positive and negative form, and look like this:

(?=...)

Positive lookahead assertion. This succeeds if the contained regular expression, represented here by ..., successfully matches at the current location, and fails otherwise. But, once the contained expression has been tried, the matching engine doesn't advance at all; the rest of the pattern is tried right where the assertion started.

(?!...)

Negative lookahead assertion. This is the opposite of the positive assertion; it succeeds if the contained expression doesn’t match at the current position in the string.

To make this concrete, let’s look at a case where a lookahead is useful. Consider a simple pattern to match a filename and split it apart into a base name and an extension, separated by a .. For example, in news.rc, news is the base name, and rc is the filename's extension.

The pattern to match this is quite simple:

.*[.].*$

Notice that the . needs to be treated specially because it’s a metacharacter, so it’s inside a character class to only match that specific character. Also notice the trailing $; this is added to ensure that all the rest of the string must be included in the extension. This regular expression matches foo.bar and autoexec.bat and sendmail.cf and printers.conf.
Now, consider complicating the problem a bit; what if you want to match filenames where the extension is not bat? Some incorrect attempts:

\*\.[\^b].*\$  The first attempt above tries to exclude bat by requiring that the first character of the extension is not a b. This is wrong, because the pattern also doesn't match foo.bar.

\*\.[\(\[^b\]..|\.[^a].|..[^t]\)]\$  The expression gets messier when you try to patch up the first solution by requiring one of the following cases to match: the first character of the extension isn’t b; the second character isn’t a; or the third character isn’t t. This accepts foo.bar and rejects autoexec.bat, but it requires a three-letter extension and won’t accept a filename with a two-letter extension such as sendmail.cf. We’ll complicate the pattern again in an effort to fix it.

\*\.[\(\[^b\].?.?|\.[^a].?.?|..[^t]?)\$  In the third attempt, the second and third letters are all made optional in order to allow matching extensions shorter than three characters, such as sendmail.cf.

The pattern’s getting really complicated now, which makes it hard to read and understand. Worse, if the problem changes and you want to exclude both bat and exe as extensions, the pattern would get even more complicated and confusing.

A negative lookahead cuts through all this confusion:

\*\.[\(?!bat\$)[\^.]\$  The negative lookahead means: if the
expression bat doesn’t match at this point, try the rest of the pattern; if bat$ does match, the whole pattern will fail. The trailing $ is required to ensure that something like sample.batch, where the extension only starts with bat, will be allowed. The [^.]* makes sure that the pattern works when there are multiple dots in the filename.

Excluding another filename extension is now easy; simply add it as an alternative inside the assertion. The following pattern excludes filenames that end in either bat or exe:

.*[\.[?!bat\$|exe\$][^.]\)*$
Modifying Strings

Up to this point, we’ve simply performed searches against a static string. Regular expressions are also commonly used to modify strings in various ways, using the following pattern methods:

<table>
<thead>
<tr>
<th>Method/Attribute</th>
<th>Purpose</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>split()</code></td>
<td>Split the string into a list, splitting it wherever the RE matches</td>
</tr>
<tr>
<td><code>sub()</code></td>
<td>Find all substrings where the RE matches, and replace them with a different string</td>
</tr>
<tr>
<td><code>subn()</code></td>
<td>Does the same thing as <code>sub()</code>, but returns the new string and the number of replacements</td>
</tr>
</tbody>
</table>

Splitting Strings

The `split()` method of a pattern splits a string apart wherever the RE matches, returning a list of the pieces. It’s similar to the `split()` method of strings but provides much more generality in the delimiters that you can split by; string `split()` only supports splitting by whitespace or by a fixed string. As you’d expect, there’s a module-level `re.split()` function, too.

```
.split(string[, maxsplit=0])
```

Split `string` by the matches of the regular expression. If capturing parentheses are used in the RE, then their contents will also be returned as part of the resulting list. If `maxsplit` is nonzero, at most `maxsplit` splits are performed.

You can limit the number of splits made, by passing a value for `maxsplit`. When `maxsplit` is nonzero, at most `maxsplit` splits will be
made, and the remainder of the string is returned as the final element of the list. In the following example, the delimiter is any sequence of non-alphanumeric characters.

```python
g>>> p = re.compile(r'\W+')
g>>> p.split('This is a test, short and sweet, of split().')
['This', 'is', 'a', 'test', 'short', 'and', 'sweet', 'of split().']
```

Sometimes you’re not only interested in what the text between delimiters is, but also need to know what the delimiter was. If capturing parentheses are used in the RE, then their values are also returned as part of the list. Compare the following calls:

```python
g>>> p = re.compile(r'\W+')
g>>> p2 = re.compile(r'([^\W]+)')
g>>> p.split('This... is a test.')
['This', 'is', 'a', 'test', '']
g>>> p2.split('This... is a test.')
['This', '...', 'is', '', 'a', '', 'test', '.']
```

The module-level function `re.split()` adds the RE to be used as the first argument, but is otherwise the same.

```python
g>>> re.split('[\W]+', 'Words, words, words.')
['Words', 'words', 'words', '']
g>>> re.split('([^\W]+)', 'Words, words, words.')
['Words', '', '', 'words', '', 'words', '.']
g>>> re.split('[\W]+', 'Words, words, words.', 1)
['Words', 'words, words.']['Search and Replace
Another common task is to find all the matches for a pattern, and replace them with a different string. The sub() method takes a replacement value, which can be either a string or a function, and the string to be processed.

```
sub(replacement, string[, count=0])
```

Returns the string obtained by replacing the leftmost non-overlapping occurrences of the RE in string by the replacement replacement. If the pattern isn’t found, string is returned unchanged.

The optional argument count is the maximum number of pattern occurrences to be replaced; count must be a non-negative integer. The default value of 0 means to replace all occurrences.

Here’s a simple example of using the sub() method. It replaces colour names with the word `colour`:

```python
>>> p = re.compile('(blue|white|red)')
>>> p.sub('colour', 'blue socks and red shoes')
'colour socks and colour shoes'
>>> p.sub('colour', 'blue socks and red shoes', count)
'colour socks and red shoes'
```

The subn() method does the same work, but returns a 2-tuple containing the new string value and the number of replacements that were performed:

```python
>>> p = re.compile('(blue|white|red)')
>>> p.subn('colour', 'blue socks and red shoes')
('colour socks and colour shoes', 2)
>>> p.subn('colour', 'no colours at all')
```
Empty matches are replaced only when they're not adjacent to a previous match.

```python
g = re.compile('x*')
g.sub('-', 'abx')
'-a-b-d-'
```

If `replacement` is a string, any backslash escapes in it are processed. That is, `\n` is converted to a single newline character, `\r` is converted to a carriage return, and so forth. Unknown escapes such as `\&` are left alone. Backreferences, such as `\6`, are replaced with the substring matched by the corresponding group in the RE. This lets you incorporate portions of the original text in the resulting replacement string.

This example matches the word `section` followed by a string enclosed in `{, }`, and changes `section` to `subsection`:

```python
g = re.compile('section{ ( [^}]*) }', re.VERBOSE)
g.sub(r'subsection{\1}', 'section{First} subsection{Second}')
'subsection{First} subsection{Second}'
```

There's also a syntax for referring to named groups as defined by the `(?P<name>...)` syntax. `\g<name>` will use the substring matched by the group named `name`, and `\g<number>` uses the corresponding group number. `\g<2>` is therefore equivalent to `\2`, but isn't ambiguous in a replacement string such as `\g<2>0`. (`\20` would be interpreted as a reference to group 20, not a reference to group 2 followed by the literal character `0`). The following substitutions are all equivalent, but use all three variations of the replacement string.
replacement can also be a function, which gives you even more control. If replacement is a function, the function is called for every non-overlapping occurrence of pattern. On each call, the function is passed a match object argument for the match and can use this information to compute the desired replacement string and return it.

In the following example, the replacement function translates decimals into hexadecimal:

```python
>>> def hexrepl(match):
...     "Return the hex string for a decimal number"
...     value = int(match.group())
...     return hex(value)
...
>>> p = re.compile(r'\d+')
>>> p.sub(hexrepl, 'Call 65490 for printing, 49152 for user code.')
'Call 0xffd2 for printing, 0xc000 for user code.'
```

When using the module-level `re.sub()` function, the pattern is passed as the first argument. The pattern may be provided as an object or as a string; if you need to specify regular expression flags, you must either use a pattern object as the first parameter, or use embedded modifiers in the pattern string, e.g. `sub("(?i)b+", "x", "bbbb BBBB")` returns `x x`.
Common Problems

Regular expressions are a powerful tool for some applications, but in some ways their behaviour isn’t intuitive and at times they don’t behave the way you may expect them to. This section will point out some of the most common pitfalls.

Use String Methods

Sometimes using the `re` module is a mistake. If you’re matching a fixed string, or a single character class, and you’re not using any `re` features such as the IGNORECASE flag, then the full power of regular expressions may not be required. Strings have several methods for performing operations with fixed strings and they’re usually much faster, because the implementation is a single small C loop that’s been optimized for the purpose, instead of the large, more generalized regular expression engine.

One example might be replacing a single fixed string with another one; for example, you might replace `word` with `deed`. `re.sub()` seems like the function to use for this, but consider the `replace()` method. Note that `replace()` will also replace `word` inside words, turning `swordfish` into `sdeedfish`, but the naive RE `word` would have done that, too. (To avoid performing the substitution on parts of words, the pattern would have to be `\bword\b`, in order to require that `word` have a word boundary on either side. This takes the job beyond `replace()`’s abilities.)

Another common task is deleting every occurrence of a single character from a string or replacing it with another single character.
You might do this with something like `re.sub(\n', ' ', S)`, but `translate()` is capable of doing both tasks and will be faster than any regular expression operation can be.

In short, before turning to the `re` module, consider whether your problem can be solved with a faster and simpler string method.

**match() versus search()**

The `match()` function only checks if the RE matches at the beginning of the string while `search()` will scan forward through the string for a match. It's important to keep this distinction in mind. Remember, `match()` will only report a successful match which will start at 0; if the match wouldn’t start at zero, `match()` will *not* report it.

```python
>>> print(re.match('super', 'superstition').span())
(0, 5)
>>> print(re.match('super', 'insuperable'))
None
```

On the other hand, `search()` will scan forward through the string, reporting the first match it finds.

```python
>>> print(re.search('super', 'superstition').span())
(0, 5)
>>> print(re.search('super', 'insuperable').span())
(2, 7)
```

Sometimes you'll be tempted to keep using `re.match()`, and just add `.*` to the front of your RE. Resist this temptation and use `re.search()` instead. The regular expression compiler does some analysis of REs in order to speed up the process of looking for a
match. One such analysis figures out what the first character of a match must be; for example, a pattern starting with Crow must match starting with a 'C'. The analysis lets the engine quickly scan through the string looking for the starting character, only trying the full match if a 'C' is found.

Adding .* defeats this optimization, requiring scanning to the end of the string and then backtracking to find a match for the rest of the RE. Use re.search() instead.

**Greedy versus Non-Greedy**

When repeating a regular expression, as in a*, the resulting action is to consume as much of the pattern as possible. This fact often bites you when you're trying to match a pair of balanced delimiters, such as the angle brackets surrounding an HTML tag. The naive pattern for matching a single HTML tag doesn't work because of the greedy nature of .*.

```python
>>> s = '<html><head><title>Title</title>'
>>> len(s)
32
>>> print(re.match('<.*>', s).span())
(0, 32)
>>> print(re.match('<.*>', s).group())
<html><head><title>Title</title>
```

The RE matches the '<' in <html>, and the .* consumes the rest of the string. There's still more left in the RE, though, and the > can't match at the end of the string, so the regular expression engine has to backtrack character by character until it finds a match for the >. The final match extends from the '<' in <html> to the '>' in </title>,
which isn’t what you want.

In this case, the solution is to use the non-greedy qualifiers *?, +?, ??, or {m,n}??, which match as little text as possible. In the above example, the '>' is tried immediately after the first '<' matches, and when it fails, the engine advances a character at a time, retrying the '>' at every step. This produces just the right result:

```python
>>> print(re.match('<.*?>', s).group())
<html>
```

(Note that parsing HTML or XML with regular expressions is painful. Quick-and-dirty patterns will handle common cases, but HTML and XML have special cases that will break the obvious regular expression; by the time you’ve written a regular expression that handles all of the possible cases, the patterns will be very complicated. Use an HTML or XML parser module for such tasks.)

**Using re.VERBOSE**

By now you’ve probably noticed that regular expressions are a very compact notation, but they’re not terribly readable. REs of moderate complexity can become lengthy collections of backslashes, parentheses, and metacharacters, making them difficult to read and understand.

For such REs, specifying the `re.VERBOSE` flag when compiling the regular expression can be helpful, because it allows you to format the regular expression more clearly.

The `re.VERBOSE` flag has several effects. Whitespace in the regular expression that isn’t inside a character class is ignored. This means
that an expression such as `dog | cat` is equivalent to the less readable `dog|cat`, but `[a b]` will still match the characters 'a', 'b', or a space. In addition, you can also put comments inside a RE; comments extend from a `#` character to the next newline. When used with triple-quoted strings, this enables REs to be formatted more neatly:

```python
pat = re.compile(r""
\s* # Skip leading whitespace
(?P<header>[^:]+) # Header name
\s* : # Whitespace, and a colon
(?P<value>.*?) # The header's value -- *? used
\s*$ # lose the following trailing whitespace
""", re.VERBOSE)
```

This is far more readable than:

```python
pat = re.compile(r"\s*(?P<header>[^:]+)\s*:(?P<value>.*?)")
```
Feedback

Regular expressions are a complicated topic. Did this document help you understand them? Were there parts that were unclear, or Problems you encountered that weren't covered here? If so, please send suggestions for improvements to the author.

The most complete book on regular expressions is almost certainly Jeffrey Friedl's Mastering Regular Expressions, published by O'Reilly. Unfortunately, it exclusively concentrates on Perl and Java's flavours of regular expressions, and doesn't contain any Python material at all, so it won't be useful as a reference for programming in Python. (The first edition covered Python's now-removed regex module, which won't help you much.) Consider checking it out from your library.
Socket Programming HOWTO

Author: Gordon McMillan

Abstract

Sockets are used nearly everywhere, but are one of the most severely misunderstood technologies around. This is a 10,000 foot overview of sockets. It’s not really a tutorial - you’ll still have work to do in getting things operational. It doesn’t cover the fine points (and there are a lot of them), but I hope it will give you enough background to begin using them decently.
Sockets

I’m only going to talk about INET (i.e. IPv4) sockets, but they account for at least 99% of the sockets in use. And I’ll only talk about STREAM (i.e. TCP) sockets - unless you really know what you’re doing (in which case this HOWTO isn’t for you!), you’ll get better behavior and performance from a STREAM socket than anything else. I will try to clear up the mystery of what a socket is, as well as some hints on how to work with blocking and non-blocking sockets. But I’ll start by talking about blocking sockets. You’ll need to know how they work before dealing with non-blocking sockets.

Part of the trouble with understanding these things is that “socket” can mean a number of subtly different things, depending on context. So first, let’s make a distinction between a “client” socket - an endpoint of a conversation, and a “server” socket, which is more like a switchboard operator. The client application (your browser, for example) uses “client” sockets exclusively; the web server it’s talking to uses both “server” sockets and “client” sockets.

History

Of the various forms of IPC, sockets are by far the most popular. On any given platform, there are likely to be other forms of IPC that are faster, but for cross-platform communication, sockets are about the only game in town.

They were invented in Berkeley as part of the BSD flavor of Unix. They spread like wildfire with the Internet. With good reason — the combination of sockets with INET makes talking to arbitrary machines around the world unbelievably easy (at least compared to other
schemes).
Creating a Socket

Roughly speaking, when you clicked on the link that brought you to this page, your browser did something like the following:

```
# create an INET, STREAMing socket
s = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
# now connect to the web server on port 80 - the normal http port
s.connect(('www.python.org', 80))
```

When the `connect` completes, the socket `s` can be used to send in a request for the text of the page. The same socket will read the reply, and then be destroyed. That’s right, destroyed. Client sockets are normally only used for one exchange (or a small set of sequential exchanges).

What happens in the web server is a bit more complex. First, the web server creates a “server socket”:

```
# create an INET, STREAMing socket
serversocket = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
# bind the socket to a public host, and a well-known port
serversocket.bind((socket.gethostname(), 80))
# become a server socket
serversocket.listen(5)
```

A couple things to notice: we used `socket.gethostname()` so that the socket would be visible to the outside world. If we had used `s.bind(('localhost', 80))` or `s.bind(('127.0.0.1', 80))` we would still have a “server” socket, but one that was only visible within the same machine. `s.bind(('', 80))` specifies that
the socket is reachable by any address the machine happens to have.

A second thing to note: low number ports are usually reserved for “well known” services (HTTP, SNMP etc). If you’re playing around, use a nice high number (4 digits).

Finally, the argument to `listen` tells the socket library that we want it to queue up as many as 5 connect requests (the normal max) before refusing outside connections. If the rest of the code is written properly, that should be plenty.

Now that we have a “server” socket, listening on port 80, we can enter the mainloop of the web server:

```python
while True:
    # accept connections from outside
    (clientsocket, address) = serversocket.accept()
    # now do something with the clientsocket
    # in this case, we'll pretend this is a threaded server
    ct = client_thread(clientsocket)
    ct.run()
```

There's actually 3 general ways in which this loop could work - dispatching a thread to handle `clientsocket`, create a new process to handle `clientsocket`, or restructure this app to use non-blocking sockets, and multiplex between our “server” socket and any active `clientsockets` using `select`. More about that later. The important thing to understand now is this: this is all a “server” socket does. It doesn’t send any data. It doesn’t receive any data. It just produces “client” sockets. Each `clientsocket` is created in response to some other “client” socket doing a `connect()` to the host and port we're bound to. As soon as we've created that `clientsocket`, we go back to listening for more connections. The two “clients” are free to chat it
up - they are using some dynamically allocated port which will be recycled when the conversation ends.

**IPC**

If you need fast IPC between two processes on one machine, you should look into pipes or shared memory. If you do decide to use AF_INET sockets, bind the “server” socket to `localhost`. On most platforms, this will take a shortcut around a couple of layers of network code and be quite a bit faster.

See also: The multiprocessing integrates cross-platform IPC into a higher-level API.
Using a Socket

The first thing to note, is that the web browser’s “client” socket and the web server’s “client” socket are identical beasts. That is, this is a “peer to peer” conversation. Or to put it another way, as the designer, you will have to decide what the rules of etiquette are for a conversation. Normally, the connecting socket starts the conversation, by sending in a request, or perhaps a signon. But that’s a design decision - it’s not a rule of sockets.

Now there are two sets of verbs to use for communication. You can use send and recv, or you can transform your client socket into a file-like beast and use read and write. The latter is the way Java presents its sockets. I’m not going to talk about it here, except to warn you that you need to use flush on sockets. These are buffered “files”, and a common mistake is to write something, and then read for a reply. Without a flush in there, you may wait forever for the reply, because the request may still be in your output buffer.

Now we come to the major stumbling block of sockets - send and recv operate on the network buffers. They do not necessarily handle all the bytes you hand them (or expect from them), because their major focus is handling the network buffers. In general, they return when the associated network buffers have been filled (send) or emptied (recv). They then tell you how many bytes they handled. It is your responsibility to call them again until your message has been completely dealt with.

When a recv returns 0 bytes, it means the other side has closed (or is in the process of closing) the connection. You will not receive any more data on this connection. Ever. You may be able to send data
successfully; I’ll talk more about this later.

A protocol like HTTP uses a socket for only one transfer. The client sends a request, then reads a reply. That’s it. The socket is discarded. This means that a client can detect the end of the reply by receiving 0 bytes.

But if you plan to reuse your socket for further transfers, you need to realize that there is no EOT on a socket. I repeat: if a socket send or recv returns after handling 0 bytes, the connection has been broken. If the connection has not been broken, you may wait on a recv forever, because the socket will not tell you that there’s nothing more to read (for now). Now if you think about that a bit, you’ll come to realize a fundamental truth of sockets: messages must either be fixed length (yuck), or be delimited (shrug), or indicate how long they are (much better), or end by shutting down the connection. The choice is entirely yours, (but some ways are righter than others).

Assuming you don’t want to end the connection, the simplest solution is a fixed length message:

```python
class MySocket:
    """demonstration class only
    - coded for clarity, not efficiency
    ""
    def __init__(self, sock=None):
        if sock is None:
            self.sock = socket.socket(socket.AF_INET, socket.SOCK_STREAM)
        else:
            self.sock = sock

    def connect(self, host, port):
```

self.sock.connect((host, port))

def mysend(self, msg):
    totalsent = 0
    while totalsent < MSGLEN:
        sent = self.sock.send(msg[totalsent:])
        if sent == 0:
            raise RuntimeError("socket connection broken")
        totalsent = totalsent + sent

def myreceive(self):
    chunks = []
    bytes_recd = 0
    while bytes_recd < MSGLEN:
        chunk = self.sock.recv(min(MSGLEN - bytes_recd, 2048))
        if chunk == b'':
            raise RuntimeError("socket connection broken")
        chunks.append(chunk)
        bytes_recd = bytes_recd + len(chunk)
    return b''.join(chunks)

The sending code here is usable for almost any messaging scheme -
in Python you send strings, and you can use \texttt{len()} to determine its
length (even if it has embedded \texttt{\0} characters). It's mostly the
receiving code that gets more complex. (And in C, it's not much worse,
except you can't use \texttt{strlen} if the message has embedded \texttt{\0}s.)

The easiest enhancement is to make the first character of the
message an indicator of message type, and have the type determine
the length. Now you have two \texttt{recvs} - the first to get (at least) that
first character so you can look up the length, and the second in a loop
to get the rest. If you decide to go the delimited route, you'll be
receiving in some arbitrary chunk size, (4096 or 8192 is frequently a
good match for network buffer sizes), and scanning what you've
received for a delimiter.

One complication to be aware of: if your conversational protocol allows multiple messages to be sent back to back (without some kind of reply), and you pass \texttt{recv} an arbitrary chunk size, you may end up reading the start of a following message. You'll need to put that aside and hold onto it, until it's needed.

Prefixing the message with its length (say, as 5 numeric characters) gets more complex, because (believe it or not), you may not get all 5 characters in one \texttt{recv}. In playing around, you'll get away with it; but in high network loads, your code will very quickly break unless you use two \texttt{recv} loops - the first to determine the length, the second to get the data part of the message. Nasty. This is also when you'll discover that \texttt{send} does not always manage to get rid of everything in one pass. And despite having read this, you will eventually get bit by it!

In the interests of space, building your character, (and preserving my competitive position), these enhancements are left as an exercise for the reader. Lets move on to cleaning up.

**Binary Data**

It is perfectly possible to send binary data over a socket. The major problem is that not all machines use the same formats for binary data. For example, a Motorola chip will represent a 16 bit integer with the value 1 as the two hex bytes 00 01. Intel and DEC, however, are byte-reversed - that same 1 is 01 00. Socket libraries have calls for converting 16 and 32 bit integers - \texttt{ntohl}, \texttt{htonl}, \texttt{ntohs}, \texttt{htons} where “n” means network and “h” means host, “s” means short and “l” means long. Where network order is host order, these do nothing, but where the machine is byte-reversed, these swap the bytes around
appropriately.

In these days of 32 bit machines, the ascii representation of binary data is frequently smaller than the binary representation. That's because a surprising amount of the time, all those longs have the value 0, or maybe 1. The string "0" would be two bytes, while binary is four. Of course, this doesn't fit well with fixed-length messages. Decisions, decisions.
Disconnecting

Strictly speaking, you’re supposed to use `shutdown` on a socket before you `close` it. The `shutdown` is an advisory to the socket at the other end. Depending on the argument you pass it, it can mean “I’m not going to send anymore, but I’ll still listen”, or “I’m not listening, good riddance!”. Most socket libraries, however, are so used to programmers neglecting to use this piece of etiquette that normally a `close` is the same as `shutdown(); close()`. So in most situations, an explicit `shutdown` is not needed.

One way to use `shutdown` effectively is in an HTTP-like exchange. The client sends a request and then does a `shutdown(1)`. This tells the server “This client is done sending, but can still receive.” The server can detect “EOF” by a receive of 0 bytes. It can assume it has the complete request. The server sends a reply. If the `send` completes successfully then, indeed, the client was still receiving.

Python takes the automatic shutdown a step further, and says that when a socket is garbage collected, it will automatically do a `close` if it’s needed. But relying on this is a very bad habit. If your socket just disappears without doing a `close`, the socket at the other end may hang indefinitely, thinking you’re just being slow. Please `close` your sockets when you’re done.

When Sockets Die

Probably the worst thing about using blocking sockets is what happens when the other side comes down hard (without doing a `close`). Your socket is likely to hang. TCP is a reliable protocol, and it will wait a
long, long time before giving up on a connection. If you’re using threads, the entire thread is essentially dead. There's not much you can do about it. As long as you aren't doing something dumb, like holding a lock while doing a blocking read, the thread isn’t really consuming much in the way of resources. Do not try to kill the thread - part of the reason that threads are more efficient than processes is that they avoid the overhead associated with the automatic recycling of resources. In other words, if you do manage to kill the thread, your whole process is likely to be screwed up.
Non-blocking Sockets

If you’ve understood the preceding, you already know most of what you need to know about the mechanics of using sockets. You’ll still use the same calls, in much the same ways. It’s just that, if you do it right, your app will be almost inside-out.

In Python, you use `socket.setblocking(0)` to make it non-blocking. In C, it’s more complex, (for one thing, you’ll need to choose between the BSD flavor `O_NONBLOCK` and the almost indistinguishable Posix flavor `O_NDELAY`, which is completely different from `TCP_NODELAY`), but it’s the exact same idea. You do this after creating the socket, but before using it. (Actually, if you’re nuts, you can switch back and forth.)

The major mechanical difference is that `send`, `recv`, `connect` and `accept` can return without having done anything. You have (of course) a number of choices. You can check return code and error codes and generally drive yourself crazy. If you don’t believe me, try it sometime. Your app will grow large, buggy and suck CPU. So let’s skip the brain-dead solutions and do it right.

Use `select`.

In C, coding `select` is fairly complex. In Python, it's a piece of cake, but it's close enough to the C version that if you understand `select` in Python, you'll have little trouble with it in C:

```python
ready_to_read, ready_to_write, in_error = 
    select.select(  
        potential_readers,  
        potential_writers,  
        [])
```
You pass `select` three lists: the first contains all sockets that you might want to try reading; the second all the sockets you might want to try writing to, and the last (normally left empty) those that you want to check for errors. You should note that a socket can go into more than one list. The `select` call is blocking, but you can give it a timeout. This is generally a sensible thing to do - give it a nice long timeout (say a minute) unless you have good reason to do otherwise.

In return, you will get three lists. They contain the sockets that are actually readable, writable and in error. Each of these lists is a subset (possibly empty) of the corresponding list you passed in.

If a socket is in the output readable list, you can be as-close-to-certain-as-we-ever-get-in-this-business that a `recv` on that socket will return `something`. Same idea for the writable list. You’ll be able to send `something`. Maybe not all you want to, but `something` is better than nothing. (Actually, any reasonably healthy socket will return as writable - it just means outbound network buffer space is available.)

If you have a “server” socket, put it in the potential_readers list. If it comes out in the readable list, your `accept` will (almost certainly) work. If you have created a new socket to `connect` to someone else, put it in the potential_writers list. If it shows up in the writable list, you have a decent chance that it has connected.

Actually, `select` can be handy even with blocking sockets. It’s one way of determining whether you will block - the socket returns as readable when there’s something in the buffers. However, this still doesn’t help with the problem of determining whether the other end is done, or just busy with something else.
**Portability alert:** On Unix, `select` works both with the sockets and files. Don’t try this on Windows. On Windows, `select` works with sockets only. Also note that in C, many of the more advanced socket options are done differently on Windows. In fact, on Windows I usually use threads (which work very, very well) with my sockets.
Python lists have a built-in `list.sort()` method that modifies the list in-place. There is also a `sorted()` built-in function that builds a new sorted list from an iterable.

In this document, we explore the various techniques for sorting data using Python.
Sorting Basics

A simple ascending sort is very easy: just call the `sorted()` function. It returns a new sorted list:

```python
>>> sorted([5, 2, 3, 1, 4])
[1, 2, 3, 4, 5]
```

You can also use the `list.sort()` method. It modifies the list in-place (and returns `None` to avoid confusion). Usually it's less convenient than `sorted()` - but if you don't need the original list, it's slightly more efficient.

```python
>>> a = [5, 2, 3, 1, 4]
>>> a.sort()
>>> a
[1, 2, 3, 4, 5]
```

Another difference is that the `list.sort()` method is only defined for lists. In contrast, the `sorted()` function accepts any iterable.

```python
[1, 2, 3, 4, 5]
```
Key Functions

Both `list.sort()` and `sorted()` have a key parameter to specify a function to be called on each list element prior to making comparisons.

For example, here’s a case-insensitive string comparison:

```
>>> sorted("This is a test string from Andrew".split)
['a', 'Andrew', 'from', 'is', 'string', 'test', 'This']
```

The value of the `key` parameter should be a function that takes a single argument and returns a key to use for sorting purposes. This technique is fast because the key function is called exactly once for each input record.

A common pattern is to sort complex objects using some of the object’s indices as keys. For example:

```
>>> student_tuples = [
    ...     ('john', 'A', 15),
    ...     ('jane', 'B', 12),
    ...     ('dave', 'B', 10),
    ... ]
>>> sorted(student_tuples, key=lambda student: student)
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

The same technique works for objects with named attributes. For example:

```
>>> class Student:
...     def __init__(self, name, grade, age):
```
...    self.name = name
...    self.grade = grade
...    self.age = age
...    def __repr__(self):
...        return repr((self.name, self.grade, self.age))

>>> student_objects = [
...    Student('john', 'A', 15),
...    Student('jane', 'B', 12),
...    Student('dave', 'B', 10),
...]

>>> sorted(student_objects, key=lambda student: student[0])
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
Operator Module Functions

The key-function patterns shown above are very common, so Python provides convenience functions to make accessor functions easier and faster. The operator module has `itemgetter()`, `attrgetter()`, and a `methodcaller()` function.

Using those functions, the above examples become simpler and faster:

```python
>>> from operator import itemgetter, attrgetter

>>> sorted(student_tuples, key=itemgetter(2))
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]

>>> sorted(student_objects, key=attrgetter('age'))
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]

The operator module functions allow multiple levels of sorting. For example, to sort by grade then by age:

```python
>>> sorted(student_tuples, key=itemgetter(1, 2))
[('john', 'A', 15), ('dave', 'B', 10), ('jane', 'B', 12)]

>>> sorted(student_objects, key=attrgetter('grade', 'age'))
[('john', 'A', 15), ('dave', 'B', 10), ('jane', 'B', 12)]
```
Ascending and Descending

Both `list.sort()` and `sorted()` accept a `reverse` parameter with a boolean value. This is used to flag descending sorts. For example, to get the student data in reverse age order:

```python
>>> sorted(student_tuples, key=itemgetter(2), reverse=True)
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]

>>> sorted(student_objects, key=attrgetter('age'), reverse=True)
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```
Sort Stability and Complex Sorts

Sorts are guaranteed to be stable. That means that when multiple records have the same key, their original order is preserved.

```python
>>> data = [('red', 1), ('blue', 1), ('red', 2), ('blue', 2), ('red', 2)]
>>> sorted(data, key=itemgetter(0))
['red', 1], ['red', 2], ['blue', 1], ['blue', 2], ['red', 2]
```

Notice how the two records for blue retain their original order so that ('blue', 1) is guaranteed to precede ('blue', 2).

This wonderful property lets you build complex sorts in a series of sorting steps. For example, to sort the student data by descending grade and then ascending age, do the age sort first and then sort again using grade:

```python
>>> s = sorted(student_objects, key=attrgetter('age'))
>>> sorted(s, key=attrgetter('grade'), reverse=True)
['dave', 'B', 10], ['jane', 'B', 12], ['john', 'A',
```

The Timsort algorithm used in Python does multiple sorts efficiently because it can take advantage of any ordering already present in a dataset.
The Old Way Using Decorate-Sort-Undecorate

This idiom is called Decorate-Sort-Undecorate after its three steps:

- First, the initial list is decorated with new values that control the sort order.
- Second, the decorated list is sorted.
- Finally, the decorations are removed, creating a list that contains only the initial values in the new order.

For example, to sort the student data by grade using the DSU approach:

```python
>>> decorated = [(student.grade, i, student) for i, student in decorated]
>>> decorated.sort()
>>> [student for grade, i, student in decorated]
[('john', 'A', 15), ('jane', 'B', 12), ('dave', 'B', 10)]
```

This idiom works because tuples are compared lexicographically; the first items are compared; if they are the same then the second items are compared, and so on.

It is not strictly necessary in all cases to include the index $i$ in the decorated list, but including it gives two benefits:

- The sort is stable – if two items have the same key, their order will be preserved in the sorted list.
- The original items do not have to be comparable because the ordering of the decorated tuples will be determined by at most the first two items. So for example the original list could contain complex numbers which cannot be sorted directly.
Another name for this idiom is **Schwartzian transform**, after Randal L. Schwartz, who popularized it among Perl programmers.

Now that Python sorting provides key-functions, this technique is not often needed.
The Old Way Using the `cmp` Parameter

Many constructs given in this HOWTO assume Python 2.4 or later. Before that, there was no `sorted()` builtin and `list.sort()` took no keyword arguments. Instead, all of the Py2.x versions supported a `cmp` parameter to handle user specified comparison functions.

In Py3.0, the `cmp` parameter was removed entirely (as part of a larger effort to simplify and unify the language, eliminating the conflict between rich comparisons and the `__cmp__()` magic method).

In Py2.x, sort allowed an optional function which can be called for doing the comparisons. That function should take two arguments to be compared and then return a negative value for less-than, return zero if they are equal, or return a positive value for greater-than. For example, we can do:

```python
>>> def numeric_compare(x, y):
...     return x - y
>>> sorted([5, 2, 4, 1, 3], cmp=numeric_compare)
[1, 2, 3, 4, 5]
```

Or you can reverse the order of comparison with:

```python
>>> def reverse_numeric(x, y):
...     return y - x
>>> sorted([5, 2, 4, 1, 3], cmp=reverse_numeric)
[5, 4, 3, 2, 1]
```

When porting code from Python 2.x to 3.x, the situation can arise when you have the user supplying a comparison function and you need to convert that to a key function. The following wrapper makes that easy to do:
**def** `cmp_to_key`(mycmp):
    'Convert a cmp= function into a key= function'

    **class** `K`:
    **def** `__init__`(self, obj, *args):
        self.obj = obj
    **def** `__lt__`(self, other):
        return mycmp(self.obj, other.obj) < 0
    **def** `__gt__`(self, other):
        return mycmp(self.obj, other.obj) > 0
    **def** `__eq__`(self, other):
        return mycmp(self.obj, other.obj) == 0
    **def** `__le__`(self, other):
        return mycmp(self.obj, other.obj) <= 0
    **def** `__ge__`(self, other):
        return mycmp(self.obj, other.obj) >= 0
    **def** `__ne__`(self, other):
        return mycmp(self.obj, other.obj) != 0
    **return** `K`

To convert to a key function, just wrap the old comparison function:

```python
>>> sorted([5, 2, 4, 1, 3], key=cmp_to_key(reverse_numeric))
[5, 4, 3, 2, 1]
```

In Python 3.2, the `functools.cmp_to_key()` function was added to the `functools` module in the standard library.
Odd and Ends

- For locale aware sorting, use `locale.strxfrm()` for a key function or `locale.strcoll()` for a comparison function.

- The `reverse` parameter still maintains sort stability (so that records with equal keys retain the original order). Interestingly, that effect can be simulated without the parameter by using the built-in `reversed()` function twice:

```python
>>> data = [('red', 1), ('blue', 1), ('red', 2),
          ('blue', 1), ('red', 2), ('blue', 1), ('blue', 2),
          ('blue', 1), ('red', 1), ('red', 2), ('blue', 1), ('blue', 2)]
>>> standard_way = sorted(data, key=itemgetter(0), reverse=True)
>>> double_reversed = list(reversed(sorted(reversed(data))))
>>> assert standard_way == double_reversed
>>> standard_way
[('red', 1), ('red', 2), ('blue', 1), ('blue', 2)]
```

- The sort routines are guaranteed to use `__lt__()` when making comparisons between two objects. So, it is easy to add a standard sort order to a class by defining an `__lt__()` method:

```python
>>> Student.__lt__ = lambda self, other: self.age < other.age
>>> sorted(student_objects)
[('dave', 'B', 10), ('jane', 'B', 12), ('john', 'A', 15)]
```

- Key functions need not depend directly on the objects being sorted. A key function can also access external resources. For instance, if the student grades are stored in a dictionary, they can be used to sort a separate list of student names:

```python
>>> students = ['dave', 'john', 'jane']
>>> newgrades = {'john': 'F', 'jane': 'A', 'dave':
```
```python
>>> sorted(students, key=newgrades.__getitem__)
['jane', 'dave', 'john']
```
This HOWTO discusses Python support for Unicode, and explains various problems that people commonly encounter when trying to work with Unicode.
Introduction to Unicode

History of Character Codes

In 1968, the American Standard Code for Information Interchange, better known by its acronym ASCII, was standardized. ASCII defined numeric codes for various characters, with the numeric values running from 0 to 127. For example, the lowercase letter ‘a’ is assigned 97 as its code value.

ASCII was an American-developed standard, so it only defined unaccented characters. There was an ‘é’, but no ‘é’ or ‘Í’. This meant that languages which required accented characters couldn’t be faithfully represented in ASCII. (Actually the missing accents matter for English, too, which contains words such as ‘naïve’ and ‘café’, and some publications have house styles which require spellings such as ‘coöperate’.)

For a while people just wrote programs that didn’t display accents. In the mid-1980s an Apple II BASIC program written by a French speaker might have lines like these:

```
PRINT "MISE A JOUR TERMINEE"
PRINT "PARAMETRES ENREGISTRES"
```

Those messages should contain accents (terminée, paramètre, enregistrés) and they just look wrong to someone who can read French.

In the 1980s, almost all personal computers were 8-bit, meaning that bytes could hold values ranging from 0 to 255. ASCII codes only went up to 127, so some machines assigned values between 128 and 255.
to accented characters. Different machines had different codes, however, which led to problems exchanging files. Eventually various commonly used sets of values for the 128–255 range emerged. Some were true standards, defined by the International Organization for Standardization, and some were de facto conventions that were invented by one company or another and managed to catch on.

255 characters aren’t very many. For example, you can’t fit both the accented characters used in Western Europe and the Cyrillic alphabet used for Russian into the 128–255 range because there are more than 128 such characters.

You could write files using different codes (all your Russian files in a coding system called KOI8, all your French files in a different coding system called Latin1), but what if you wanted to write a French document that quotes some Russian text? In the 1980s people began to want to solve this problem, and the Unicode standardization effort began.

Unicode started out using 16-bit characters instead of 8-bit characters. 16 bits means you have $2^{16} = 65,536$ distinct values available, making it possible to represent many different characters from many different alphabets; an initial goal was to have Unicode contain the alphabets for every single human language. It turns out that even 16 bits isn’t enough to meet that goal, and the modern Unicode specification uses a wider range of codes, 0 through 1,114,111 (0x10FFFF in base 16).

There’s a related ISO standard, ISO 10646. Unicode and ISO 10646 were originally separate efforts, but the specifications were merged with the 1.1 revision of Unicode.

(This discussion of Unicode’s history is highly simplified. The precise
historical details aren’t necessary for understanding how to use Unicode effectively, but if you’re curious, consult the Unicode consortium site listed in the References or the Wikipedia entry for Unicode for more information.)

Definitions

A **character** is the smallest possible component of a text. ‘A’, ‘B’, ‘C’, etc., are all different characters. So are ‘Ê’ and ‘Í’. Characters are abstractions, and vary depending on the language or context you’re talking about. For example, the symbol for ohms (Ω) is usually drawn much like the capital letter omega (Ω) in the Greek alphabet (they may even be the same in some fonts), but these are two different characters that have different meanings.

The Unicode standard describes how characters are represented by **code points**. A code point is an integer value, usually denoted in base 16. In the standard, a code point is written using the notation U+12CA to mean the character with value 0x12ca (4,810 decimal). The Unicode standard contains a lot of tables listing characters and their corresponding code points:

<table>
<thead>
<tr>
<th>Code Point</th>
<th>Character</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0061</td>
<td>'a';</td>
<td>LATIN SMALL LETTER A</td>
</tr>
<tr>
<td>0062</td>
<td>'b';</td>
<td>LATIN SMALL LETTER B</td>
</tr>
<tr>
<td>0063</td>
<td>'c';</td>
<td>LATIN SMALL LETTER C</td>
</tr>
<tr>
<td>...</td>
<td></td>
<td></td>
</tr>
<tr>
<td>007B</td>
<td>'{';</td>
<td>LEFT CURLY BRACKET</td>
</tr>
</tbody>
</table>

Strictly, these definitions imply that it’s meaningless to say ‘this is character U+12CA’. U+12CA is a code point, which represents some particular character; in this case, it represents the character ‘ETHIOPIIC SYLLABLE WI’.

In informal contexts, this distinction
between code points and characters will sometimes be forgotten.

A character is represented on a screen or on paper by a set of graphical elements that's called a **glyph**. The glyph for an uppercase A, for example, is two diagonal strokes and a horizontal stroke, though the exact details will depend on the font being used. Most Python code doesn’t need to worry about glyphs; figuring out the correct glyph to display is generally the job of a GUI toolkit or a terminal’s font renderer.

**Encodings**

To summarize the previous section: a Unicode string is a sequence of code points, which are numbers from 0 through \(0x10FFFF\) (1,114,111 decimal). This sequence needs to be represented as a set of bytes (meaning, values from 0 through 255) in memory. The rules for translating a Unicode string into a sequence of bytes are called an **encoding**.

The first encoding you might think of is an array of 32-bit integers. In this representation, the string “Python” would look like this:

<table>
<thead>
<tr>
<th>P</th>
<th>y</th>
<th>t</th>
<th>h</th>
</tr>
</thead>
<tbody>
<tr>
<td>0x50</td>
<td>79</td>
<td>74</td>
<td>68</td>
</tr>
<tr>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>

This representation is straightforward but using it presents a number of problems.

1. It’s not portable; different processors order the bytes differently.
2. It’s very wasteful of space. In most texts, the majority of the code points are less than 127, or less than 255, so a lot of space is
occupied by \texttt{0x00} bytes. The above string takes 24 bytes compared to the 6 bytes needed for an ASCII representation. Increased RAM usage doesn’t matter too much (desktop computers have gigabytes of RAM, and strings aren’t usually that large), but expanding our usage of disk and network bandwidth by a factor of 4 is intolerable.

3. It’s not compatible with existing C functions such as \texttt{strlen()}, so a new family of wide string functions would need to be used.

4. Many Internet standards are defined in terms of textual data, and can’t handle content with embedded zero bytes.

Generally people don’t use this encoding, instead choosing other encodings that are more efficient and convenient. UTF-8 is probably the most commonly supported encoding; it will be discussed below.

Encodings don’t have to handle every possible Unicode character, and most encodings don’t. The rules for converting a Unicode string into the ASCII encoding, for example, are simple; for each code point:

1. If the code point is $< 128$, each byte is the same as the value of the code point.

2. If the code point is $128$ or greater, the Unicode string can’t be represented in this encoding. (Python raises a \texttt{UnicodeEncodeError} exception in this case.)

Latin-1, also known as ISO-8859-1, is a similar encoding. Unicode code points $0–255$ are identical to the Latin-1 values, so converting to this encoding simply requires converting code points to byte values; if a code point larger than 255 is encountered, the string can’t be encoded into Latin-1.

Encodings don’t have to be simple one-to-one mappings like Latin-1. Consider IBM’s EBCDIC, which was used on IBM mainframes. Letter values weren’t in one block: ‘a’ through ‘i’ had values from 129 to 137,
but ‘j’ through ‘r’ were 145 through 153. If you wanted to use EBCDIC as an encoding, you’d probably use some sort of lookup table to perform the conversion, but this is largely an internal detail.

UTF-8 is one of the most commonly used encodings. UTF stands for “Unicode Transformation Format”, and the ‘8’ means that 8-bit numbers are used in the encoding. (There are also a UTF-16 and UTF-32 encodings, but they are less frequently used than UTF-8.) UTF-8 uses the following rules:

1. If the code point is < 128, it’s represented by the corresponding byte value.
2. If the code point is >= 128, it’s turned into a sequence of two, three, or four bytes, where each byte of the sequence is between 128 and 255.

UTF-8 has several convenient properties:

1. It can handle any Unicode code point.
2. A Unicode string is turned into a sequence of bytes containing no embedded zero bytes. This avoids byte-ordering issues, and means UTF-8 strings can be processed by C functions such as `strcpy()` and sent through protocols that can’t handle zero bytes.
3. A string of ASCII text is also valid UTF-8 text.
4. UTF-8 is fairly compact; the majority of commonly used characters can be represented with one or two bytes.
5. If bytes are corrupted or lost, it’s possible to determine the start of the next UTF-8-encoded code point and resynchronize. It’s also unlikely that random 8-bit data will look like valid UTF-8.

References

The Unicode Consortium site has character charts, a glossary, and
PDF versions of the Unicode specification. Be prepared for some difficult reading. A chronology of the origin and development of Unicode is also available on the site.

To help understand the standard, Jukka Korpela has written an introductory guide to reading the Unicode character tables.

Another good introductory article was written by Joel Spolsky. If this introduction didn’t make things clear to you, you should try reading this alternate article before continuing.

Wikipedia entries are often helpful; see the entries for “character encoding” and UTF-8, for example.
Python’s Unicode Support

Now that you’ve learned the rudiments of Unicode, we can look at Python’s Unicode features.

The String Type

Since Python 3.0, the language features a `str` type that contain Unicode characters, meaning any string created using "unicode rocks!", 'unicode rocks!', or the triple-quoted string syntax is stored as Unicode.

The default encoding for Python source code is UTF-8, so you can simply include a Unicode character in a string literal:

```python
try:
    with open('/tmp/input.txt', 'r') as f:
        ...
except OSError:
    # 'File not found' error message.
    print("Fichier non trouvé")
```

You can use a different encoding from UTF-8 by putting a specially-formatted comment as the first or second line of the source code:

```python
# -*- coding: <encoding name> -*-
```

Side note: Python 3 also supports using Unicode characters in identifiers:

```python
répertoire = "/tmp/records.log"
with open(répertoire, "w") as f:
```
f.write("test
")

If you can’t enter a particular character in your editor or want to keep the source code ASCII-only for some reason, you can also use escape sequences in string literals. (Depending on your system, you may see the actual capital-delta glyph instead of a \u escape.)

```python
>>> "\N{GREEK CAPITAL LETTER DELTA}"  # Using the character name
\u0394
>>> "\u0394"  # Using a 16-bit hex value
\u0394
>>> "\U00000394"  # Using a 32-bit hex value
\u0394
```

In addition, one can create a string using the `decode()` method of `bytes`. This method takes an `encoding` argument, such as UTF-8, and optionally an `errors` argument.

The `errors` argument specifies the response when the input string can’t be converted according to the encoding’s rules. Legal values for this argument are `'strict'` (raise a `UnicodeDecodeError` exception), `'replace'` (use U+FFFD, REPLACEMENT CHARACTER), `'ignore'` (just leave the character out of the Unicode result), or `'backslashreplace'` (inserts a `\xNN` escape sequence). The following examples show the differences:

```python
>>> b'\x80abc'.decode("utf-8", "strict")
Traceback (most recent call last):
  ...
UnicodeDecodeError: 'utf-8' codec can't decode byte invalid start byte
>>> b'\x80abc'.decode("utf-8", "replace")
'\ufffdabc'
```
Encodings are specified as strings containing the encoding’s name. Python 3.2 comes with roughly 100 different encodings; see the Python Library Reference at Standard Encodings for a list. Some encodings have multiple names; for example, 'latin-1', 'iso_8859_1' and '8859' are all synonyms for the same encoding.

One-character Unicode strings can also be created with the chr() built-in function, which takes integers and returns a Unicode string of length 1 that contains the corresponding code point. The reverse operation is the built-in ord() function that takes a one-character Unicode string and returns the code point value:

```python
>>> chr(57344)
'\ue000'
>>> ord('\ue000')
57344
```

Converting to Bytes

The opposite method of bytes.decode() is str.encode(), which returns a bytes representation of the Unicode string, encoded in the requested encoding.

The errors parameter is the same as the parameter of the decode() method but supports a few more possible handlers. As well as 'strict', 'ignore', and 'replace' (which in this case inserts a question mark instead of the unencodable character), there is also...
xmlcharrefreplace (inserts an XML character reference), backslashreplace (inserts a \uNNNN escape sequence) and namereplace (inserts a \N{...} escape sequence).

The following example shows the different results:

```python
>>> u = chr(40960) + 'abcd' + chr(1972)
>>> u.encode('utf-8')
b'\xe8\x80\x80abcd\xde\xb4'
>>> u.encode('ascii')
Traceback (most recent call last):
 ...  
UnicodeEncodeError: 'ascii' codec can't encode character ' ' in position 0: ordinal not in range(128)
>>> u.encode('ascii', 'ignore')
b'abcd'
>>> u.encode('ascii', 'replace')
b'?abcd?'
>>> u.encode('ascii', 'xmlcharrefreplace')
b'\&#40960;abcd&#1972;'
>>> u.encode('ascii', 'backslashreplace')
b'\ua000abcd\u07b4'
>>> u.encode('ascii', 'namereplace')
b'\N{YI SYLLABLE IT}abcd\u07b4'
```

The low-level routines for registering and accessing the available encodings are found in the codecs module. Implementing new encodings also requires understanding the codecs module. However, the encoding and decoding functions returned by this module are usually more low-level than is comfortable, and writing new encodings is a specialized task, so the module won’t be covered in this HOWTO.

Unicode Literals in Python Source Code
In Python source code, specific Unicode code points can be written using the `\u` escape sequence, which is followed by four hex digits giving the code point. The `\U` escape sequence is similar, but expects eight hex digits, not four:

```python
>>> s = "a\xac\u1234\u20ac\U00008000"
... # ^^^^ two-digit hex escape
... # ^^^^^^ four-digit Unicode escape
... # ^^^^^^^^^ eight-digit Unicode escape
>>> [ord(c) for c in s]
[97, 172, 4660, 8364, 32768]
```

Using escape sequences for code points greater than 127 is fine in small doses, but becomes an annoyance if you’re using many accented characters, as you would in a program with messages in French or some other accent-using language. You can also assemble strings using the `chr()` built-in function, but this is even more tedious.

Ideally, you’d want to be able to write literals in your language’s natural encoding. You could then edit Python source code with your favorite editor which would display the accented characters naturally, and have the right characters used at runtime.

Python supports writing source code in UTF-8 by default, but you can use almost any encoding if you declare the encoding being used. This is done by including a special comment as either the first or second line of the source file:

```
#!/usr/bin/env python
# -*- coding: latin-1 -*-

u = 'abcdé'
print(ord(u[-1]))
```
The syntax is inspired by Emacs's notation for specifying variables local to a file. Emacs supports many different variables, but Python only supports ‘coding’. The -*- symbols indicate to Emacs that the comment is special; they have no significance to Python but are a convention. Python looks for `coding: name` or `coding=name` in the comment.

If you don’t include such a comment, the default encoding used will be UTF-8 as already mentioned. See also PEP 263 for more information.

**Unicode Properties**

The Unicode specification includes a database of information about code points. For each defined code point, the information includes the character's name, its category, the numeric value if applicable (Unicode has characters representing the Roman numerals and fractions such as one-third and four-fifths). There are also properties related to the code point's use in bidirectional text and other display-related properties.

The following program displays some information about several characters, and prints the numeric value of one particular character:

```python
import unicodedata

u = chr(233) + chr(0x0bf2) + chr(3972) + chr(6000) +
for i, c in enumerate(u):
    print(i, '%04x' % ord(c), unicodedata.category(c),
    print(unicodedata.name(c))

# Get numeric value of second character
print(unicodedata.numeric(u[1]))
```
When run, this prints:

```
0 00e9  Ll  LATIN SMALL LETTER E WITH ACUTE
1 0bf2  No  TAMIL NUMBER ONE THOUSAND
2 0f84  Mn  TIBETAN MARK HALANTA
3 1770  Lo  TAGBANWA LETTER SA
4 33af  So  SQUARE RAD OVER S SQUARED
1000.0
```

The category codes are abbreviations describing the nature of the character. These are grouped into categories such as “Letter”, “Number”, “Punctuation”, or “Symbol”, which in turn are broken up into subcategories. To take the codes from the above output, 'Ll' means 'Letter, lowercase', 'No' means “Number, other”, 'Mn' is “Mark, nonspacing”, and 'So' is “Symbol, other”. See the General Category Values section of the Unicode Character Database documentation for a list of category codes.

## Unicode Regular Expressions

The regular expressions supported by the re module can be provided either as bytes or strings. Some of the special character sequences such as `\d` and `\w` have different meanings depending on whether the pattern is supplied as bytes or a string. For example, `\d` will match the characters `[0-9]` in bytes but in strings will match any character that's in the 'Nd' category.

The string in this example has the number 57 written in both Thai and Arabic numerals:

```python
import re
p = re.compile('\\d+')
```
s = "Over \u0e55\u0e57 57 flavours"
m = p.search(s)
print(repr(m.group()))

When executed, \d+ will match the Thai numerals and print them out. If you supply the re.ASCII flag to compile(), \d+ will match the substring “57” instead.

Similarly, \w matches a wide variety of Unicode characters but only [a-zA-Z0-9_] in bytes or if re.ASCII is supplied, and \s will match either Unicode whitespace characters or [\t\n\r\f\v].

The documentation for the codecs module.

Marc-André Lemburg gave a presentation titled “Python and Unicode” (PDF slides) at EuroPython 2002. The slides are an excellent overview of the design of Python 2’s Unicode features (where the Unicode string type is called unicode and literals start with u).
Reading and Writing Unicode Data

Once you’ve written some code that works with Unicode data, the next problem is input/output. How do you get Unicode strings into your program, and how do you convert Unicode into a form suitable for storage or transmission?

It’s possible that you may not need to do anything depending on your input sources and output destinations; you should check whether the libraries used in your application support Unicode natively. XML parsers often return Unicode data, for example. Many relational databases also support Unicode-valued columns and can return Unicode values from an SQL query.

Unicode data is usually converted to a particular encoding before it gets written to disk or sent over a socket. It’s possible to do all the work yourself: open a file, read an 8-bit bytes object from it, and convert the bytes with `bytes.decode(encoding)`. However, the manual approach is not recommended.

One problem is the multi-byte nature of encodings; one Unicode character can be represented by several bytes. If you want to read the file in arbitrary-sized chunks (say, 1024 or 4096 bytes), you need to write error-handling code to catch the case where only part of the bytes encoding a single Unicode character are read at the end of a chunk. One solution would be to read the entire file into memory and then perform the decoding, but that prevents you from working with files that are extremely large; if you need to read a 2 GiB file, you need 2 GiB of RAM. (More, really, since for at least a moment you’d need to have both the encoded string and its Unicode version in memory.)

The solution would be to use the low-level decoding interface to catch
the case of partial coding sequences. The work of implementing this has already been done for you: the built-in `open()` function can return a file-like object that assumes the file's contents are in a specified encoding and accepts Unicode parameters for methods such as `read()` and `write()`. This works through `open()`'s `encoding` and `errors` parameters which are interpreted just like those in `str.encode()` and `bytes.decode()`.

Reading Unicode from a file is therefore simple:

```python
with open('unicode.txt', encoding='utf-8') as f:
    for line in f:
        print(repr(line))
```

It's also possible to open files in update mode, allowing both reading and writing:

```python
with open('test', encoding='utf-8', mode='w+') as f:
    f.write('䔀 blah blah blah
')
    f.seek(0)
    print(repr(f.readline()[1:]))
```

The Unicode character U+FEFF is used as a byte-order mark (BOM), and is often written as the first character of a file in order to assist with autodetection of the file's byte ordering. Some encodings, such as UTF-16, expect a BOM to be present at the start of a file; when such an encoding is used, the BOM will be automatically written as the first character and will be silently dropped when the file is read. There are variants of these encodings, such as ‘utf-16-le’ and ‘utf-16-be’ for little-endian and big-endian encodings, that specify one particular byte ordering and don’t skip the BOM.

In some areas, it is also convention to use a “BOM” at the start of
UTF-8 encoded files; the name is misleading since UTF-8 is not byte-order dependent. The mark simply announces that the file is encoded in UTF-8. Use the ‘utf-8-sig’ codec to automatically skip the mark if present for reading such files.

Unicode filenames

Most of the operating systems in common use today support filenames that contain arbitrary Unicode characters. Usually this is implemented by converting the Unicode string into some encoding that varies depending on the system. For example, Mac OS X uses UTF-8 while Windows uses a configurable encoding; on Windows, Python uses the name “mbcs” to refer to whatever the currently configured encoding is. On Unix systems, there will only be a filesystem encoding if you’ve set the **LANG** or **LC_CTYPE** environment variables; if you haven’t, the default encoding is UTF-8.

The `sys.getfilesystemencoding()` function returns the encoding to use on your current system, in case you want to do the encoding manually, but there’s not much reason to bother. When opening a file for reading or writing, you can usually just provide the Unicode string as the filename, and it will be automatically converted to the right encoding for you:

```python
filename = 'filename\u4500abc'
with open(filename, 'w') as f:
    f.write('blah\n')
```

Functions in the `os` module such as `os.stat()` will also accept Unicode filenames.

The `os.listdir()` function returns filenames and raises an issue:
should it return the Unicode version of filenames, or should it return bytes containing the encoded versions? `os.listdir()` will do both, depending on whether you provided the directory path as bytes or a Unicode string. If you pass a Unicode string as the path, filenames will be decoded using the filesystem's encoding and a list of Unicode strings will be returned, while passing a byte path will return the filenames as bytes. For example, assuming the default filesystem encoding is UTF-8, running the following program:

```python
fn = 'filename\u4500abc'
f = open(fn, 'w')
f.close()

import os
print(os.listdir(b'.'))
print(os.listdir('.'))
```

will produce the following output:

```
amk:~$ python t.py
[b'filename\xe4\x94\x80abc', ...]
['filename\u4500abc', ...]
```

The first list contains UTF-8-encoded filenames, and the second list contains the Unicode versions.

Note that on most occasions, the Unicode APIs should be used. The bytes APIs should only be used on systems where undecodable file names can be present, i.e. Unix systems.

**Tips for Writing Unicode-aware Programs**

This section provides some suggestions on writing software that deals
The most important tip is:

Software should only work with Unicode strings internally, decoding the input data as soon as possible and encoding the output only at the end.

If you attempt to write processing functions that accept both Unicode and byte strings, you will find your program vulnerable to bugs wherever you combine the two different kinds of strings. There is no automatic encoding or decoding: if you do e.g. `str + bytes`, a `TypeError` will be raised.

When using data coming from a web browser or some other untrusted source, a common technique is to check for illegal characters in a string before using the string in a generated command line or storing it in a database. If you’re doing this, be careful to check the decoded string, not the encoded bytes data; some encodings may have interesting properties, such as not being bijective or not being fully ASCII-compatible. This is especially true if the input data also specifies the encoding, since the attacker can then choose a clever way to hide malicious text in the encoded bytestream.

Converting Between File Encodings

The `StreamRecoder` class can transparently convert between encodings, taking a stream that returns data in encoding #1 and behaving like a stream returning data in encoding #2.

For example, if you have an input file $f$ that’s in Latin-1, you can wrap it with a `StreamRecoder` to return bytes encoded in UTF-8:
new_f = codecs.StreamRecoder(f,
    # en/decoder: used by read() to encode its results
    # by write() to decode its input.
    codecs.getencoder('utf-8'), codecs.getdecoder('utf-8'),
    # reader/writer: used to read and write to the stream.
    codecs.getreader('latin-1'), codecs.getwriter('latin-1'))

Files in an Unknown Encoding

What can you do if you need to make a change to a file, but don't know the file's encoding? If you know the encoding is ASCII-compatible and only want to examine or modify the ASCII parts, you can open the file with the surrogateescape error handler:

```python
with open(fname, 'r', encoding="ascii", errors="surrogateescape")
data = f.read()

# make changes to the string 'data'
with open(fname + '.new', 'w',
    encoding="ascii", errors="surrogateescape")
f.write(data)
```

The surrogateescape error handler will decode any non-ASCII bytes as code points in the Unicode Private Use Area ranging from U+DC80 to U+DCFF. These private code points will then be turned back into the same bytes when the surrogateescape error handler is used when encoding the data and writing it back out.

HOWTO Fetch Internet Resources Using The urllib Package

**Author:** Michael Foord

**Note:** There is a French translation of an earlier revision of this HOWTO, available at [urllib2 - Le Manuel manquant](http://example.com).
Introduction

**urllib.request** is a Python module for fetching URLs (Uniform Resource Locators). It offers a very simple interface, in the form of the *urlopen* function. This is capable of fetching URLs using a variety of different protocols. It also offers a slightly more complex interface for handling common situations - like basic authentication, cookies, proxies and so on. These are provided by objects called handlers and openers.

**urllib.request** supports fetching URLs for many “URL schemes” (identified by the string before the "":" in URL - for example "ftp" is the URL scheme of "ftp://python.org/") using their associated network protocols (e.g. FTP, HTTP). This tutorial focuses on the most common case, HTTP.

For straightforward situations *urlopen* is very easy to use. But as soon as you encounter errors or non-trivial cases when opening HTTP URLs, you will need some understanding of the HyperText Transfer Protocol. The most comprehensive and authoritative reference to HTTP is **RFC 2616**. This is a technical document and not intended to be easy to read. This HOWTO aims to illustrate using *urllib*, with enough detail about HTTP to help you through. It is not intended to replace the **urllib.request** docs, but is supplementary to them.
Fetching URLs

The simplest way to use urllib.request is as follows:

```python
import urllib.request
with urllib.request.urlopen('http://python.org/') as html:
    html = response.read()
```

If you wish to retrieve a resource via URL and store it in a temporary location, you can do so via the `urlretrieve()` function:

```python
import urllib.request
local_filename, headers = urllib.request.urlretrieve()
html = open(local_filename)
```

Many uses of urllib will be that simple (note that instead of an ‘http:’ URL we could have used a URL starting with ‘ftp:’, ‘file:’, etc.). However, it’s the purpose of this tutorial to explain the more complicated cases, concentrating on HTTP.

HTTP is based on requests and responses - the client makes requests and servers send responses. urllib.request mirrors this with a Request object which represents the HTTP request you are making. In its simplest form you create a Request object that specifies the URL you want to fetch. Calling `urlopen` with this Request object returns a response object for the URL requested. This response is a file-like object, which means you can for example call `.read()` on the response:

```python
import urllib.request
```
req = urllib.request.Request('http://www.voidspace.org.uk')
with urllib.request.urlopen(req) as response:
    the_page = response.read()

Note that urllib.request makes use of the same Request interface to handle all URL schemes. For example, you can make an FTP request like so:

req = urllib.request.Request('ftp://example.com/')

In the case of HTTP, there are two extra things that Request objects allow you to do: First, you can pass data to be sent to the server. Second, you can pass extra information ("metadata") about the data or the about request itself, to the server - this information is sent as HTTP "headers". Let's look at each of these in turn.

Data

Sometimes you want to send data to a URL (often the URL will refer to a CGI (Common Gateway Interface) script or other web application). With HTTP, this is often done using what’s known as a POST request. This is often what your browser does when you submit a HTML form that you filled in on the web. Not all POSTs have to come from forms: you can use a POST to transmit arbitrary data to your own application. In the common case of HTML forms, the data needs to be encoded in a standard way, and then passed to the Request object as the data argument. The encoding is done using a function from the urllib.parse library.

```python
import urllib.parse
import urllib.request
```
```python
url = 'http://www.someserver.com/cgi-bin/register.cgi'
values = {'name': 'Michael Foord',
          'location': 'Northampton',
          'language': 'Python'}

data = urllib.parse.urlencode(values)  # data should be bytes
req = urllib.request.Request(url, data)
with urllib.request.urlopen(req) as response:
    the_page = response.read()
```

Note that other encodings are sometimes required (e.g. for file upload from HTML forms - see HTML Specification, Form Submission for more details).

If you do not pass the `data` argument, `urllib` uses a `GET` request. One way in which `GET` and `POST` requests differ is that `POST` requests often have "side-effects": they change the state of the system in some way (for example by placing an order with the website for a hundredweight of tinned spam to be delivered to your door). Though the HTTP standard makes it clear that `POSTs` are intended to always cause side-effects, and `GET` requests never to cause side-effects, nothing prevents a `GET` request from having side-effects, nor a `POST` requests from having no side-effects. Data can also be passed in an HTTP `GET` request by encoding it in the URL itself.

This is done as follows:

```python
>>> import urllib.request
>>> import urllib.parse
>>> data = {}
>>> data['name'] = 'Somebody Here'
>>> data['location'] = 'Northampton'
>>> data['language'] = 'Python'
```
Notice that the full URL is created by adding a ? to the URL, followed by the encoded values.

**Headers**

We'll discuss here one particular HTTP header, to illustrate how to add headers to your HTTP request.

Some websites [1] dislike being browsed by programs, or send different versions to different browsers [2]. By default urllib identifies itself as *Python-urllib/x.y* (where *x* and *y* are the major and minor version numbers of the Python release, e.g. *Python-urllib/2.5*), which may confuse the site, or just plain not work. The way a browser identifies itself is through the `User-Agent` header [3]. When you create a Request object you can pass a dictionary of headers in. The following example makes the same request as above, but identifies itself as a version of Internet Explorer [4].
headers = {'User-Agent': user_agent}

data = urllib.parse.urlencode(values)
data = data.encode('ascii')
req = urllib.request.Request(url, data, headers)
with urllib.request.urlopen(req) as response:
    the_page = response.read()

The response also has two useful methods. See the section on info and geturl which comes after we have a look at what happens when things go wrong.
Handling Exceptions

`urlopen` raises `URLError` when it cannot handle a response (though as usual with Python APIs, built-in exceptions such as `ValueError`, `TypeError` etc. may also be raised).

`HTTPError` is the subclass of `URLError` raised in the specific case of HTTP URLs.

The exception classes are exported from the `urllib.error` module.

**URLError**

Often, `URLError` is raised because there is no network connection (no route to the specified server), or the specified server doesn’t exist. In this case, the exception raised will have a ‘reason’ attribute, which is a tuple containing an error code and a text error message.

E.g.

```python
>>> req = urllib.request.Request('http://www.pretend_server.org')
>>> try:
...     urllib.request.urlopen(req)
... except urllib.error.URLError as e:
...     print(e.reason)
...
(4, 'getaddrinfo failed')
```

**HTTPError**

Every HTTP response from the server contains a numeric “status code”. Sometimes the status code indicates that the server is unable
to fulfil the request. The default handlers will handle some of these responses for you (for example, if the response is a “redirection” that requests the client fetch the document from a different URL, urllib will handle that for you). For those it can’t handle, urlopen will raise an HTTPError. Typical errors include ‘404’ (page not found), ‘403’ (request forbidden), and ‘401’ (authentication required).

See section 10 of RFC 2616 for a reference on all the HTTP error codes.

The HTTPError instance raised will have an integer ‘code’ attribute, which corresponds to the error sent by the server.

Error Codes

Because the default handlers handle redirects (codes in the 300 range), and codes in the 100–299 range indicate success, you will usually only see error codes in the 400–599 range.

http.server.BaseHTTPRequestHandler.responses is a useful dictionary of response codes in that shows all the response codes used by RFC 2616. The dictionary is reproduced here for convenience

```python
# Table mapping response codes to messages; entries # form {code: (shortmessage, longmessage)}.
responses = {
    100: ('Continue', 'Request received, please cont
    101: ('Switching Protocols',
         'Switching to new protocol; obey Upgrade H
    200: ('OK', 'Request fulfilled, document follows
    201: ('Created', 'Document created, URL follows'
    202: ('Accepted',
         'Request accepted, processing continues of
```
203: ('Non-Authoritative Information', 'Request fulfilled, information comes from cache')
204: ('No Content', 'Request fulfilled, nothing follows')
205: ('Reset Content', 'Clear input form for further input.')
206: ('Partial Content', 'Partial content follows.')
300: ('Multiple Choices', 'Object has several resources -- see URI list')
301: ('Moved Permanently', 'Object moved permanently -- see URI list')
302: ('Found', 'Object moved temporarily -- see URI list')
303: ('See Other', 'Object moved -- see Method and URL list')
304: ('Not Modified', 'Document has not changed since given time')
305: ('Use Proxy', 'You must use proxy specified in Location resource.')
307: ('Temporary Redirect', 'Object moved temporarily -- see URI list')
400: ('Bad Request', 'Bad request syntax or unsupported method')
401: ('Unauthorized', 'No permission -- see authorization schemes')
402: ('Payment Required', 'No payment -- see charging schemes')
403: ('Forbidden', 'Request forbidden -- authorization will not help')
404: ('Not Found', 'Nothing matches the given URI')
405: ('Method Not Allowed', 'Specified method is invalid for this server')
406: ('Not Acceptable', 'URI not available in preferred format')
407: ('Proxy Authentication Required', 'You must authenticate with this proxy before proceeding.')
408: ('Request Timeout', 'Request timed out; try again later')
409: ('Conflict', 'Request conflict')
410: ('Gone', 'URI no longer exists and has been permanently removed')
411: ('Length Required', 'Client must specify Content-Length')
When an error is raised the server responds by returning an HTTP error code and an error page. You can use the HTTPError instance as a response on the page returned. This means that as well as the code attribute, it also has read, geturl, and info, methods as returned by the urllib.response module:

```python
def main():
    req = urllib.request.Request('http://www.python.org/fish.html')
    try:
        urllib.request.urlopen(req)
    except urllib.error.HTTPError as e:
        print(e.code)
        print(e.read())
    print(404)
```
Wrapping it Up

So if you want to be prepared for HTTPError or URLError there are two basic approaches. I prefer the second approach.

Number 1

```python
from urllib.request import Request, urlopen
from urllib.error import URLError, HTTPError
req = Request(someurl)
try:
    response = urlopen(req)
except HTTPError as e:
    print('The server couldn\'t fulfill the request.
print('Error code: ', e.code)
except URLError as e:
    print('We failed to reach a server.')
print('Reason: ', e.reason)
else:
    # everything is fine
```

**Note:** The except HTTPError *must* come first, otherwise except URLError will also catch an HTTPError.

Number 2

```python
from urllib.request import Request, urlopen
```
from urllib.error import URLError
req = Request(someurl)
try:
    response = urlopen(req)
except URLError as e:
    if hasattr(e, 'reason'):
        print('We failed to reach a server.')
        print('Reason: ', e.reason)
    elif hasattr(e, 'code'):
        print('The server couldn\'t fulfill the request.
        print('Error code: ', e.code)
else:
    # everything is fine
info and geturl

The response returned by urlopen (or the HTTPError instance) has two useful methods `info()` and `geturl()` and is defined in the module `urllib.response`.

**geturl** - this returns the real URL of the page fetched. This is useful because `urlopen` (or the opener object used) may have followed a redirect. The URL of the page fetched may not be the same as the URL requested.

**info** - this returns a dictionary-like object that describes the page fetched, particularly the headers sent by the server. It is currently an `http.client.HTTPMessage` instance.

Typical headers include ‘Content-length’, ‘Content-type’, and so on. See the [Quick Reference to HTTP Headers](#) for a useful listing of HTTP headers with brief explanations of their meaning and use.
Openers and Handlers

When you fetch a URL you use an opener (an instance of the perhaps confusingly-named `urllib.request.OpenerDirector`). Normally we have been using the default opener - via `urlopen` - but you can create custom openers. Openers use handlers. All the “heavy lifting” is done by the handlers. Each handler knows how to open URLs for a particular URL scheme (http, ftp, etc.), or how to handle an aspect of URL opening, for example HTTP redirections or HTTP cookies.

You will want to create openers if you want to fetch URLs with specific handlers installed, for example to get an opener that handles cookies, or to get an opener that does not handle redirections.

To create an opener, instantiate an `OpenerDirector`, and then call `.add_handler(some_handler_instance)` repeatedly.

Alternatively, you can use `build_opener`, which is a convenience function for creating opener objects with a single function call. `build_opener` adds several handlers by default, but provides a quick way to add more and/or override the default handlers.

Other sorts of handlers you might want to can handle proxies, authentication, and other common but slightly specialised situations.

`install_opener` can be used to make an `opener` object the (global) default opener. This means that calls to `urlopen` will use the opener you have installed.

Opener objects have an `open` method, which can be called directly to fetch urls in the same way as the `urlopen` function: there's no need to call `install_opener`, except as a convenience.
Basic Authentication

To illustrate creating and installing a handler we will use the HTTPBasicAuthHandler. For a more detailed discussion of this subject – including an explanation of how Basic Authentication works - see the Basic Authentication Tutorial.

When authentication is required, the server sends a header (as well as the 401 error code) requesting authentication. This specifies the authentication scheme and a ‘realm’. The header looks like: WWW-Authenticate: SCHEME realm="REALM".

e.g.

WWW-Authenticate: Basic realm="cPanel Users"

The client should then retry the request with the appropriate name and password for the realm included as a header in the request. This is ‘basic authentication’. In order to simplify this process we can create an instance of HTTPBasicAuthHandler and an opener to use this handler.

The HTTPBasicAuthHandler uses an object called a password manager to handle the mapping of URLs and realms to passwords and usernames. If you know what the realm is (from the authentication header sent by the server), then you can use a HTTPPasswordMgr. Frequently one doesn’t care what the realm is. In that case, it is convenient to use HTTPPasswordMgrWithDefaultRealm. This allows you to specify a default username and password for a URL. This will be supplied in the absence of you providing an alternative combination for a specific realm. We indicate this by providing None
as the realm argument to the **add_password** method.

The top-level URL is the first URL that requires authentication. URLs “deeper” than the URL you pass to `.add_password()` will also match.

```python
# create a password manager
password_mgr = urllib.request.HTTPPasswordMgrWithDefaultRealm

# Add the username and password.
# If we knew the realm, we could use it instead of None.
# If we knew the realm, we could use it instead of None.
top_level_url = "http://example.com/foo/"
password_mgr.add_password(None, top_level_url, username, password)

handler = urllib.request.HTTPBasicAuthHandler(password_mgr)

# create "opener" (OpenerDirector instance)
opener = urllib.request.build_opener(handler)

# use the opener to fetch a URL
opener.open(a_url)

# Install the opener.
# Now all calls to urllib.request.urlopen use our opener.
urllib.request.install_opener(opener)
```

**Note:** In the above example we only supplied our HTTPBasicAuthHandler to build_opener. By default openers have the handlers for normal situations – ProxyHandler (if a proxy setting such as an http_proxy environment variable is set), UnknownHandler, HTTPHandler, HTTPDefaultErrorHandler, HTTPRedirectHandler, FTPHandler, FileHandler, DataHandler, HTTPErrorProcessor.
top_level_url is in fact *either* a full URL (including the ‘http’ scheme component and the hostname and optionally the port number) e.g. "http://example.com/" or an “authority” (i.e. the hostname, optionally including the port number) e.g. "example.com" or "example.com:8080" (the latter example includes a port number). The authority, if present, must NOT contain the “userinfo” component – for example "joe:password@example.com" is not correct.
Proxies

`urllib` will auto-detect your proxy settings and use those. This is through the `ProxyHandler`, which is part of the normal handler chain when a proxy setting is detected. Normally that’s a good thing, but there are occasions when it may not be helpful [5]. One way to do this is to setup our own `ProxyHandler`, with no proxies defined. This is done using similar steps to setting up a Basic Authentication handler:

```python
>>> proxy_support = urllib.request.ProxyHandler({})
>>> opener = urllib.request.build_opener(proxy_support)
>>> urllib.request.install_opener(opener)
```

**Note:** Currently `urllib.request` does not support fetching of `https` locations through a proxy. However, this can be enabled by extending `urllib.request` as shown in the recipe [6].

**Note:** `HTTP_PROXY` will be ignored if a variable `REQUEST_METHOD` is set; see the documentation on `getproxies()`.
Sockets and Layers

The Python support for fetching resources from the web is layered. urllib uses the `http.client` library, which in turn uses the socket library.

As of Python 2.3 you can specify how long a socket should wait for a response before timing out. This can be useful in applications which have to fetch web pages. By default the socket module has no timeout and can hang. Currently, the socket timeout is not exposed at the http.client or urllib.request levels. However, you can set the default timeout globally for all sockets using

```python
import socket
import urllib.request

# timeout in seconds
timeout = 10
socket.setdefaulttimeout(timeout)

# this call to urllib.request.urlopen now uses the default timeout we have set in the socket module
req = urllib.request.Request('http://www.voidspace.org.uk')
response = urllib.request.urlopen(req)
```
Footnotes

This document was reviewed and revised by John Lee.

Browser sniffing is a very bad practice for website design - building sites using web standards is much more sensible. Unfortunately a lot of sites still send different versions to different browsers.

[2] The user agent for MSIE 6 is ‘Mozilla/4.0 (compatible; MSIE 6.0; Windows NT 5.1; SV1; .NET CLR 1.1.4322)’

[3] For details of more HTTP request headers, see Quick Reference to HTTP Headers.

[4] In my case I have to use a proxy to access the internet at work. If you attempt to fetch localhost URLs through this proxy it blocks them. IE is set to use the proxy, which urllib picks up on. In order to test scripts with a localhost server, I have to prevent urllib from using the proxy.

Argparse Tutorial

**author:** Tshepang Lekhonkhobe

This tutorial is intended to be a gentle introduction to **argparse**, the recommended command-line parsing module in the Python standard library.

**Note:** There are two other modules that fulfill the same task, namely **getopt** (an equivalent for getopt() from the C language) and the deprecated **optparse**. Note also that **argparse** is based on **optparse**, and therefore very similar in terms of usage.
Concepts

Let's show the sort of functionality that we are going to explore in this introductory tutorial by making use of the `ls` command:

```
$ ls
cpython devguide prog.py pypy rm-unused-function
$ ls pypy
ctypes_configure demo dotviewer include lib_pypy
$ ls -l
  total 20
  drwxr-xr-x 19 wena wena 4096 Feb 18 18:51 cpython
  drwxr-xr-x  4 wena wena 4096 Feb  8 12:04 devguide
-rwxr-xr-x  1 wena wena  535 Feb 19 00:05 prog.py
  drwxr-xr-x 14 wena wena 4096 Feb  7 00:59 pypy
-rw-r--r--  1 wena wena  741 Feb 18 01:01 rm-unused-function
$ ls --help
Usage: ls [OPTION]... [FILE]...
List information about the FILEs (the current directory by default)
Sort entries alphabetically if none of -cftuvSUX nor --sort is specified.
```

A few concepts we can learn from the four commands:

- The `ls` command is useful when run without any options at all. It defaults to displaying the contents of the current directory.
- If we want beyond what it provides by default, we tell it a bit more. In this case, we want it to display a different directory, `pypy`. What we did is specify what is known as a positional argument. It's named so because the program should know what to do with the value, solely based on where it appears on the command line. This concept is more relevant to a command like `cp`, whose most basic usage is `cp SRC DEST`. The first position is `what you want copied`, and the second position is `where you want it copied to`. 
Now, say we want to change behaviour of the program. In our example, we display more info for each file instead of just showing the file names. The `-l` in that case is known as an optional argument.

That's a snippet of the help text. It's very useful in that you can come across a program you have never used before, and can figure out how it works simply by reading its help text.
The basics

Let us start with a very simple example which does (almost) nothing:

```python
import argparse
parser = argparse.ArgumentParser()
parser.parse_args()
```

Following is a result of running the code:

```
$ python3 prog.py
$ python3 prog.py --help
usage: prog.py [-h]

optional arguments:
  -h, --help    show this help message and exit
$ python3 prog.py --verbose
usage: prog.py [-h]
prog.py: error: unrecognized arguments: --verbose
$ python3 prog.py foo
usage: prog.py [-h]
prog.py: error: unrecognized arguments: foo
```

Here is what is happening:

- Running the script without any options results in nothing displayed to stdout. Not so useful.
- The second one starts to display the usefulness of the `argparse` module. We have done almost nothing, but already we get a nice help message.
- The `--help` option, which can also be shortened to `-h`, is the only option we get for free (i.e. no need to specify it). Specifying anything else results in an error. But even then, we do get a useful usage message, also for free.
Introducing Positional arguments

An example:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("echo")
args = parser.parse_args()
print(args.echo)
```

And running the code:

```
$ python3 prog.py
usage: prog.py [-h] echo
prog.py: error: the following arguments are required
$ python3 prog.py --help
usage: prog.py [-h] echo

positional arguments:
  echo

optional arguments:
  -h, --help    show this help message and exit
```

Here is what's happening:

- We've added the `add_argument()` method, which is what we use to specify which command-line options the program is willing to accept. In this case, I've named it `echo` so that it's in line with its function.
- Calling our program now requires us to specify an option.
- The `parse_args()` method actually returns some data from the
options specified, in this case, `echo`.
- The variable is some form of ‘magic’ that `argparse` performs for free (i.e. no need to specify which variable that value is stored in). You will also notice that its name matches the string argument given to the method, `echo`.

Note however that, although the help display looks nice and all, it currently is not as helpful as it can be. For example we see that we got `echo` as a positional argument, but we don’t know what it does, other than by guessing or by reading the source code. So, let’s make it a bit more useful:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("echo", help="echo the string you use there")
args = parser.parse_args()
print(args.echo)
```

And we get:

```
$ python3 prog.py -h
usage: prog.py [-h] echo

positional arguments:
  echo                echo the string you use here

optional arguments:
  -h, --help  show this help message and exit
```

Now, how about doing something even more useful:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", help="display a square")
```
```python
args = parser.parse_args()
print(args.square**2)
```

Following is a result of running the code:

```
$ python3 prog.py 4
Traceback (most recent call last):
  File "prog.py", line 5, in <module>
    print(args.square**2)
TypeError: unsupported operand type(s) for ** or pow
```

That didn't go so well. That's because `argparse` treats the options we give it as strings, unless we tell it otherwise. So, let's tell `argparse` to treat that input as an integer:

```python
import argparse
parser = argparse.ArgumentParser()
parsing.add_argument("square", help="display a square of given number")
parser.parse_args()
args = parser.parse_args()
print(args.square**2)
```

Following is a result of running the code:

```
$ python3 prog.py 4
16
$ python3 prog.py four
usage: prog.py [-h] square
prog.py: error: argument square: invalid int value:
```

That went well. The program now even helpfully quits on bad illegal input before proceeding.
Introducing Optional arguments

So far we have been playing with positional arguments. Let us have a look on how to add optional ones:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("--verbosity", help="increase output verbosity")
args = parser.parse_args()
if args.verbosity:
    print("verbosity turned on")
```

And the output:

```
$ python3 prog.py --verbosity 1
verbosity turned on
$ python3 prog.py
$ python3 prog.py --help
usage: prog.py [-h] [--verbosity VERBOSITY]

optional arguments:
  -h, --help            show this help message and exit
  --verbosity VERBOSITY  increase output verbosity

$ python3 prog.py --verbosity
usage: prog.py [-h] [--verbosity VERBOSITY]
prog.py: error: argument --verbosity: expected one argument
```

Here is what is happening:

- The program is written so as to display something when `--verbosity` is specified and display nothing when not.
- To show that the option is actually optional, there is no error when
running the program without it. Note that by default, if an optional argument isn't used, the relevant variable, in this case `args.verbosity`, is given None as a value, which is the reason it fails the truth test of the if statement.

- The help message is a bit different.
- When using the `--verbosity` option, one must also specify some value, any value.

The above example accepts arbitrary integer values for `--verbosity`, but for our simple program, only two values are actually useful, True or False. Let's modify the code accordingly:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("--verbose", help="increase output verbosity", action="store_true")
args = parser.parse_args()
if args.verbose:
    print("verbosity turned on")
```

And the output:

```bash
$ python3 prog.py --verbose
verbosity turned on
$ python3 prog.py --verbose 1
usage: prog.py [-h] [--verbose]
prog.py: error: unrecognized arguments: 1
$ python3 prog.py --help
usage: prog.py [-h] [--verbose]

optional arguments:
  -h, --help      show this help message and exit
  --verbose       increase output verbosity
```
Here is what is happening:

- The option is now more of a flag than something that requires a value. We even changed the name of the option to match that idea. Note that we now specify a new keyword, `action`, and give it the value "store_true". This means that, if the option is specified, assign the value True to `args.verbose`. Not specifying it implies False.
- It complains when you specify a value, in true spirit of what flags actually are.
- Notice the different help text.

**Short options**

If you are familiar with command line usage, you will notice that I haven't yet touched on the topic of short versions of the options. It's quite simple:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("-v", "--verbose", help="increase output verbosity",
    action="store_true")
args = parser.parse_args()
if args.verbose:
    print("verbosity turned on")
```

And here goes:

```
$ python3 prog.py -v
verbosity turned on
$ python3 prog.py --help
usage: prog.py [-h] [-v]
optional arguments:
```
-h, --help  show this help message and exit
-v, --verbose  increase output verbosity

Note that the new ability is also reflected in the help text.
Combining Positional and Optional arguments

Our program keeps growing in complexity:

```python
import argparse
parser = argparse.ArgumentParser("square", type=int,
                             help="display a square of a given number")
parser.add_argument("-v", "--verbose", action="store_true",
                             help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbose:
    print("the square of {} equals {}".format(args.square, answer))
else:
    print(answer)
```

And now the output:

```
$ python3 prog.py
usage: prog.py [-h] [-v] square
prog.py: error: the following arguments are required
$ python3 prog.py 4
16
$ python3 prog.py 4 --verbose
the square of 4 equals 16
$ python3 prog.py --verbose 4
the square of 4 equals 16
```

- We’ve brought back a positional argument, hence the complaint.
- Note that the order does not matter.
How about we give this program of ours back the ability to have multiple verbosity values, and actually get to use them:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
                    help="display a square of a given number")
parser.add_argument("-v", "--verbosity", type=int,
                    help="increase output verbosity")
args = parser.parse_args()
answer = args.square ** 2
if args.verbosity == 2:
    print("the square of {} equals {}".format(args.square, answer))
elif args.verbosity == 1:
    print("{}^2 == {}".format(args.square, answer))
else:
    print(answer)
```

And the output:

```
$ python3 prog.py 4
16
$ python3 prog.py 4 -v
usage: prog.py [-h] [-v VERBOSITY] square
prog.py: error: argument -v/--verbosity: expected one argument
$ python3 prog.py 4 -v 1
4^2 == 16
$ python3 prog.py 4 -v 2
the square of 4 equals 16
$ python3 prog.py 4 -v 3
16
```

These all look good except the last one, which exposes a bug in our program. Let’s fix it by restricting the values the `--verbosity` option
can accept:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
                     help="display a square of a given")
parser.add_argument("-v", "--verbosity", type=int, choices={0,1,2},
                     help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbosity == 2:
    print("the square of {} equals {}".format(args.square, answer))
elif args.verbosity == 1:
    print("{}^2 == {}").format(args.square, answer))
else:
    print(answer)
```

And the output:

```
$ python3 prog.py 4 -v 3
usage: prog.py [-h] [-v {0,1,2}] square
prog.py: error: argument -v/--verbosity: invalid choice: 3 (expected one of [0, 1, 2])
$ python3 prog.py 4 -h
usage: prog.py [-h] [-v {0,1,2}] square

positional arguments:
    square                      display a square of a given

optional arguments:
    -h, --help                  show this help message and exit
    -v {0,1,2}, --verbosity {0,1,2}
                                increase output verbosity
```

Note that the change also reflects both in the error message as well as the help string.
Now, let’s use a different approach of playing with verbosity, which is pretty common. It also matches the way the CPython executable handles its own verbosity argument (check the output of `python --help`):

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
                     help="display the square of a given number")
parser.add_argument("-v", "--verbosity", action="count",
                     help="increase output verbosity")
args = parser.parse_args()
answer = args.square**2
if args.verbosity == 2:
    print("the square of {} equals {}").format(args.square, answer)
elif args.verbosity == 1:
    print("{}^2 == {}").format(args.square, answer)
else:
    print(answer)
```

We have introduced another action, “count”, to count the number of occurrences of a specific optional arguments:

```
$ python3 prog.py 4
16
$ python3 prog.py 4 -v
4^2 == 16
$ python3 prog.py 4 -vv
the square of 4 equals 16
$ python3 prog.py 4 --verbosity --verbosity
the square of 4 equals 16
$ python3 prog.py 4 -v 1
usage: prog.py [-h] [-v] square
prog.py: error: unrecognized arguments: 1
$ python3 prog.py 4 -h
```
usage: prog.py [-h] [-v] square

positional arguments:
    square       display a square of a given number

optional arguments:
    -h, --help    show this help message and exit
    -v, --verbosity  increase output verbosity

$ python3 prog.py 4 -vvv
16

- Yes, it's now more of a flag (similar to action="store_true") in the previous version of our script. That should explain the complaint.
- It also behaves similar to “store_true” action.
- Now here's a demonstration of what the “count” action gives. You've probably seen this sort of usage before.
- And if you don't specify the -v flag, that flag is considered to have None value.
- As should be expected, specifying the long form of the flag, we should get the same output.
- Sadly, our help output isn't very informative on the new ability our script has acquired, but that can always be fixed by improving the documentation for our script (e.g. via the help keyword argument).
- That last output exposes a bug in our program.

Let's fix:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
                    help="display a square of a given number")
parser.add_argument("-v", "--verbosity", action="count",
                    help="increase output verbosity")
```
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("square", type=int,
    help="display a square of a given number")
parser.add_argument("-v", "--verbosity", action="count",
    help="increase output verbosity")

args = parser.parse_args()
answer = args.square**2

# bugfix: replace == with >=
if args.verbosity >= 2:
    print("the square of {} equals {}".format(args.square, answer))
elif args.verbosity >= 1:
    print("{}^2 == {}".format(args.square, answer))
else:
    print(answer)

And this is what it gives:

$ python3 prog.py 4 -vv
the square of 4 equals 16
$ python3 prog.py 4 -vvvv
the square of 4 equals 16
$ python3 prog.py 4
Traceback (most recent call last):
  File "prog.py", line 11, in <module>
    if args.verbosity >= 2:
TypeError: '==' not supported between instances of 'NoneType'

- First output went well, and fixes the bug we had before. That is, we want any value >= 2 to be as verbose as possible.
- Third output not so good.

Let's fix that bug:
args = parser.parse_args()
answer = args.square**2
if args.verbosity >= 2:
    print("the square of {} equals {}").format(args.square, answer)
elif args.verbosity >= 1:
    print("{}^2 == {}").format(args.square, answer)
else:
    print(answer)

We've just introduced yet another keyword, default. We've set it to 0 in order to make it comparable to the other int values. Remember that by default, if an optional argument isn't specified, it gets the None value, and that cannot be compared to an int value (hence the TypeError exception).

And:

$ python3 prog.py 4
16

You can go quite far just with what we've learned so far, and we have only scratched the surface. The argparse module is very powerful, and we'll explore a bit more of it before we end this tutorial.
Getting a little more advanced

What if we wanted to expand our tiny program to perform other powers, not just squares:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")
parser.add_argument("-v", "--verbosity", action="count")
args = parser.parse_args()
answer = args.x**args.y
if args.verbosity >= 2:
    print("{} to the power {} equals {}".format(args.x, args.y, answer))
elif args.verbosity >= 1:
    print("{}^{} == {}".format(args.x, args.y, answer))
else:
    print(answer)
```

Output:

```
$ python3 prog.py
usage: prog.py [-h] [-v] x y
prog.py: error: the following arguments are required
$ python3 prog.py -h
usage: prog.py [-h] [-v] x y

positional arguments:
  x            the base
  y            the exponent

optional arguments:
  -h, --help    show this help message and exit
  -v, --verbosity
```
Notice that so far we've been using verbosity level to *change* the text that gets displayed. The following example instead uses verbosity level to display *more* text instead:

```python
import argparse
parser = argparse.ArgumentParser()
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")
parser.add_argument("-v", "--verbosity", action="count")
args = parser.parse_args()
answer = args.x**args.y
if args.verbosity >= 2:
    print("Running '{0}'".format(__file__))
if args.verbosity >= 1:
    print("{{0}}^{{1}} == {{2}}").format(args.x, args.y), end="")
print(answer)
```

Output:

```
$ python3 prog.py 4 2
16
$ python3 prog.py 4 2 -v
4^2 == 16
$ python3 prog.py 4 2 -vv
Running 'prog.py'
4^2 == 16
```

**Conflicting options**

So far, we have been working with two methods of an
argparse.ArgumentParser instance. Let's introduce a third one, 
add_mutually_exclusive_group(). It allows for us to specify 
options that conflict with each other. Let's also change the rest of the 
program so that the new functionality makes more sense: we'll 
introduce the --quiet option, which will be the opposite of the --verbose one:

```python
import argparse

parser = argparse.ArgumentParser()
group = parser.add_mutually_exclusive_group()
    group.add_argument("-v", "--verbose", action="store_true")
    group.add_argument("-q", "--quiet", action="store_true")
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")

args = parser.parse_args()
answer = args.x**args.y

if args.quiet:
    print(answer)
elif args.verbose:
    print("{} to the power {} equals {}".format(args.x, args.y, answer))
else:
    print("{}^{} == {}".format(args.x, args.y, answer))
```

Our program is now simpler, and we've lost some functionality for the 
sake of demonstration. Anyways, here's the output:

```
$ python3 prog.py 4 2
4^2 == 16
$ python3 prog.py 4 2 -q
16
$ python3 prog.py 4 2 -v
4 to the power 2 equals 16
```
That should be easy to follow. I’ve added that last output so you can see the sort of flexibility you get, i.e. mixing long form options with short form ones.

Before we conclude, you probably want to tell your users the main purpose of your program, just in case they don’t know:

```python
import argparse

parser = argparse.ArgumentParser(description="calculate X to the power Y")
group = parser.add_mutually_exclusive_group()
group.add_argument("-v", "--verbose", action="store_true")
group.add_argument("-q", "--quiet", action="store_true")
parser.add_argument("x", type=int, help="the base")
parser.add_argument("y", type=int, help="the exponent")
args = parser.parse_args()
answer = args.x**args.y

if args.quiet:
    print(answer)
elif args.verbose:
    print("{} to the power {} equals {}".format(args.x, args.y, answer))
else:
    print("{}^{} == {}").format(args.x, args.y, answer)
```

Note that slight difference in the usage text. Note the \([-v | -q]\), which tells us that we can either use \(-v\) or \(-q\), but not both at the
same time:

```
$ python3 prog.py --help
usage: prog.py [-h] [-v | -q] x y

calculate X to the power of Y

positional arguments:
  x                the base
  y                the exponent

optional arguments:
  -h, --help       show this help message and exit
  -v, --verbose
  -q, --quiet
```
Conclusion

The `argparse` module offers a lot more than shown here. Its docs are quite detailed and thorough, and full of examples. Having gone through this tutorial, you should easily digest them without feeling overwhelmed.
An introduction to the ipaddress module

<table>

</tr>
</tbody>
</table>

Overview

This document aims to provide a gentle introduction to the ipaddress module. It is aimed primarily at users that aren’t already familiar with IP networking terminology, but may also be useful to network engineers wanting an overview of how ipaddress represents IP network addressing concepts.
Creating Address/Network/Interface objects

Since `ipaddress` is a module for inspecting and manipulating IP addresses, the first thing you'll want to do is create some objects. You can use `ipaddress` to create objects from strings and integers.

A Note on IP Versions

For readers that aren't particularly familiar with IP addressing, it's important to know that the Internet Protocol is currently in the process of moving from version 4 of the protocol to version 6. This transition is occurring largely because version 4 of the protocol doesn't provide enough addresses to handle the needs of the whole world, especially given the increasing number of devices with direct connections to the internet.

Explaining the details of the differences between the two versions of the protocol is beyond the scope of this introduction, but readers need to at least be aware that these two versions exist, and it will sometimes be necessary to force the use of one version or the other.

IP Host Addresses

Addresses, often referred to as “host addresses” are the most basic unit when working with IP addressing. The simplest way to create addresses is to use the `ipaddress.ip_address()` factory function, which automatically determines whether to create an IPv4 or IPv6 address based on the passed in value:
Addresses can also be created directly from integers. Values that will fit within 32 bits are assumed to be IPv4 addresses:

```python
>>> ipaddress.ip_address('192.0.2.1')
IPv4Address('192.0.2.1')
>>> ipaddress.ip_address('2001:DB8::1')
IPv6Address('2001:db8::1')
```

To force the use of IPv4 or IPv6 addresses, the relevant classes can be invoked directly. This is particularly useful to force creation of IPv6 addresses for small integers:

```python
>>> ipaddress.ip_address(3221225985)
IPv4Address('192.0.2.1')
>>> ipaddress.ip_address(42540766412825928569039849)
IPv6Address('2001:db8::1')
```

**Defining Networks**

Host addresses are usually grouped together into IP networks, so `ipaddress` provides a way to create, inspect and manipulate network definitions. IP network objects are constructed from strings that define the range of host addresses that are part of that network. The simplest form for that information is a “network address/network prefix” pair, where the prefix defines the number of leading bits that are compared to determine whether or not an address is part of the network and the
network address defines the expected value of those bits.

As for addresses, a factory function is provided that determines the correct IP version automatically:

```python
g>>> ipaddress.ip_network('192.0.2.0/24')
IPv4Network('192.0.2.0/24')
g>>> ipaddress.ip_network('2001:db8::0/96')
IPv6Network('2001:db8::/96')
```

Network objects cannot have any host bits set. The practical effect of this is that `192.0.2.1/24` does not describe a network. Such definitions are referred to as interface objects since the ip-on-a-network notation is commonly used to describe network interfaces of a computer on a given network and are described further in the next section.

By default, attempting to create a network object with host bits set will result in `ValueError` being raised. To request that the additional bits instead be coerced to zero, the flag `strict=False` can be passed to the constructor:

```python
g>>> ipaddress.ip_network('192.0.2.1/24')
Traceback (most recent call last):
...
ValueError: 192.0.2.1/24 has host bits set
g>>> ipaddress.ip_network('192.0.2.1/24', strict=False)
IPv4Network('192.0.2.0/24')
```

While the string form offers significantly more flexibility, networks can also be defined with integers, just like host addresses. In this case, the network is considered to contain only the single address identified by the integer, so the network prefix includes the entire network address:
As with addresses, creation of a particular kind of network can be forced by calling the class constructor directly instead of using the factory function.

### Host Interfaces

As mentioned just above, if you need to describe an address on a particular network, neither the address nor the network classes are sufficient. Notation like `192.0.2.1/24` is commonly used by network engineers and the people who write tools for firewalls and routers as shorthand for “the host 192.0.2.1 on the network 192.0.2.0/24”, Accordingly, `ipaddress` provides a set of hybrid classes that associate an address with a particular network. The interface for creation is identical to that for defining network objects, except that the address portion isn’t constrained to being a network address.

```python
>>> import ipaddress

>>> ipaddress.ip_network(3221225984)
IPv4Network('192.0.2.0/32')

>>> ipaddress.ip_network(42540766411282592856903984951653826560)
IPv6Network('2001:db8::/128')
```

```python
>>> ipaddress.ip_network('192.0.2.1/24')
IPv4Network('192.0.2.0/24')

>>> ipaddress.ip_network('2001:db8::1/96')
IPv6Network('2001:db8::/128')
```

Integer inputs are accepted (as with networks), and use of a particular IP version can be forced by calling the relevant constructor directly.
Inspecting Address/Network/Interface Objects

You’ve gone to the trouble of creating an IPv(4|6) (Address|Network|Interface) object, so you probably want to get information about it. `ipaddress` tries to make doing this easy and intuitive.

Extracting the IP version:

```
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> addr6 = ipaddress.ip_address('2001:db8::1')
>>> addr6.version
6
>>> addr4.version
4
```

Obtaining the network from an interface:

```
>>> host4 = ipaddress.ip_interface('192.0.2.1/24')
>>> host4.network
IPv4Network('192.0.2.0/24')
>>> host6 = ipaddress.ip_interface('2001:db8::1/96')
>>> host6.network
IPv6Network('2001:db8::/96')
```

Finding out how many individual addresses are in a network:

```
>>> net4 = ipaddress.ip_network('192.0.2.0/24')
>>> net4.num_addresses
256
>>> net6 = ipaddress.ip_network('2001:db8::/96')
>>> net6.num_addresses
```
Iterating through the “usable” addresses on a network:

```python
>>> net4 = ipaddress.ip_network('192.0.2.0/24')
>>> for x in net4.hosts():
...     print(x)
192.0.2.1
192.0.2.2
192.0.2.3
192.0.2.4
...
192.0.2.252
192.0.2.253
192.0.2.254
```

Obtaining the netmask (i.e. set bits corresponding to the network prefix) or the hostmask (any bits that are not part of the netmask):

```python
>>> net4.netmask
IPv4Address('255.255.255.0')
>>> net4.hostmask
IPv4Address('0.0.0.255')
>>> net6 = ipaddress.ip_network('2001:db8::/96')
>>> net6.netmask
>>> net6.hostmask
IPv6Address('::ffff:ffff')
```

Exploding or compressing the address:

```python
>>> addr6.exploded
'2001:0db8:0000:0000:0000:0000:0000:0001'
>>> addr6.compressed
'2001:db8::1'
```
While IPv4 doesn’t support explosion or compression, the associated objects still provide the relevant properties so that version neutral code can easily ensure the most concise or most verbose form is used for IPv6 addresses while still correctly handling IPv4 addresses.
Networks as lists of Addresses

It’s sometimes useful to treat networks as lists. This means it is possible to index them like this:

```
>>> net4[1]
IPv4Address('192.0.2.1')
>>> net4[-1]
IPv4Address('192.0.2.255')
>>> net6[1]
IPv6Address('2001:db8::1')
>>> net6[-1]
IPv6Address('2001:db8::ffff:ffff')
```

It also means that network objects lend themselves to using the list membership test syntax like this:

```
if address in network:
    # do something
```

Containment testing is done efficiently based on the network prefix:

```
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> addr4 in ipaddress.ip_network('192.0.2.0/24')
True
>>> addr4 in ipaddress.ip_network('192.0.3.0/24')
False
```
Comparisons

`ipaddress` provides some simple, hopefully intuitive ways to compare objects, where it makes sense:

```python
>>> ipaddress.ip_address('192.0.2.1') < ipaddress.ip_address('192.0.2.2')
True
```

A `TypeError` exception is raised if you try to compare objects of different versions or different types.
Using IP Addresses with other modules

Other modules that use IP addresses (such as `socket`) usually won’t accept objects from this module directly. Instead, they must be coerced to an integer or string that the other module will accept:

```python
>>> addr4 = ipaddress.ip_address('192.0.2.1')
>>> str(addr4)
'192.0.2.1'
>>> int(addr4)
3221225985
```
Getting more detail when instance creation fails

When creating address/network/interface objects using the version-agnostic factory functions, any errors will be reported as `ValueError` with a generic error message that simply says the passed in value was not recognized as an object of that type. The lack of a specific error is because it’s necessary to know whether the value is *supposed* to be IPv4 or IPv6 in order to provide more detail on why it has been rejected.

To support use cases where it is useful to have access to this additional detail, the individual class constructors actually raise the `ValueError` subclasses `ipaddress.AddressValueError` and `ipaddress.NetmaskValueError` to indicate exactly which part of the definition failed to parse correctly.

The error messages are significantly more detailed when using the class constructors directly. For example:

```python
>>> ipaddress.ip_address("192.168.0.256")
Traceback (most recent call last):
... 
ValueError: '192.168.0.256' does not appear to be an IPv4 or IPv6 address

>>> ipaddress.IPv4Address("192.168.0.256")
Traceback (most recent call last):
...
ipaddress.AddressValueError: Octet 256 (> 255) not permitted in '192.168.0.256'

>>> ipaddress.ip_network("192.168.0.1/64")
Traceback (most recent call last):
... 
ValueError: '192.168.0.1/64' does not appear to be a
```
>>> ipaddress.IPv4Network("192.168.0.1/64")
Traceback (most recent call last):
...
ipaddress.NetmaskValueError: '64' is not a valid netmask

However, both of the module specific exceptions have `ValueError` as their parent class, so if you’re not concerned with the particular type of error, you can still write code like the following:

```python
try:
    network = ipaddress.IPv4Network(address)
except ValueError:
    print('address/netmask is invalid for IPv4:', address)
```
Argument Clinic How-To

**Abstract**

Argument Clinic is a preprocessor for CPython C files. Its purpose is to automate all the boilerplate involved with writing argument parsing code for “builtins”. This document shows you how to convert your first C function to work with Argument Clinic, and then introduces some advanced topics on Argument Clinic usage.

Currently Argument Clinic is considered internal-only for CPython. Its use is not supported for files outside CPython, and no guarantees are made regarding backwards compatibility for future versions. In other words: if you maintain an external C extension for CPython, you're welcome to experiment with Argument Clinic in your own code. But the version of Argument Clinic that ships with CPython 3.5 *could* be totally incompatible and break all your code.
The Goals Of Argument Clinic

Argument Clinic’s primary goal is to take over responsibility for all argument parsing code inside CPython. This means that, when you convert a function to work with Argument Clinic, that function should no longer do any of its own argument parsing—the code generated by Argument Clinic should be a “black box” to you, where CPython calls in at the top, and your code gets called at the bottom, with `PyObject *args` (and maybe `PyObject *kwargs`) magically converted into the C variables and types you need.

In order for Argument Clinic to accomplish its primary goal, it must be easy to use. Currently, working with CPython’s argument parsing library is a chore, requiring maintaining redundant information in a surprising number of places. When you use Argument Clinic, you don’t have to repeat yourself.

Obviously, no one would want to use Argument Clinic unless it’s solving their problem—and without creating new problems of its own. So it’s paramount that Argument Clinic generate correct code. It’d be nice if the code was faster, too, but at the very least it should not introduce a major speed regression. (Eventually Argument Clinic should make a major speedup possible—we could rewrite its code generator to produce tailor-made argument parsing code, rather than calling the general-purpose CPython argument parsing library. That would make for the fastest argument parsing possible!)

Additionally, Argument Clinic must be flexible enough to work with any approach to argument parsing. Python has some functions with some very strange parsing behaviors; Argument Clinic’s goal is to support all of them.
Finally, the original motivation for Argument Clinic was to provide introspection “signatures” for CPython builtins. It used to be, the introspection query functions would throw an exception if you passed in a builtin. With Argument Clinic, that’s a thing of the past!

One idea you should keep in mind, as you work with Argument Clinic: the more information you give it, the better job it’ll be able to do. Argument Clinic is admittedly relatively simple right now. But as it evolves it will get more sophisticated, and it should be able to do many interesting and smart things with all the information you give it.
Basic Concepts And Usage

Argument Clinic ships with CPython; you’ll find it in Tools/clinic/clinic.py. If you run that script, specifying a C file as an argument:

```
$ python3 Tools/clinic/clinic.py foo.c
```

Argument Clinic will scan over the file looking for lines that look exactly like this:

```
/*[clinic input]
```

When it finds one, it reads everything up to a line that looks exactly like this:

```
[clinic start generated code]*/
```

Everything in between these two lines is input for Argument Clinic. All of these lines, including the beginning and ending comment lines, are collectively called an Argument Clinic “block”.

When Argument Clinic parses one of these blocks, it generates output. This output is rewritten into the C file immediately after the block, followed by a comment containing a checksum. The Argument Clinic block now looks like this:

```
/*[clinic input]
... clinic input goes here ...
[clinic start generated code]*/
... clinic output goes here ...
/*[clinic end generated code: checksum=...]*/
```
If you run Argument Clinic on the same file a second time, Argument Clinic will discard the old output and write out the new output with a fresh checksum line. However, if the input hasn’t changed, the output won’t change either.

You should never modify the output portion of an Argument Clinic block. Instead, change the input until it produces the output you want. (That’s the purpose of the checksum—to detect if someone changed the output, as these edits would be lost the next time Argument Clinic writes out fresh output.)

For the sake of clarity, here’s the terminology we’ll use with Argument Clinic:

- The first line of the comment (/*[clinic input]) is the start line.
- The last line of the initial comment ([clinic start generated code]*) is the end line.
- The last line (/*[clinic end generated code: checksum=...]*/) is the checksum line.
- In between the start line and the end line is the input.
- In between the end line and the checksum line is the output.
- All the text collectively, from the start line to the checksum line inclusively, is the block. (A block that hasn’t been successfully processed by Argument Clinic yet doesn’t have output or a checksum line, but it’s still considered a block.)
Converting Your First Function

The best way to get a sense of how Argument Clinic works is to convert a function to work with it. Here, then, are the bare minimum steps you'd need to follow to convert a function to work with Argument Clinic. Note that for code you plan to check in to CPython, you really should take the conversion farther, using some of the advanced concepts you'll see later on in the document (like “return converters” and “self converters”). But we'll keep it simple for this walkthrough so you can learn.

Let's dive in!

0. Make sure you’re working with a freshly updated checkout of the CPython trunk.

1. Find a Python builtin that calls either PyArg_ParseTuple() or PyArg_ParseTupleAndKeywords(), and hasn't been converted to work with Argument Clinic yet. For my example I’m using _pickle.Pickler.dump().

2. If the call to the PyArg_Parse function uses any of the following format units:

   0&
   0!
   es
   es#
   et
   et#

   or if it has multiple calls to PyArg_ParseTuple(), you should choose a different function. Argument Clinic does support all of
these scenarios. But these are advanced topics—let’s do something simpler for your first function.

Also, if the function has multiple calls to `PyArg_ParseTuple()` or `PyArg_ParseTupleAndKeywords()` where it supports different types for the same argument, or if the function uses something besides `PyArg_Parse` functions to parse its arguments, it probably isn't suitable for conversion to Argument Clinic. Argument Clinic doesn't support generic functions or polymorphic parameters.

3. Add the following boilerplate above the function, creating our block:

```c
/*[clinic input] [clinic start generated code]*/
```

4. Cut the docstring and paste it in between the `[clinic]` lines, removing all the junk that makes it a properly quoted C string. When you're done you should have just the text, based at the left margin, with no line wider than 80 characters. (Argument Clinic will preserve indents inside the docstring.)

If the old docstring had a first line that looked like a function signature, throw that line away. (The docstring doesn’t need it anymore—when you use `help()` on your builtin in the future, the first line will be built automatically based on the function’s signature.)

Sample:

```c
/*[clinic input]
Write a pickled representation of obj to the open file.*/
```
5. If your docstring doesn’t have a “summary” line, Argument Clinic will complain. So let’s make sure it has one. The “summary” line should be a paragraph consisting of a single 80-column line at the beginning of the docstring.

(Our example docstring consists solely of a summary line, so the sample code doesn’t have to change for this step.)

6. Above the docstring, enter the name of the function, followed by a blank line. This should be the Python name of the function, and should be the full dotted path to the function—it should start with the name of the module, include any sub-modules, and if the function is a method on a class it should include the class name too.

Sample:

/*[clinic input]
_pickle.Pickler.dump

Write a pickled representation of obj to the open file
[clinic start generated code]*/

7. If this is the first time that module or class has been used with Argument Clinic in this C file, you must declare the module and/or class. Proper Argument Clinic hygiene prefers declaring these in a separate block somewhere near the top of the C file, in the same way that include files and statics go at the top. (In our sample code we’ll just show the two blocks next to each other.)

The name of the class and module should be the same as the one
seen by Python. Check the name defined in the `PyModuleDef` or `PyTypeObject` as appropriate.

When you declare a class, you must also specify two aspects of its type in C: the type declaration you’d use for a pointer to an instance of this class, and a pointer to the `PyTypeObject` for this class.

Sample:

```c
/*[clinic input]
module _pickle
class _pickle.Pickler "PicklerObject *" "&Pickler
[clinic start generated code]*/

/*[clinic input]
_pickle.Pickler.dump

Write a pickled representation of obj to the open
[clinic start generated code]*/
```

8. Declare each of the parameters to the function. Each parameter should get its own line. All the parameter lines should be indented from the function name and the docstring.

The general form of these parameter lines is as follows:

```python
name_of_parameter: converter
```

If the parameter has a default value, add that after the converter:

```python
name_of_parameter: converter = default_value
```

Argument Clinic’s support for “default values” is quite
sophisticated; please see the section below on default values for more information.

Add a blank line below the parameters.

What’s a “converter”? It establishes both the type of the variable used in C, and the method to convert the Python value into a C value at runtime. For now you’re going to use what’s called a “legacy converter”—a convenience syntax intended to make porting old code into Argument Clinic easier.

For each parameter, copy the “format unit” for that parameter from the PyArg_Parse() format argument and specify that as its converter, as a quoted string. (“format unit” is the formal name for the one-to-three character substring of the format parameter that tells the argument parsing function what the type of the variable is and how to convert it. For more on format units please see Parsing arguments and building values.)

For multicharacter format units like z#, use the entire two-or-three character string.

Sample:

```c
/*[clinic input]
module _pickle
class _pickle.Pickler "PicklerObject *" "&Pickler
[clinic start generated code]*/

/*[clinic input]
_pickle.Pickler.dump

    obj: 'O'

Write a pickled representation of obj to the open
```
9. If your function has `|` in the format string, meaning some parameters have default values, you can ignore it. Argument Clinic infers which parameters are optional based on whether or not they have default values.

If your function has `$` in the format string, meaning it takes keyword-only arguments, specify `*` on a line by itself before the first keyword-only argument, indented the same as the parameter lines.

```python
(_pickle.Pickler.dump has neither, so our sample is unchanged.)
```

10. If the existing C function calls `PyArg_ParseTuple()` (as opposed to `PyArg_ParseTupleAndKeywords()`), then all its arguments are positional-only.

To mark all parameters as positional-only in Argument Clinic, add a `/` on a line by itself after the last parameter, indented the same as the parameter lines.

Currently this is all-or-nothing; either all parameters are positional-only, or none of them are. (In the future Argument Clinic may relax this restriction.)

Sample:
11. It's helpful to write a per-parameter docstring for each parameter. But per-parameter docstrings are optional; you can skip this step if you prefer.

Here's how to add a per-parameter docstring. The first line of the per-parameter docstring must be indented further than the parameter definition. The left margin of this first line establishes the left margin for the whole per-parameter docstring; all the text you write will be outdented by this amount. You can write as much text as you like, across multiple lines if you wish.

Sample:
12. Save and close the file, then run Tools/clinic/clinic.py on it. With luck everything worked—your block now has output, and a .c.h file has been generated! Reopen the file in your text editor to see:

```c
/*[clinic input]
_pickled.Pickler.dump

    obj: 'O'
        The object to be pickled.
/
Write a pickled representation of obj to the open file.
[clinic start generated code]*/

static PyObject *
pickled_Pickler_dump(PicklerObject *self, PyObject */

/*[clinic end generated code: output=87ecad1261e02ac7 input=552eb1c0f52260d9]*/
```

Obviously, if Argument Clinic didn’t produce any output, it’s because it found an error in your input. Keep fixing your errors and retrying until Argument Clinic processes your file without complaint.

For readability, most of the glue code has been generated to a .c.h file. You’ll need to include that in your original .c file, typically right after the clinic module block:

```c
#include "clinic/_pickle.c.h"
```
13. Double-check that the argument-parsing code Argument Clinic generated looks basically the same as the existing code.

First, ensure both places use the same argument-parsing function. The existing code must call either `PyArg_ParseTuple()` or `PyArg_ParseTupleAndKeywords()`; ensure that the code generated by Argument Clinic calls the exact same function.

Second, the format string passed in to `PyArg_ParseTuple()` or `PyArg_ParseTupleAndKeywords()` should be exactly the same as the hand-written one in the existing function, up to the colon or semi-colon.

(Argument Clinic always generates its format strings with a `:` followed by the name of the function. If the existing code’s format string ends with `;`, to provide usage help, this change is harmless —don’t worry about it.)

Third, for parameters whose format units require two arguments (like a length variable, or an encoding string, or a pointer to a conversion function), ensure that the second argument is exactly the same between the two invocations.

Fourth, inside the output portion of the block you’ll find a preprocessor macro defining the appropriate static `PyMethodDef` structure for this builtin:

```c
#define __PICKLE_PICKLER_DUMP_METHODDEF "dump", (PyCFunction)__pickle_Pickler_dump, METH_O, __pickle_Pickler_dump__doc__
```

This static structure should be exactly the same as the existing
static PyMethodDef structure for this builtin.

If any of these items differ in any way, adjust your Argument Clinic function specification and rerun Tools/clinic/clinic.py until they are the same.

14. Notice that the last line of its output is the declaration of your “impl” function. This is where the builtin’s implementation goes. Delete the existing prototype of the function you’re modifying, but leave the opening curly brace. Now delete its argument parsing code and the declarations of all the variables it dumps the arguments into. Notice how the Python arguments are now arguments to this impl function; if the implementation used different names for these variables, fix it.

Let’s reiterate, just because it’s kind of weird. Your code should now look like this:

```c
static return_type
your_function_impl( ... )
/* [clinic end generated code: checksum=...] */
{
  ...
```

Argument Clinic generated the checksum line and the function prototype just above it. You should write the opening (and closing) curly braces for the function, and the implementation inside.

Sample:

```c
/* [clinic input]
module _pickle
class _pickle.Pickler "PicklerObject *" 
"&PicklerObject";
[clinic start generated code]*/
```
Write a pickled representation of obj to the open file.

PyDoc_STRVAR(_pickle_Pickler_dump__doc__,
"Write a pickled representation of obj to the open file."
...
static PyObject *
_pickle_Pickler_dump_impl(PicklerObject *self, PyObject *)
{
    /* Check whether the Pickler was initialized
       Developers often forget to call __init__(),
       which would trigger a segfault without this check */
    if (self->write == NULL) {
        PyErr_Format(PicklingError,
                     "Pickler.__init__() was not called by %s.__init__()",
                     Py_TYPE(self)->tp_name);
        return NULL;
    }

    if (_Pickler_ClearBuffer(self) < 0)
        return NULL;
...

15. Remember the macro with the PyMethodDef structure for this
function? Find the existing `PyMethodDef` structure for this function and replace it with a reference to the macro. (If the builtin is at module scope, this will probably be very near the end of the file; if the builtin is a class method, this will probably be below but relatively near to the implementation.)

Note that the body of the macro contains a trailing comma. So when you replace the existing static `PyMethodDef` structure with the macro, don't add a comma to the end.

Sample:

```
static struct PyMethodDef Pickler_methods[] = {
    __PICKLE_PICKLER_DUMP_METHODDEF
    __PICKLE_PICKLER_CLEAR_MEMO_METHODDEF
    {NULL, NULL}          /* sentinel */
};
```

16. Compile, then run the relevant portions of the regression-test suite. This change should not introduce any new compile-time warnings or errors, and there should be no externally-visible change to Python's behavior.

Well, except for one difference: `inspect.signature()` run on your function should now provide a valid signature!

Congratulations, you've ported your first function to work with Argument Clinic!
Advanced Topics

Now that you've had some experience working with Argument Clinic, it's time for some advanced topics.

Symbolic default values

The default value you provide for a parameter can't be any arbitrary expression. Currently the following are explicitly supported:

- Numeric constants (integer and float)
- String constants
- True, False, and None
- Simple symbolic constants like `sys.maxsize`, which must start with the name of the module

In case you're curious, this is implemented in `from_builtin()` in `Lib/inspect.py`.

(In the future, this may need to get even more elaborate, to allow full expressions like `CONSTANT - 1`.)

Renaming the C functions and variables generated by Argument Clinic

Argument Clinic automatically names the functions it generates for you. Occasionally this may cause a problem, if the generated name collides with the name of an existing C function. There's an easy solution: override the names used for the C functions. Just add the keyword "as" to your function declaration line, followed by the function name you wish to use. Argument Clinic will use that function
name for the base (generated) function, then add "_impl" to the end and use that for the name of the impl function.

For example, if we wanted to rename the C function names generated for pickle.Pickler.dump, it'd look like this:

```c
/*[clinic input]
pickle.Pickler.dump as pickler_dumper
...
```

The base function would now be named `pickler_dumper()`, and the impl function would now be named `pickler_dumper_impl()`.

Similarly, you may have a problem where you want to give a parameter a specific Python name, but that name may be inconvenient in C. Argument Clinic allows you to give a parameter different names in Python and in C, using the same "as" syntax:

```c
/*[clinic input]
pickle.Pickler.dump

    obj: object
    file as file_obj: object
    protocol: object = NULL
    *
    fix_imports: bool = True
```

Here, the name used in Python (in the signature and the keywords array) would be `file`, but the C variable would be named `file_obj`.

You can use this to rename the `self` parameter too!

**Converting functions using PyArg_UnpackTuple**
To convert a function parsing its arguments with `PyArg_UnpackTuple()`, simply write out all the arguments, specifying each as an object. You may specify the type argument to cast the type as appropriate. All arguments should be marked positional-only (add a `/` on a line by itself after the last argument).

Currently the generated code will use `PyArg_ParseTuple()`, but this will change soon.

**Optional Groups**

Some legacy functions have a tricky approach to parsing their arguments: they count the number of positional arguments, then use a switch statement to call one of several different `PyArg_ParseTuple()` calls depending on how many positional arguments there are. (These functions cannot accept keyword-only arguments.) This approach was used to simulate optional arguments back before `PyArg_ParseTupleAndKeywords()` was created.

While functions using this approach can often be converted to use `PyArg_ParseTupleAndKeywords()`, optional arguments, and default values, it’s not always possible. Some of these legacy functions have behaviors `PyArg_ParseTupleAndKeywords()` doesn’t directly support. The most obvious example is the built-in function `range()`, which has an optional argument on the left side of its required argument! Another example is `curses.window.addch()`, which has a group of two arguments that must always be specified together. (The arguments are called `x` and `y`; if you call the function passing in `x`, you must also pass in `y` — and if you don’t pass in `x` you may not pass in `y` either.)
In any case, the goal of Argument Clinic is to support argument parsing for all existing CPython builtins without changing their semantics. Therefore Argument Clinic supports this alternate approach to parsing, using what are called optional groups. Optional groups are groups of arguments that must all be passed in together. They can be to the left or the right of the required arguments. They can only be used with positional-only parameters.

**Note:** Optional groups are only intended for use when converting functions that make multiple calls to `PyArg_ParseTuple()`! Functions that use any other approach for parsing arguments should almost never be converted to Argument Clinic using optional groups. Functions using optional groups currently cannot have accurate signatures in Python, because Python just doesn’t understand the concept. Please avoid using optional groups wherever possible.

To specify an optional group, add a [ on a line by itself before the parameters you wish to group together, and a ] on a line by itself after these parameters. As an example, here’s how `curses.window.addch` uses optional groups to make the first two parameters and the last parameter optional:

```c
/*[clinic input]
curses.window.addch

[ [ x: int
   X-coordinate.
y: int
   Y-coordinate.
] ]```
ch: object
    Character to add.

[  
    attr: long  
    Attributes for the character.  
] /  

Notes:

- For every optional group, one additional parameter will be passed into the impl function representing the group. The parameter will be an int named `group_{direction}_{number}`, where `{direction}` is either right or left depending on whether the group is before or after the required parameters, and `{number}` is a monotonically increasing number (starting at 1) indicating how far away the group is from the required parameters. When the impl is called, this parameter will be set to zero if this group was unused, and set to non-zero if this group was used. (By used or unused, I mean whether or not the parameters received arguments in this invocation.)
- If there are no required arguments, the optional groups will behave as if they're to the right of the required arguments.
- In the case of ambiguity, the argument parsing code favors parameters on the left (before the required parameters).
- Optional groups can only contain positional-only parameters.
- Optional groups are only intended for legacy code. Please do not use optional groups for new code.

Using real Argument Clinic converters, instead of “legacy converters”
To save time, and to minimize how much you need to learn to achieve your first port to Argument Clinic, the walkthrough above tells you to use “legacy converters”. “Legacy converters” are a convenience, designed explicitly to make porting existing code to Argument Clinic easier. And to be clear, their use is acceptable when porting code for Python 3.4.

However, in the long term we probably want all our blocks to use Argument Clinic’s real syntax for converters. Why? A couple reasons:

- The proper converters are far easier to read and clearer in their intent.
- There are some format units that are unsupported as “legacy converters”, because they require arguments, and the legacy converter syntax doesn’t support specifying arguments.
- In the future we may have a new argument parsing library that isn’t restricted to what `PyArg_ParseTuple()` supports; this flexibility won’t be available to parameters using legacy converters.

Therefore, if you don’t mind a little extra effort, please use the normal converters instead of legacy converters.

In a nutshell, the syntax for Argument Clinic (non-legacy) converters looks like a Python function call. However, if there are no explicit arguments to the function (all functions take their default values), you may omit the parentheses. Thus `bool` and `bool()` are exactly the same converters.

All arguments to Argument Clinic converters are keyword-only. All Argument Clinic converters accept the following arguments:

- `c_default`:
  - The default value for this parameter when defined in C.
Specifically, this will be the initializer for the variable declared in the “parse function”. See the section on default values for how to use this. Specified as a string.

**annotation**

The annotation value for this parameter. Not currently supported, because PEP 8 mandates that the Python library may not use annotations.

In addition, some converters accept additional arguments. Here is a list of these arguments, along with their meanings:

**accept**

A set of Python types (and possibly pseudo-types); this restricts the allowable Python argument to values of these types. (This is not a general-purpose facility; as a rule it only supports specific lists of types as shown in the legacy converter table.)

To accept None, add NoneType to this set.

**bitwise**

Only supported for unsigned integers. The native integer value of this Python argument will be written to the parameter without any range checking, even for negative values.

**converter**

Only supported by the object converter. Specifies the name of a C “converter function” to use to convert this object to a native type.

**encoding**

Only supported for strings. Specifies the encoding to use when converting this string from a Python str (Unicode) value into a C char * value.
subclass_of
Only supported for the `object` converter. Requires that the Python value be a subclass of a Python type, as expressed in C.

type
Only supported for the `object` and `self` converters. Specifies the C type that will be used to declare the variable. Default value is "PyObject *".

zeroes
Only supported for strings. If true, embedded NUL bytes ("\0") are permitted inside the value. The length of the string will be passed in to the impl function, just after the string parameter, as a parameter named `<parameter_name>_length`.

Please note, not every possible combination of arguments will work. Usually these arguments are implemented by specific `PyArg_ParseTuple` format units, with specific behavior. For example, currently you cannot call `unsigned_short` without also specifying `bitwise=True`. Although it's perfectly reasonable to think this would work, these semantics don't map to any existing format unit. So Argument Clinic doesn't support it. (Or, at least, not yet.)

Below is a table showing the mapping of legacy converters into real Argument Clinic converters. On the left is the legacy converter, on the right is the text you’d replace it with.

<table>
<thead>
<tr>
<th>Legacy</th>
<th>New Converter</th>
</tr>
</thead>
<tbody>
<tr>
<td>'B'</td>
<td>unsigned_char(bitwise=True)</td>
</tr>
<tr>
<td>'b'</td>

<td>PyBytesObject</td>
</tr>
<tr>
<td>'s'</td>
<td>str</td>
</tr>
<tr>
<td>'s#'</td>
<td>str(zeroes=True)</td>
</tr>
</tbody>
</table>
As an example, here's our sample `pickle.Pickler.dump` using the proper converter:

```c
/*[clinic input]
pickle.Pickler.dump

    obj: object
      The object to be pickled.
/

Write a pickled representation of obj to the open file
[clinic start generated code]*/
```
Argument Clinic will show you all the converters it has available. For each converter it'll show you all the parameters it accepts, along with the default value for each parameter. Just run `Tools/clinic/clinic.py --converters` to see the full list.

Py_buffer

When using the `Py_buffer` converter (or the `'s*`, `'w*`, `'y`', or `'z*` legacy converters), you must not call `PyBuffer_Release()` on the provided buffer. Argument Clinic generates code that does it for you (in the parsing function).

Advanced converters

Remember those format units you skipped for your first time because they were advanced? Here's how to handle those too.

The trick is, all those format units take arguments—either conversion functions, or types, or strings specifying an encoding. (But “legacy converters” don't support arguments. That's why we skipped them for your first function.) The argument you specified to the format unit is now an argument to the converter; this argument is either converter (for `0&`), subclass_of (for `0!`), or encoding (for all the format units that start with e).

When using subclass_of, you may also want to use the other custom argument for object(): type, which lets you set the type actually used for the parameter. For example, if you want to ensure that the object is a subclass of `PyUnicode_Type`, you probably want to use the converter object(type='PyUnicodeObject *', subclass_of='&PyUnicode_Type').
One possible problem with using Argument Clinic: it takes away some possible flexibility for the format units starting with e. When writing a PyArg_Parse call by hand, you could theoretically decide at runtime what encoding string to pass in to PyArg_ParseTuple(). But now this string must be hard-coded at Argument-Clinic-preprocessing-time. This limitation is deliberate; it made supporting this format unit much easier, and may allow for future optimizations. This restriction doesn’t seem unreasonable; CPython itself always passes in static hard-coded encoding strings for parameters whose format units start with e.

Parameter default values

Default values for parameters can be any of a number of values. At their simplest, they can be string, int, or float literals:

```python
goog: str = "abc"
bar: int = 123
bat: float = 45.6
```

They can also use any of Python’s built-in constants:

```python
yep: bool = True
nope: bool = False
nada: object = None
```

There’s also special support for a default value of NULL, and for simple expressions, documented in the following sections.

The NULL default value

For string and object parameters, you can set them to None to indicate that there’s no default. However, that means the C variable
will be initialized to Py_None. For convenience’s sakes, there’s a special value called NULL for just this reason: from Python’s perspective it behaves like a default value of None, but the C variable is initialized with NULL.

Expressions specified as default values

The default value for a parameter can be more than just a literal value. It can be an entire expression, using math operators and looking up attributes on objects. However, this support isn’t exactly simple, because of some non-obvious semantics.

Consider the following example:

```
foo: Py_ssize_t = sys.maxsize - 1
```

sys.maxsize can have different values on different platforms. Therefore Argument Clinic can’t simply evaluate that expression locally and hard-code it in C. So it stores the default in such a way that it will get evaluated at runtime, when the user asks for the function’s signature.

What namespace is available when the expression is evaluated? It’s evaluated in the context of the module the builtin came from. So, if your module has an attribute called “max_widgets”, you may simply use it:

```
foo: Py_ssize_t = max_widgets
```

If the symbol isn’t found in the current module, it fails over to looking in sys.modules. That’s how it can find sys.maxsize for example. (Since you don’t know in advance what modules the user will load into
their interpreter, it’s best to restrict yourself to modules that are preloaded by Python itself.)

Evaluating default values only at runtime means Argument Clinic can’t compute the correct equivalent C default value. So you need to tell it explicitly. When you use an expression, you must also specify the equivalent expression in C, using the `c_default` parameter to the converter:

```
foo: Py_ssize_t(c_default="PY_SSIZE_T_MAX - 1") = sys
```

Another complication: Argument Clinic can’t know in advance whether or not the expression you supply is valid. It parses it to make sure it looks legal, but it can’t actually know. You must be very careful when using expressions to specify values that are guaranteed to be valid at runtime!

Finally, because expressions must be representable as static C values, there are many restrictions on legal expressions. Here’s a list of Python features you’re not permitted to use:

- Function calls.
- Inline if statements (`3 if foo else 5`).
- Automatic sequence unpacking (`*[1, 2, 3]`).
- List/set/dict comprehensions and generator expressions.
- Tuple/list/set/dict literals.

Using a return converter

By default the impl function Argument Clinic generates for you returns `PyObject *`. But your C function often computes some C type, then converts it into the `PyObject *` at the last moment. Argument Clinic
handles converting your inputs from Python types into native C types—why not have it convert your return value from a native C type into a Python type too?

That’s what a “return converter” does. It changes your impl function to return some C type, then adds code to the generated (non-impl) function to handle converting that value into the appropriate Python type.

The syntax for return converters is similar to that of parameter converters. You specify the return converter like it was a return annotation on the function itself. Return converters behave much the same as parameter converters; they take arguments, the arguments are all keyword-only, and if you’re not changing any of the default arguments you can omit the parentheses.

(If you use both "as" and a return converter for your function, the "as" should come before the return converter.)

There’s one additional complication when using return converters: how do you indicate an error has occurred? Normally, a function returns a valid (non-NULL) pointer for success, and NULL for failure. But if you use an integer return converter, all integers are valid. How can Argument Clinic detect an error? Its solution: each return converter implicitly looks for a special value that indicates an error. If you return that value, and an error has been set (PyErr_Occurred() returns a true value), then the generated code will propagate the error. Otherwise it will encode the value you return like normal.

Currently Argument Clinic supports only a few return converters:

```plaintext
bool
int
```
None of these take parameters. For the first three, return -1 to indicate error. For DecodeFSDefault, the return type is `char *`; return a NULL pointer to indicate an error.

(There’s also an experimental `NoneType` converter, which lets you return `Py_None` on success or `NULL` on failure, without having to increment the reference count on `Py_None`. I’m not sure it adds enough clarity to be worth using.)

To see all the return converters Argument Clinic supports, along with their parameters (if any), just run `Tools/clinic/clinic.py --converters` for the full list.

**Cloning existing functions**

If you have a number of functions that look similar, you may be able to use Clinic’s “clone” feature. When you clone an existing function, you reuse:

- its parameters, including
  - their names,
  - their converters, with all parameters,
  - their default values,
  - their per-parameter docstrings,
  - their `kind` (whether they’re positional only, positional or
keyword, or keyword only), and

- its return converter.

The only thing not copied from the original function is its docstring; the syntax allows you to specify a new docstring.

Here's the syntax for cloning a function:

```c
/*[clinic input]
module.class.new_function [as c_basename] = module.class.existing_function

Docstring for new_function goes here.
[clinic start generated code]*/
```

(The functions can be in different modules or classes. I wrote `module.class` in the sample just to illustrate that you must use the full path to both functions.)

Sorry, there's no syntax for partially-cloning a function, or cloning a function then modifying it. Cloning is an all-or nothing proposition.

Also, the function you are cloning from must have been previously defined in the current file.

### Calling Python code

The rest of the advanced topics require you to write Python code which lives inside your C file and modifies Argument Clinic's runtime state. This is simple: you simply define a Python block.

A Python block uses different delimiter lines than an Argument Clinic function block. It looks like this:
All the code inside the Python block is executed at the time it’s parsed. All text written to stdout inside the block is redirected into the “output” after the block.

As an example, here's a Python block that adds a static integer variable to the C code:

```python
print('static int __ignored_unused_variable__ = 0;')
```

Using a “self converter”

Argument Clinic automatically adds a “self” parameter for you using a default converter. It automatically sets the type of this parameter to the “pointer to an instance” you specified when you declared the type. However, you can override Argument Clinic’s converter and specify one yourself. Just add your own self parameter as the first parameter in a block, and ensure that its converter is an instance of self_converter or a subclass thereof.

What’s the point? This lets you override the type of self, or give it a different default name.

How do you specify the custom type you want to cast self to? If you only have one or two functions with the same type for self, you can
directly use Argument Clinic's existing `self` converter, passing in the type you want to use as the `type` parameter:

```c++
/*[clinic input]

_pickle.Pickler.dump

    self: self(type="PicklerObject *")
    obj: object

Write a pickled representation of the given object to the open file.
[clinic start generated code]*/
```

On the other hand, if you have a lot of functions that will use the same type for `self`, it's best to create your own converter, subclassing `self_converter` but overwriting the `type` member:

```python
/*[python input]
class PicklerObject_converter(self_converter):
    type = "PicklerObject *
[python start generated code]*/

/*[clinic input]

_pickle.Pickler.dump

    self: PicklerObject
    obj: object

Write a pickled representation of the given object to the open file.
[clinic start generated code]*/
```
Writing a custom converter

As we hinted at in the previous section... you can write your own converters! A converter is simply a Python class that inherits from `CConverter`. The main purpose of a custom converter is if you have a parameter using the 0& format unit—parsing this parameter means calling a `PyArg_ParseTuple()` “converter function”.

Your converter class should be named `*something*_converter`. If the name follows this convention, then your converter class will be automatically registered with Argument Clinic; its name will be the name of your class with the `_converter` suffix stripped off. (This is accomplished with a metaclass.)

You shouldn't subclass `CConverter.__init__`. Instead, you should write a `converter_init()` function. `converter_init()` always accepts a `self` parameter; after that, all additional parameters must be keyword-only. Any arguments passed in to the converter in Argument Clinic will be passed along to your `converter_init()`.

There are some additional members of `CConverter` you may wish to specify in your subclass. Here’s the current list:

- **type**
  The C type to use for this variable. `type` should be a Python string specifying the type, e.g. `int`. If this is a pointer type, the type string should end with `' *'`.

- **default**
  The Python default value for this parameter, as a Python value. Or the magic value `unspecified` if there is no default.
**default** as it should appear in Python code, as a string. Or **None** if there is no default.

**c_default**

**default** as it should appear in C code, as a string. Or **None** if there is no default.

**c_ignored_default**

The default value used to initialize the C variable when there is no default, but not specifying a default may result in an “uninitialized variable” warning. This can easily happen when using option groups—although properly-written code will never actually use this value, the variable does get passed in to the impl, and the C compiler will complain about the “use” of the uninitialized value. This value should always be a non-empty string.

**converter**

The name of the C converter function, as a string.

**impl_by_reference**

A boolean value. If true, Argument Clinic will add a & in front of the name of the variable when passing it into the impl function.

**parse_by_reference**

A boolean value. If true, Argument Clinic will add a & in front of the name of the variable when passing it into `PyArg_ParseTuple()`.

Here's the simplest example of a custom converter, from `Modules/zlibmodule.c`:

```python
/*[python input]*/

class ssize_t_converter(CConverter):
    type = 'Py_ssize_t'
    converter = 'ssize_t_converter'

[python start generated code]*/
```
This block adds a converter to Argument Clinic named `ssize_t`. Parameters declared as `ssize_t` will be declared as type `Py_ssize_t`, and will be parsed by the `'0&'` format unit, which will call the `ssize_t_converter` converter function. `ssize_t` variables automatically support default values.

More sophisticated custom converters can insert custom C code to handle initialization and cleanup. You can see more examples of custom converters in the CPython source tree; grep the C files for the string `CConverter`.

**Writing a custom return converter**

Writing a custom return converter is much like writing a custom converter. Except it’s somewhat simpler, because return converters are themselves much simpler.

Return converters must subclass `CReturnConverter`. There are no examples yet of custom return converters, because they are not widely used yet. If you wish to write your own return converter, please read `Tools/clinic/clinic.py`, specifically the implementation of `CReturnConverter` and all its subclasses.

**METH_O and METH_NOARGS**

To convert a function using `METH_O`, make sure the function’s single argument is using the `object` converter, and mark the arguments as positional-only:
To convert a function using METH_NOARGS, just don't specify any arguments.

You can still use a self converter, a return converter, and specify a type argument to the object converter for METH_O.

**tp_new and tp_init functions**

You can convert `tp_new` and `tp_init` functions. Just name them `__new__` or `__init__` as appropriate. Notes:

- The function name generated for `__new__` doesn't end in `__new__` like it would by default. It's just the name of the class, converted into a valid C identifier.
- No `PyMethodDef` define is generated for these functions.
- `__init__` functions return `int`, not `PyObject` *.
- Use the docstring as the class docstring.
- Although `__new__` and `__init__` functions must always accept both the `args` and `kwargs` objects, when converting you may specify any signature for these functions that you like. (If your function doesn’t support keywords, the parsing function generated will throw an exception if it receives any.)

**Changing and redirecting Clinic’s output**

It can be inconvenient to have Clinic's output interspersed with your
conventional hand-edited C code. Luckily, Clinic is configurable: you can buffer up its output for printing later (or earlier!), or write its output to a separate file. You can also add a prefix or suffix to every line of Clinic’s generated output.

While changing Clinic’s output in this manner can be a boon to readability, it may result in Clinic code using types before they are defined, or your code attempting to use Clinic-generated code before it is defined. These problems can be easily solved by rearranging the declarations in your file, or moving where Clinic’s generated code goes. (This is why the default behavior of Clinic is to output everything into the current block; while many people consider this hampers readability, it will never require rearranging your code to fix definition-before-use problems.)

Let's start with defining some terminology:

field

A field, in this context, is a subsection of Clinic's output. For example, the `#define` for the PyMethodDef structure is a field, called `methoddef_define`. Clinic has seven different fields it can output per function definition:

```
docstring_prototype
docstring_definition
methoddef_define
impl_prototype
parser_prototype
parser_definition
impl_definition
```

All the names are of the form "<a>_<b>", where "<a>" is the semantic object represented (the parsing function, the impl
function, the docstring, or the methoddef structure) and "<b>" represents what kind of statement the field is. Field names that end in "_prototype" represent forward declarations of that thing, without the actual body/data of the thing; field names that end in "_definition" represent the actual definition of the thing, with the body/data of the thing. ("methoddef" is special, it's the only one that ends with "_define", representing that it's a preprocessor #define.)

**destination**

A destination is a place Clinic can write output to. There are five built-in destinations:

**block**

The default destination: printed in the output section of the current Clinic block.

**buffer**

A text buffer where you can save text for later. Text sent here is appended to the end of any existing text. It's an error to have any text left in the buffer when Clinic finishes processing a file.

**file**

A separate “clinic file” that will be created automatically by Clinic. The filename chosen for the file is `{basename}.clinic{extension}`, where `basename` and `extension` were assigned the output from `os.path.splitext()` run on the current file. (Example: the file destination for `_pickle.c` would be written to `_pickle.clinic.c`.)

**Important:** When using a file destination, you **must check in the generated file!**
two-pass
A buffer like buffer. However, a two-pass buffer can only be dumped once, and it prints out all text sent to it during all processing, even from Clinic blocks after the dumping point.

suppress
The text is suppressed—thrown away.

Clinic defines five new directives that let you reconfigure its output.

The first new directive is dump:

dump <destination>

This dumps the current contents of the named destination into the output of the current block, and empties it. This only works with buffer and two-pass destinations.

The second new directive is output. The most basic form of output is like this:

output <field> <destination>

This tells Clinic to output field to destination. output also supports a special meta-destination, called everything, which tells Clinic to output all fields to that destination.

output has a number of other functions:

output push
output pop
output preset <preset>

output push and output pop allow you to push and pop
configurations on an internal configuration stack, so that you can temporarily modify the output configuration, then easily restore the previous configuration. Simply push before your change to save the current configuration, then pop when you wish to restore the previous configuration.

`output preset` sets Clinic's output to one of several built-in preset configurations, as follows:

**block**

Clinic's original starting configuration. Writes everything immediately after the input block.

Suppress the `parser_prototype` and `docstring_prototype`, write everything else to `block`.

**file**

Designed to write everything to the “clinic file” that it can. You then `#include` this file near the top of your file. You may need to rearrange your file to make this work, though usually this just means creating forward declarations for various `typedef` and `PyTypeObject` definitions.

Suppress the `parser_prototype` and `docstring_prototype`, write the `impl_definition` to `block`, and write everything else to `file`.

The default filename is "{dirname}/clinic/{basename}.h".

**buffer**

Save up most of the output from Clinic, to be written into your file near the end. For Python files implementing modules or
builtin types, it’s recommended that you dump the buffer just above the static structures for your module or builtin type; these are normally very near the end. Using buffer may require even more editing than file, if your file has static PyMethodDef arrays defined in the middle of the file.

Suppress the parser_prototype, impl_prototype, and docstring_prototype, write the impl_definition to block, and write everything else to file.

two-pass
Similar to the buffer preset, but writes forward declarations to the two-pass buffer, and definitions to the buffer. This is similar to the buffer preset, but may require less editing than buffer. Dump the two-pass buffer near the top of your file, and dump the buffer near the end just like you would when using the buffer preset.

Suppresses the impl_prototype, write the impl_definition to block, write docstring_prototype, methoddef_define, and parser_prototype to two-pass, write everything else to buffer.

partial-buffer
Similar to the buffer preset, but writes more things to block, only writing the really big chunks of generated code to buffer. This avoids the definition-before-use problem of buffer completely, at the small cost of having slightly more stuff in the block’s output. Dump the buffer near the end, just like you would when using the buffer preset.
Suppresses the `impl_prototype`, write the `docstring_definition` and `parser_definition` to buffer, write everything else to block.

The third new directive is `destination`:

```
destination <name> <command> [...]  
```

This performs an operation on the destination named `name`.

There are two defined subcommands: `new` and `clear`.

The `new` subcommand works like this:

```
destination <name> new <type>  
```

This creates a new destination with name `name` and type `type`.

There are five destination types:

- `suppress`
  - Throws the text away.
- `block`
  - Writes the text to the current block. This is what Clinic originally did.
- `buffer`
  - A simple text buffer, like the “buffer” builtin destination above.
- `file`
  - A text file. The file destination takes an extra argument, a template to use for building the filename, like so:
```
destination <name> new <type> <file_template>  
```
The template can use three strings internally that will be replaced by bits of the filename:

{path}
The full path to the file, including directory and full filename.

{dirname}
The name of the directory the file is in.

{basename}
Just the name of the file, not including the directory.

{basename_root}
Basename with the extension clipped off (everything up to but not including the last ‘.’).

{basename_extension}
The last ‘.’ and everything after it. If the basename does not contain a period, this will be the empty string.

If there are no periods in the filename, {basename} and {filename} are the same, and {extension} is empty. “{basename}{extension}” is always exactly the same as “{filename}”.

two-pass
A two-pass buffer, like the “two-pass” builtin destination above.

The clear subcommand works like this:

```
destination <name> clear
```

It removes all the accumulated text up to this point in the destination. (I don’t know what you’d need this for, but I thought maybe it’d be useful while someone’s experimenting.)
The fourth new directive is `set`:

```
set line_prefix "string"
set line_suffix "string"
```

`set` lets you set two internal variables in Clinic. `line_prefix` is a string that will be prepended to every line of Clinic's output; `line_suffix` is a string that will be appended to every line of Clinic's output.

Both of these support two format strings:

```
{block comment start}
    Turns into the string /*, the start-comment text sequence for C files.
{block comment end}
    Turns into the string */, the end-comment text sequence for C files.
```

The final new directive is one you shouldn’t need to use directly, called `preserve`:

```
preserve
```

This tells Clinic that the current contents of the output should be kept, unmodified. This is used internally by Clinic when dumping output into `file` files; wrapping it in a Clinic block lets Clinic use its existing checksum functionality to ensure the file was not modified by hand before it gets overwritten.

**The #ifdef trick**
If you're converting a function that isn't available on all platforms, there's a trick you can use to make life a little easier. The existing code probably looks like this:

```
#ifdef HAVE_FUNCTIONNAME
static module_functionname(...) 
{
...
}
#endif /* HAVE_FUNCTIONNAME */
```

And then in the `PyMethodDef` structure at the bottom the existing code will have:

```
#ifdef HAVE_FUNCTIONNAME
{"functionname", ... },
#endif /* HAVE_FUNCTIONNAME */
```

In this scenario, you should enclose the body of your impl function inside the `#ifdef`, like so:

```
#ifdef HAVE_FUNCTIONNAME
/*[clinic input]*/
module.functionname
...
[clinic start generated code]*/
static module_functionname(...)
{
...
}
#endif /* HAVE_FUNCTIONNAME */
```

Then, remove those three lines from the `PyMethodDef` structure, replacing them with the macro Argument Clinic generated:
(You can find the real name for this macro inside the generated code. Or you can calculate it yourself: it’s the name of your function as defined on the first line of your block, but with periods changed to underscores, uppercased, and "_METHODDEF" added to the end.)

Perhaps you’re wondering: what if HAVE_FUNCTIONNAME isn’t defined? The MODULE_FUNCTIONNAME_METHODDEF macro won’t be defined either!

Here’s where Argument Clinic gets very clever. It actually detects that the Argument Clinic block might be deactivated by the #ifdef. When that happens, it generates a little extra code that looks like this:

```
#ifndef MODULE_FUNCTIONNAME_METHODDEF
#define MODULE_FUNCTIONNAME_METHODDEF
#endif /* !defined(MODULE_FUNCTIONNAME_METHODDEF) */
```

That means the macro always works. If the function is defined, this turns into the correct structure, including the trailing comma. If the function is undefined, this turns into nothing.

However, this causes one ticklish problem: where should Argument Clinic put this extra code when using the “block” output preset? It can’t go in the output block, because that could be deactivated by the #ifdef. (That’s the whole point!)

In this situation, Argument Clinic writes the extra code to the “buffer” destination. This may mean that you get a complaint from Argument Clinic:

Warning in file "Modules/posixmodule.c" on line 1235
When this happens, just open your file, find the dump buffer block that Argument Clinic added to your file (it'll be at the very bottom), then move it above the PyMethodDef structure where that macro is used.

Using Argument Clinic in Python files

It's actually possible to use Argument Clinic to preprocess Python files. There's no point to using Argument Clinic blocks, of course, as the output wouldn't make any sense to the Python interpreter. But using Argument Clinic to run Python blocks lets you use Python as a Python preprocessor!

Since Python comments are different from C comments, Argument Clinic blocks embedded in Python files look slightly different. They look like this:

```python
#if/*[python input]
# print("def foo(): pass")
#[python start generated code]*/
def foo(): pass
#/*[python checksum:...]*/
```

```python
Destination buffer 'buffer' not empty at end of file,
emptying.
When this happens, just open your file, find the dump buffer block
that Argument Clinic added to your file (it'll be at the very bottom), then
move it above the PyMethodDef structure where that macro is used.

Using Argument Clinic in Python files

It's actually possible to use Argument Clinic to preprocess Python files. There's no point to using Argument Clinic blocks, of course, as the output wouldn't make any sense to the Python interpreter. But using Argument Clinic to run Python blocks lets you use Python as a Python preprocessor!

```python
#/*[python input]
# print("def foo(): pass")
#[python start generated code]*/
def foo(): pass
#/*[python checksum:...]*/
```
Instrumenting CPython with DTrace and SystemTap

DTrace and SystemTap are monitoring tools, each providing a way to inspect what the processes on a computer system are doing. They both use domain-specific languages allowing a user to write scripts which:

- filter which processes are to be observed
- gather data from the processes of interest
- generate reports on the data

As of Python 3.6, CPython can be built with embedded “markers”, also known as “probes”, that can be observed by a DTrace or SystemTap script, making it easier to monitor what the CPython processes on a system are doing.

**CPython implementation detail:** DTrace markers are implementation details of the CPython interpreter. No guarantees are made about probe compatibility between versions of CPython. DTrace scripts can stop working or work incorrectly without warning when changing CPython versions.
Enabling the static markers

macOS comes with built-in support for DTrace. On Linux, in order to build CPython with the embedded markers for SystemTap, the SystemTap development tools must be installed.

On a Linux machine, this can be done via:

```
$ yum install systemtap-sdt-devel
```

or:

```
$ sudo apt-get install systemtap-sdt-dev
```

CPython must then be configured `--with-dtrace`:

```
checking for --with-dtrace... yes
```

On macOS, you can list available DTrace probes by running a Python process in the background and listing all probes made available by the Python provider:

```
$ python3.6 -q &
$ sudo dtrace -l -P python$
```

<table>
<thead>
<tr>
<th>ID</th>
<th>PROVIDER</th>
<th>MODULE</th>
<th>FUNCTION NAME</th>
</tr>
</thead>
<tbody>
<tr>
<td>29564</td>
<td>python18035</td>
<td>python3.6</td>
<td>_PyEval_EvalFrameDefault</td>
</tr>
<tr>
<td>29565</td>
<td>python18035</td>
<td>python3.6</td>
<td>_PyEval_EvalFrameDefault</td>
</tr>
<tr>
<td>29566</td>
<td>python18035</td>
<td>python3.6</td>
<td>_PyEval_EvalFrameDefault</td>
</tr>

<td>python3.6</td>
<td>_PyEval_EvalFrameDefault</td>
</tr>
<tr>
<td>29571</td>
<td>python18035</td>
<td>python3.6</td>
<td>_PyEval_EvalFrameDefault</td>
</tr>
</tbody>
</table>
On Linux, you can verify if the SystemTap static markers are present in the built binary by seeing if it contains a “.note.stapsdt” section.

```
$ readelf -S ./python | grep .note.stapsdt
[30] .note.stapsdt     NOTE      0000000000000000
```

If you've built Python as a shared library (with --enable-shared), you need to look instead within the shared library. For example:

```
$ readelf -S libpython3.3dm.so.1.0 | grep .note.stapsdt
[29] .note.stapsdt     NOTE      0000000000000000
```

Sufficiently modern readelf can print the metadata:

```
$ readelf -n ./python

    Name: gc__start
    Location: 0x000000000000000004371c3, Base: 0x0000000000000000
    Arguments: -4@%ebx
```
The above metadata contains information for SystemTap describing how it can patch strategically-placed machine code instructions to enable the tracing hooks used by a SystemTap script.
Static DTrace probes

The following example DTrace script can be used to show the call/return hierarchy of a Python script, only tracing within the invocation of a function called “start”. In other words, import-time function invocations are not going to be listed:

```plaintext
self int indent;

python$target:::function-entry
/copyinstr(arg1) == "start"/
{
    self->trace = 1;
}

python$target:::function-entry
/self->trace/
{
    printf("%d\t%*s:", timestamp, 15, probename);
    printf("%*s", self->indent, "");
    printf("%s:%s:%d\n", basename(copyinstr(arg0)),
            self->indent++;
}

python$target:::function-return
/self->trace/
{
    self->indent--;
    printf("%d\t%*s:", timestamp, 15, probename);
    printf("%*s", self->indent, "");
    printf("%s:%s:%d\n", basename(copyinstr(arg0)),
}

python$target:::function-return
/copyinstr(arg1) == "start"/
```
It can be invoked like this:

```
$ sudo dtrace -q -s call_stack.d -c "python3.6 script.py"
```

The output looks like this:

```
156641360502280    function-entry:call_stack.py:start:23
156641360518804    function-entry: call_stack.py:function_1:1
156641360532797    function-entry: call_stack.py:function_3:9
156641360546807    function-return: call_stack.py:function_3:10
156641360563367    function-return: call_stack.py:function_1:2
156641360578365    function-entry: call_stack.py:function_2:5
156641360591757    function-entry: call_stack.py:function_1:1
156641360605556    function-entry: call_stack.py:function_3:9
156641360617482    function-return: call_stack.py:function_3:10
156641360629814    function-return: call_stack.py:function_1:2
156641360642285    function-return: call_stack.py:function_2:6
156641360656770    function-entry: call_stack.py:function_3:9
156641360669707    function-return: call_stack.py:function_3:10
156641360687853    function-entry: call_stack.py:function_4:13
156641360700719    function-return: call_stack.py:function_4:14
156641360719640    function-return: call_stack.py:function_5:18
156641360732567    function-return: call_stack.py:start:28
```
Static SystemTap markers

The low-level way to use the SystemTap integration is to use the static markers directly. This requires you to explicitly state the binary file containing them.

For example, this SystemTap script can be used to show the call/return hierarchy of a Python script:

```bash
probe process("python").mark("function__entry") {
    filename = user_string($arg1);
    funcname = user_string($arg2);
    lineno = $arg3;

    printf("%s => %s in %s:%d\n",
        thread_indent(1), funcname, filename, lineno);
}

probe process("python").mark("function__return") {
    filename = user_string($arg1);
    funcname = user_string($arg2);
    lineno = $arg3;

    printf("%s <= %s in %s:%d\n",
        thread_indent(-1), funcname, filename, lineno);
}
```

It can be invoked like this:

```bash
$ stap \
  show-call-hierarchy.stp \
  -c "/python test.py"
```

The output looks like this:
where the columns are:

- time in microseconds since start of script
- name of executable
- PID of process

and the remainder indicates the call/return hierarchy as the script executes.

For a `-enable-shared` build of CPython, the markers are contained within the libpython shared library, and the probe’s dotted path needs to reflect this. For example, this line from the above example:

```python
probe process("python").mark("function__entry") {
```

should instead read:

```python
probe process("python").library("libpython3.6dm.so.1")
```

(assuming a debug build of CPython 3.6)
Available static markers

**function__entry**(str `filename`, str `funcname`, int `lineno`)

This marker indicates that execution of a Python function has begun. It is only triggered for pure-Python (bytecode) functions.

The filename, function name, and line number are provided back to the tracing script as positional arguments, which must be accessed using $arg1, $arg2, $arg3:

- $arg1 : (const char *) filename, accessible using `user_string($arg1)`
- $arg2 : (const char *) function name, accessible using `user_string($arg2)`
- $arg3 : int line number

**function__return**(str `filename`, str `funcname`, int `lineno`)

This marker is the converse of `function__entry()`, and indicates that execution of a Python function has ended (either via `return`, or via an exception). It is only triggered for pure-Python (bytecode) functions.

The arguments are the same as for `function__entry()`

**line**(str `filename`, str `funcname`, int `lineno`)

This marker indicates a Python line is about to be executed. It is the equivalent of line-by-line tracing with a Python profiler. It is not triggered within C functions.

The arguments are the same as for `function__entry()`

**gc__start**(int `generation`)
Fires when the Python interpreter starts a garbage collection cycle. 
arg0 is the generation to scan, like `gc.collect()`.

`gc__done` (long `collected`)

Fires when the Python interpreter finishes a garbage collection cycle. 
arg0 is the number of collected objects.
SystemTap Tapsets

The higher-level way to use the SystemTap integration is to use a “tapset”: SystemTap’s equivalent of a library, which hides some of the lower-level details of the static markers.

Here is a tapset file, based on a non-shared build of CPython:

```plaintext
/*
   Provide a higher-level wrapping around the function__entry and function__return markers:
 */
probe python.function.entry = process("python").mark{
    filename = user_string($arg1);
    funcname = user_string($arg2);
    lineno = $arg3;
    frameptr = $arg4
}
probe python.function.return = process("python").mark{
    filename = user_string($arg1);
    funcname = user_string($arg2);
    lineno = $arg3;
    frameptr = $arg4
}
```

If this file is installed in SystemTap’s tapset directory (e.g. `/usr/share/systemtap/tapset`), then these additional probe points become available:

```plaintext
python.function.entry(str filename, str funcname, int lineno, frameptr)
```
This probe point indicates that execution of a Python function has begun. It is only triggered for pure-python (bytecode) functions.

```python
python.function.return(str filename, str funcname, int lineno, frameptr)
```

This probe point is the converse of `python.function.return()`, and indicates that execution of a Python function has ended (either via `return`, or via an exception). It is only triggered for pure-python (bytecode) functions.
Examples

This SystemTap script uses the tapset above to more cleanly implement the example given above of tracing the Python function-call hierarchy, without needing to directly name the static markers:

```plaintext
probe python.function.entry
{
    printf("%s => %s in %s:%d\n",
            thread_indent(1),
            funcname,
            filename,
            lineno);
}

probe python.function.return
{
    printf("%s <= %s in %s:%d\n",
            thread_indent(-1),
            funcname,
            filename,
            lineno);
}
```

The following script uses the tapset above to provide a top-like view of all running CPython code, showing the top 20 most frequently-entered bytecode frames, each second, across the whole system:

```plaintext
global fn_calls;

probe python.function.entry
{
    fn_calls[pid(), filename, funcname, lineno] += 1;
}

probe timer.ms(1000) {
    printf("\033[2J\033[1;1H") /* clear screen */
    printf("%6s %80s %6s %30s %6s\n",
            "PID", "FILENAME", "LINE", "FUNCTION", "CALLS")
    foreach ([pid, filename, funcname, lineno] in fn_calls) {
        printf("%6d %80s %6s %30s %6d\n", pid, filename, funcname, lineno, fn_calls[pid, filename, funcname, lineno]);
    }
}
```
printf("%6d %80s %6d %30s %6d\n",
pid, filename, lineno, funcname,
fn_calls[pid, filename, funcname, lineno];
}
delete fn_calls;

General Information

What is Python?

Python is an interpreted, interactive, object-oriented programming language. It incorporates modules, exceptions, dynamic typing, very high level dynamic data types, and classes. Python combines remarkable power with very clear syntax. It has interfaces to many system calls and libraries, as well as to various window systems, and is extensible in C or C++. It is also usable as an extension language for applications that need a programmable interface. Finally, Python is portable: it runs on many Unix variants, on the Mac, and on Windows 2000 and later.

To find out more, start with The Python Tutorial. The Beginner’s Guide to Python links to other introductory tutorials and resources for learning Python.

What is the Python Software Foundation?

The Python Software Foundation is an independent non-profit organization that holds the copyright on Python versions 2.1 and newer. The PSF’s mission is to advance open source technology related to the Python programming language and to publicize the use of Python. The PSF’s home page is at https://www.python.org/psf/.

Donations to the PSF are tax-exempt in the US. If you use Python and find it helpful, please contribute via the PSF donation page.

Are there copyright restrictions on the use of Python?
You can do anything you want with the source, as long as you leave the copyrights in and display those copyrights in any documentation about Python that you produce. If you honor the copyright rules, it's OK to use Python for commercial use, to sell copies of Python in source or binary form (modified or unmodified), or to sell products that incorporate Python in some form. We would still like to know about all commercial use of Python, of course.

See the PSF license page to find further explanations and a link to the full text of the license.

The Python logo is trademarked, and in certain cases permission is required to use it. Consult the Trademark Usage Policy for more information.

Why was Python created in the first place?

Here's a very brief summary of what started it all, written by Guido van Rossum:

I had extensive experience with implementing an interpreted language in the ABC group at CWI, and from working with this group I had learned a lot about language design. This is the origin of many Python features, including the use of indentation for statement grouping and the inclusion of very-high-level data types (although the details are all different in Python).

I had a number of gripes about the ABC language, but also liked many of its features. It was impossible to extend the ABC language (or its implementation) to remedy my complaints – in fact its lack of extensibility was one of its biggest problems. I had some experience with using Modula-2+ and talked with the designers of Modula-3 and read the Modula-3 report. Modula-3 is
the origin of the syntax and semantics used for exceptions, and some other Python features.

I was working in the Amoeba distributed operating system group at CWI. We needed a better way to do system administration than by writing either C programs or Bourne shell scripts, since Amoeba had its own system call interface which wasn’t easily accessible from the Bourne shell. My experience with error handling in Amoeba made me acutely aware of the importance of exceptions as a programming language feature.

It occurred to me that a scripting language with a syntax like ABC but with access to the Amoeba system calls would fill the need. I realized that it would be foolish to write an Amoeba-specific language, so I decided that I needed a language that was generally extensible.

During the 1989 Christmas holidays, I had a lot of time on my hand, so I decided to give it a try. During the next year, while still mostly working on it in my own time, Python was used in the Amoeba project with increasing success, and the feedback from colleagues made me add many early improvements.

In February 1991, after just over a year of development, I decided to post to USENET. The rest is in the Misc/HISTORY file.

**What is Python good for?**

Python is a high-level general-purpose programming language that can be applied to many different classes of problems.

The language comes with a large standard library that covers areas such as string processing (regular expressions, Unicode, calculating
differences between files), Internet protocols (HTTP, FTP, SMTP, XML-RPC, POP, IMAP, CGI programming), software engineering (unit testing, logging, profiling, parsing Python code), and operating system interfaces (system calls, filesystems, TCP/IP sockets). Look at the table of contents for The Python Standard Library to get an idea of what’s available. A wide variety of third-party extensions are also available. Consult the Python Package Index to find packages of interest to you.

How does the Python version numbering scheme work?

Python versions are numbered A.B.C or A.B. A is the major version number – it is only incremented for really major changes in the language. B is the minor version number, incremented for less earth-shattering changes. C is the micro-level – it is incremented for each bugfix release. See PEP 6 for more information about bugfix releases.

Not all releases are bugfix releases. In the run-up to a new major release, a series of development releases are made, denoted as alpha, beta, or release candidate. Alphas are early releases in which interfaces aren’t yet finalized; it’s not unexpected to see an interface change between two alpha releases. Betas are more stable, preserving existing interfaces but possibly adding new modules, and release candidates are frozen, making no changes except as needed to fix critical bugs.

Alpha, beta and release candidate versions have an additional suffix. The suffix for an alpha version is “aN” for some small number N, the suffix for a beta version is “bN” for some small number N, and the suffix for a release candidate version is “cN” for some small number N. In other words, all versions labeled 2.0aN precede the versions
labeled 2.0bN, which precede versions labeled 2.0cN, and those precede 2.0.

You may also find version numbers with a “+” suffix, e.g. “2.2+”. These are unreleased versions, built directly from the CPython development repository. In practice, after a final minor release is made, the version is incremented to the next minor version, which becomes the “a0” version, e.g. “2.4a0”.

See also the documentation for `sys.version`, `sys.hexversion`, and `sys.version_info`.

**How do I obtain a copy of the Python source?**

The latest Python source distribution is always available from python.org, at [https://www.python.org/downloads/](https://www.python.org/downloads/). The latest development sources can be obtained at [https://github.com/python/cpython/](https://github.com/python/cpython/).

The source distribution is a gzipped tar file containing the complete C source, Sphinx-formatted documentation, Python library modules, example programs, and several useful pieces of freely distributable software. The source will compile and run out of the box on most UNIX platforms.

Consult the Getting Started section of the Python Developer’s Guide for more information on getting the source code and compiling it.

**How do I get documentation on Python?**

The standard documentation for the current stable version of Python is available at [https://docs.python.org/3/](https://docs.python.org/3/). PDF, plain text, and
downloadable HTML versions are also available at https://docs.python.org/3/download.html.

The documentation is written in reStructuredText and processed by the Sphinx documentation tool. The reStructuredText source for the documentation is part of the Python source distribution.

I’ve never programmed before. Is there a Python tutorial?

There are numerous tutorials and books available. The standard documentation includes The Python Tutorial.

Consult the Beginner’s Guide to find information for beginning Python programmers, including lists of tutorials.

Is there a newsgroup or mailing list devoted to Python?

There is a newsgroup, comp.lang.python, and a mailing list, python-list. The newsgroup and mailing list are gatewayed into each other – if you can read news it's unnecessary to subscribe to the mailing list. comp.lang.python is high-traffic, receiving hundreds of postings every day, and Usenet readers are often more able to cope with this volume.

Announcements of new software releases and events can be found in comp.lang.python.announce, a low-traffic moderated list that receives about five postings per day. It’s available as the python-announce mailing list.

More info about other mailing lists and newsgroups can be found at https://www.python.org/community/lists/.
How do I get a beta test version of Python?

Alpha and beta releases are available from https://www.python.org/downloads/. All releases are announced on the comp.lang.python and comp.lang.python.announce newsgroups and on the Python home page at https://www.python.org/; an RSS feed of news is available.

You can also access the development version of Python through Git. See The Python Developer’s Guide for details.

How do I submit bug reports and patches for Python?

To report a bug or submit a patch, please use the Roundup installation at https://bugs.python.org/.

You must have a Roundup account to report bugs; this makes it possible for us to contact you if we have follow-up questions. It will also enable Roundup to send you updates as we act on your bug. If you had previously used SourceForge to report bugs to Python, you can obtain your Roundup password through Roundup’s password reset procedure.

For more information on how Python is developed, consult the Python Developer’s Guide.

Are there any published articles about Python that I can reference?

It’s probably best to cite your favorite book about Python.
The very first article about Python was written in 1991 and is now quite outdated.

Are there any books on Python?

Yes, there are many, and more are being published. See the python.org wiki at https://wiki.python.org/moin/PythonBooks for a list.

You can also search online bookstores for “Python” and filter out the Monty Python references; or perhaps search for “Python” and “language”.

Where in the world is www.python.org located?

The Python project’s infrastructure is located all over the world. www.python.org is graciously hosted by Rackspace, with CDN caching provided by Fastly. Upfront Systems hosts bugs.python.org. Many other Python services like the Wiki are hosted by Oregon State University Open Source Lab.

Why is it called Python?

When he began implementing Python, Guido van Rossum was also reading the published scripts from “Monty Python’s Flying Circus”, a BBC comedy series from the 1970s. Van Rossum thought he needed a name that was short, unique, and slightly mysterious, so he decided to call the language Python.
Do I have to like “Monty Python’s Flying Circus”?

No, but it helps. :)
Python in the real world

How stable is Python?

Very stable. New, stable releases have been coming out roughly every 6 to 18 months since 1991, and this seems likely to continue. Currently there are usually around 18 months between major releases.

The developers issue “bugfix” releases of older versions, so the stability of existing releases gradually improves. Bugfix releases, indicated by a third component of the version number (e.g. 2.5.3, 2.6.2), are managed for stability; only fixes for known problems are included in a bugfix release, and it's guaranteed that interfaces will remain the same throughout a series of bugfix releases.

The latest stable releases can always be found on the Python download page. There are two recommended production-ready versions at this point in time, because at the moment there are two branches of stable releases: 2.x and 3.x. Python 3.x may be less useful than 2.x, since currently there is more third party software available for Python 2 than for Python 3. Python 2 code will generally not run unchanged in Python 3.

How many people are using Python?

There are probably tens of thousands of users, though it's difficult to obtain an exact count.

Python is available for free download, so there are no sales figures, and it's available from many different sites and packaged with many Linux distributions, so download statistics don't tell the whole story either.
The comp.lang.python newsgroup is very active, but not all Python users post to the group or even read it.

Have any significant projects been done in Python?

See https://www.python.org/about/success for a list of projects that use Python. Consulting the proceedings for past Python conferences will reveal contributions from many different companies and organizations.

High-profile Python projects include the Mailman mailing list manager and the Zope application server. Several Linux distributions, most notably Red Hat, have written part or all of their installer and system administration software in Python. Companies that use Python internally include Google, Yahoo, and Lucasfilm Ltd.

What new developments are expected for Python in the future?

See https://www.python.org/dev(peps/) for the Python Enhancement Proposals (PEPs). PEPs are design documents describing a suggested new feature for Python, providing a concise technical specification and a rationale. Look for a PEP titled “Python X.Y Release Schedule”, where X.Y is a version that hasn’t been publicly released yet.

New development is discussed on the python-dev mailing list.

Is it reasonable to propose incompatible changes to Python?
In general, no. There are already millions of lines of Python code around the world, so any change in the language that invalidates more than a very small fraction of existing programs has to be frowned upon. Even if you can provide a conversion program, there’s still the problem of updating all documentation; many books have been written about Python, and we don’t want to invalidate them all at a single stroke.

Providing a gradual upgrade path is necessary if a feature has to be changed. PEP 5 describes the procedure followed for introducing backward-incompatible changes while minimizing disruption for users.

Is Python a good language for beginning programmers?

Yes.

It is still common to start students with a procedural and statically typed language such as Pascal, C, or a subset of C++ or Java. Students may be better served by learning Python as their first language. Python has a very simple and consistent syntax and a large standard library and, most importantly, using Python in a beginning programming course lets students concentrate on important programming skills such as problem decomposition and data type design. With Python, students can be quickly introduced to basic concepts such as loops and procedures. They can probably even work with user-defined objects in their very first course.

For a student who has never programmed before, using a statically typed language seems unnatural. It presents additional complexity that the student must master and slows the pace of the course. The students are trying to learn to think like a computer, decompose
problems, design consistent interfaces, and encapsulate data. While learning to use a statically typed language is important in the long term, it is not necessarily the best topic to address in the students' first programming course.

Many other aspects of Python make it a good first language. Like Java, Python has a large standard library so that students can be assigned programming projects very early in the course that do something. Assignments aren't restricted to the standard four-function calculator and check balancing programs. By using the standard library, students can gain the satisfaction of working on realistic applications as they learn the fundamentals of programming. Using the standard library also teaches students about code reuse. Third-party modules such as PyGame are also helpful in extending the students' reach.

Python's interactive interpreter enables students to test language features while they're programming. They can keep a window with the interpreter running while they enter their program's source in another window. If they can't remember the methods for a list, they can do something like this:

```python
>>> L = []
>>> dir(L)
['__add__', '__class__', '__contains__', '__delattr__', '__dir__', '__doc__', '__eq__', '__format__', '__ge__', '__getattribute__', '__getitem__', '__gt__', '__hash__', '__imul__', '__init__', '__iter__', '__le__', '__len__', '__mul__', '__ne__', '__new__', '__reduce__', '__reduce_ex__', '__repr__', '__reversed__', '__rmul__', '__setattr__', '__sizeof__', '__str__', '__subclasshook__', 'append', 'clear', 'copy', 'count', 'extend', 'index', 'insert', 'pop', 'reverse', 'sort']
>>> [d for d in dir(L) if '__' not in d]
```
With the interpreter, documentation is never far from the student as they are programming.

There are also good IDEs for Python. IDLE is a cross-platform IDE for Python that is written in Python using Tkinter. PythonWin is a Windows-specific IDE. Emacs users will be happy to know that there is a very good Python mode for Emacs. All of these programming environments provide syntax highlighting, auto-indenting, and access to the interactive interpreter while coding. Consult the Python wiki for a full list of Python editing environments.

If you want to discuss Python’s use in education, you may be interested in joining the edu-sig mailing list.

- How do I check if an object is an instance of a given class or of a subclass of it?
- What is delegation?
- How do I call a method defined in a base class from a derived class that overrides it?
- How can I organize my code to make it easier to change the base class?
- How do I create static class data and static class methods?
- How can I overload constructors (or methods) in Python?
- I try to use __spam and I get an error about _SomeClassName__spam.
- My class defines __del__ but it is not called when I delete the object.
- How do I get a list of all instances of a given class?
- Why does the result of id() appear to be not unique?

**Modules**
- How do I create a .pyc file?
- How do I find the current module name?
- How can I have modules that mutually import each other?
- __import__('x.y.z') returns <module 'x'>; how do I get z?
- When I edit an imported module and reimport it, the
changes don’t show up. Why does this happen?
General Questions

Is there a source code level debugger with breakpoints, single-stepping, etc.?

Yes.

The pdb module is a simple but adequate console-mode debugger for Python. It is part of the standard Python library, and is documented in the Library Reference Manual. You can also write your own debugger by using the code for pdb as an example.

The IDLE interactive development environment, which is part of the standard Python distribution (normally available as Tools/scripts/idle), includes a graphical debugger.

PythonWin is a Python IDE that includes a GUI debugger based on pdb. The Pythonwin debugger colors breakpoints and has quite a few cool features such as debugging non-Pythonwin programs. Pythonwin is available as part of the Python for Windows Extensions project and as a part of the ActivePython distribution (see https://www.activestate.com/activepython).

Boa Constructor is an IDE and GUI builder that uses wxWidgets. It offers visual frame creation and manipulation, an object inspector, many views on the source like object browsers, inheritance hierarchies, doc string generated html documentation, an advanced debugger, integrated help, and Zope support.

Eric is an IDE built on PyQt and the Scintilla editing component.

Pydb is a version of the standard Python debugger pdb, modified for
use with DDD (Data Display Debugger), a popular graphical debugger front end. Pydb can be found at http://bashdb.sourceforge.net/pydb/ and DDD can be found at https://www.gnu.org/software/ddd.

There are a number of commercial Python IDEs that include graphical debuggers. They include:

- Wing IDE (https://wingware.com/)
- Komodo IDE (https://komodoide.com/)
- PyCharm (https://www.jetbrains.com/pycharm/)

**Is there a tool to help find bugs or perform static analysis?**

Yes.

PyChecker is a static analysis tool that finds bugs in Python source code and warns about code complexity and style. You can get PyChecker from http://pychecker.sourceforge.net/.

Pylint is another tool that checks if a module satisfies a coding standard, and also makes it possible to write plug-ins to add a custom feature. In addition to the bug checking that PyChecker performs, Pylint offers some additional features such as checking line length, whether variable names are well-formed according to your coding standard, whether declared interfaces are fully implemented, and more. https://docs.pylint.org/ provides a full list of Pylint’s features.

**How can I create a stand-alone binary from a Python script?**

You don’t need the ability to compile Python to C code if all you want is
a stand-alone program that users can download and run without having to install the Python distribution first. There are a number of tools that determine the set of modules required by a program and bind these modules together with a Python binary to produce a single executable.

One is to use the freeze tool, which is included in the Python source tree as `Tools/freeze`. It converts Python byte code to C arrays; a C compiler you can embed all your modules into a new program, which is then linked with the standard Python modules.

It works by scanning your source recursively for import statements (in both forms) and looking for the modules in the standard Python path as well as in the source directory (for built-in modules). It then turns the bytecode for modules written in Python into C code (array initializers that can be turned into code objects using the marshal module) and creates a custom-made config file that only contains those built-in modules which are actually used in the program. It then compiles the generated C code and links it with the rest of the Python interpreter to form a self-contained binary which acts exactly like your script.

Obviously, freeze requires a C compiler. There are several other utilities which don’t. One is Thomas Heller’s py2exe (Windows only) at [http://www.py2exe.org/](http://www.py2exe.org/)

Another tool is Anthony Tuininga’s `cx_Freeze`.

**Are there coding standards or a style guide for Python programs?**

Yes. The coding style required for standard library modules is
documented as **PEP 8**.
Why am I getting an UnboundLocalError when the variable has a value?

It can be a surprise to get the UnboundLocalError in previously working code when it is modified by adding an assignment statement somewhere in the body of a function.

This code:

```python
>>> x = 10
>>> def bar():
...     print(x)
>>> bar()
10
```

works, but this code:

```python
>>> x = 10
>>> def foo():
...     print(x)
...     x += 1
```

results in an UnboundLocalError:

```
>>> foo()
Traceback (most recent call last):
...
UnboundLocalError: local variable 'x' referenced before assignment
```

This is because when you make an assignment to a variable in a scope, that variable becomes local to that scope and shadows any
Similarly named variable in the outer scope. Since the last statement in `foo` assigns a new value to `x`, the compiler recognizes it as a local variable. Consequently when the earlier `print(x)` attempts to print the uninitialized local variable and an error results.

In the example above you can access the outer scope variable by declaring it global:

```python
>>> x = 10
>>> def foobar():
...     global x
...     print(x)
...     x += 1
>>> foobar()
10
```

This explicit declaration is required in order to remind you that (unlike the superficially analogous situation with class and instance variables) you are actually modifying the value of the variable in the outer scope:

```python
>>> print(x)
11
```

You can do a similar thing in a nested scope using the `nonlocal` keyword:

```python
>>> def foo():
...     x = 10
...     def bar():
...         nonlocal x
...         print(x)
...         x += 1
...     bar()
...     print(x)
>>> foo()
```
What are the rules for local and global variables in Python?

In Python, variables that are only referenced inside a function are implicitly global. If a variable is assigned a value anywhere within the function’s body, it’s assumed to be a local unless explicitly declared as global.

Though a bit surprising at first, a moment’s consideration explains this. On one hand, requiring `global` for assigned variables provides a bar against unintended side-effects. On the other hand, if `global` was required for all global references, you’d be using `global` all the time. You’d have to declare as global every reference to a built-in function or to a component of an imported module. This clutter would defeat the usefulness of the `global` declaration for identifying side-effects.

**Why do lambdas defined in a loop with different values all return the same result?**

Assume you use a for loop to define a few different lambdas (or even plain functions), e.g.:

```python
>>> squares = []
>>> for x in range(5):
...     squares.append(lambda: x**2)
```

This gives you a list that contains 5 lambdas that calculate `x**2`. You might expect that, when called, they would return, respectively, 0, 1,
4, 9, and 16. However, when you actually try you will see that they all return 16:

```python
global x = 4
squares = []
for x in range(5):
    squares.append(lambda n=x: n**2)
```

This happens because `x` is not local to the lambdas, but is defined in the outer scope, and it is accessed when the lambda is called — not when it is defined. At the end of the loop, the value of `x` is 4, so all the functions now return 4**2, i.e. 16. You can also verify this by changing the value of `x` and see how the results of the lambdas change:

```python
x = 8
```

In order to avoid this, you need to save the values in variables local to the lambdas, so that they don’t rely on the value of the global `x`:

```python
global x = 4
squares = []
for x in range(5):
    squares.append(lambda n: n**2)
```

Here, `n=x` creates a new variable `n` local to the lambda and computed when the lambda is defined so that it has the same value that `x` had at that point in the loop. This means that the value of `n` will be 0 in the first lambda, 1 in the second, 2 in the third, and so on. Therefore each lambda will now return the correct result:
Note that this behaviour is not peculiar to lambdas, but applies to regular functions too.

**How do I share global variables across modules?**

The canonical way to share information across modules within a single program is to create a special module (often called config or cfg). Just import the config module in all modules of your application; the module then becomes available as a global name. Because there is only one instance of each module, any changes made to the module object get reflected everywhere. For example:

**config.py:**

```python
x = 0  # Default value of the 'x' configuration setting
```

**mod.py:**

```python
import config
config.x = 1
```

**main.py:**

```python
import config
import mod
print(config.x)
```

Note that using a module is also the basis for implementing the Singleton design pattern, for the same reason.
What are the “best practices” for using import in a module?

In general, don’t use `from modulename import *`. Doing so clutters the importer’s namespace, and makes it much harder for linters to detect undefined names.

Import modules at the top of a file. Doing so makes it clear what other modules your code requires and avoids questions of whether the module name is in scope. Using one import per line makes it easy to add and delete module imports, but using multiple imports per line uses less screen space.

It’s good practice if you import modules in the following order:

1. standard library modules – e.g. `sys`, `os`, `getopt`, `re`
2. third-party library modules (anything installed in Python’s site-packages directory) – e.g. `mx.DateTime`, `ZODB`, `PIL.Image`, etc.
3. locally-developed modules

It is sometimes necessary to move imports to a function or class to avoid problems with circular imports. Gordon McMillan says:

Circular imports are fine where both modules use the “import <module>” form of import. They fail when the 2nd module wants to grab a name out of the first (“from module import name”) and the import is at the top level. That’s because names in the 1st are not yet available, because the first module is busy importing the 2nd.

In this case, if the second module is only used in one function, then the import can easily be moved into that function. By the time the import is called, the first module will have finished initializing, and the
second module can do its import.

It may also be necessary to move imports out of the top level of code if some of the modules are platform-specific. In that case, it may not even be possible to import all of the modules at the top of the file. In this case, importing the correct modules in the corresponding platform-specific code is a good option.

Only move imports into a local scope, such as inside a function definition, if it's necessary to solve a problem such as avoiding a circular import or are trying to reduce the initialization time of a module. This technique is especially helpful if many of the imports are unnecessary depending on how the program executes. You may also want to move imports into a function if the modules are only ever used in that function. Note that loading a module the first time may be expensive because of the one time initialization of the module, but loading a module multiple times is virtually free, costing only a couple of dictionary lookups. Even if the module name has gone out of scope, the module is probably available in `sys.modules`.

**Why are default values shared between objects?**

This type of bug commonly bites neophyte programmers. Consider this function:

```python
def foo(mydict={}):  # Danger: shared reference to one dict for all calls
    ... compute something ...
    mydict[key] = value
    return mydict
```

The first time you call this function, `mydict` contains a single item. The second time, `mydict` contains two items because when `foo()`
begins executing, `mydict` starts out with an item already in it.

It is often expected that a function call creates new objects for default values. This is not what happens. Default values are created exactly once, when the function is defined. If that object is changed, like the dictionary in this example, subsequent calls to the function will refer to this changed object.

By definition, immutable objects such as numbers, strings, tuples, and `None`, are safe from change. Changes to mutable objects such as dictionaries, lists, and class instances can lead to confusion.

Because of this feature, it is good programming practice to not use mutable objects as default values. Instead, use `None` as the default value and inside the function, check if the parameter is `None` and create a new list/dictionary/whatever if it is. For example, don’t write:

```python
def foo(mydict={}):
    ...
```

but:

```python
def foo(mydict=None):
    if mydict is None:
        mydict = {}  # create a new dict for local namespace
```

This feature can be useful. When you have a function that’s time-consuming to compute, a common technique is to cache the parameters and the resulting value of each call to the function, and return the cached value if the same value is requested again. This is called “memoizing”, and can be implemented like this:

```python
# Callers will never provide a third parameter for this function.
```
def expensive(arg1, arg2, _cache={}):
    if (arg1, arg2) in _cache:
        return _cache[(arg1, arg2)]

    # Calculate the value
    result = ... expensive computation ...
    _cache[(arg1, arg2)] = result  # Store result in the cache
    return result

You could use a global variable containing a dictionary instead of the default value; it’s a matter of taste.

How can I pass optional or keyword parameters from one function to another?

Collect the arguments using the * and ** specifiers in the function's parameter list; this gives you the positional arguments as a tuple and the keyword arguments as a dictionary. You can then pass these arguments when calling another function by using * and **:

def f(x, *args, **kwargs):
    ...
    kwargs['width'] = '14.3c'
    ...
    g(x, *args, **kwargs)

What is the difference between arguments and parameters?

Parameters are defined by the names that appear in a function definition, whereas arguments are the values actually passed to a function when calling it. Parameters define what types of arguments a
function can accept. For example, given the function definition:

```python
def func(foo, bar=None, **kwargs):
    pass
```

`foo`, `bar` and `kwargs` are parameters of `func`. However, when calling `func`, for example:

```python
func(42, bar=314, extra=somevar)
```

the values 42, 314, and `somevar` are arguments.

**Why did changing list ‘y’ also change list ‘x’?**

If you wrote code like:

```python
>>> x = []
>>> y = x
>>> y.append(10)
>>> y
[10]
>>> x
[10]
```

you might be wondering why appending an element to `y` changed `x` too.

There are two factors that produce this result:

1. Variables are simply names that refer to objects. Doing `y = x` doesn’t create a copy of the list – it creates a new variable `y` that refers to the same object `x` refers to. This means that there is only one object (the list), and both `x` and `y` refer to it.
2. Lists are **mutable**, which means that you can change their
content.

After the call to `append()`, the content of the mutable object has changed from `[]` to `[10]`. Since both the variables refer to the same object, using either name accesses the modified value `[10]`.

If we instead assign an immutable object to `x`:

```python
>>> x = 5  # ints are immutable
>>> y = x
>>> x = x + 1  # 5 can't be mutated, we are creating a new object
>>> x
6
>>> y
5
```

we can see that in this case `x` and `y` are not equal anymore. This is because integers are immutable, and when we do `x = x + 1` we are not mutating the int 5 by incrementing its value; instead, we are creating a new object (the int 6) and assigning it to `x` (that is, changing which object `x` refers to). After this assignment we have two objects (the ints 6 and 5) and two variables that refer to them (`x` now refers to 6 but `y` still refers to 5).

Some operations (for example `y.append(10)` and `y.sort()`) mutate the object, whereas superficially similar operations (for example `y = y + [10]` and `sorted(y)`) create a new object. In general in Python (and in all cases in the standard library) a method that mutates an object will return `None` to help avoid getting the two types of operations confused. So if you mistakenly write `y.sort()` thinking it will give you a sorted copy of `y`, you'll instead end up with `None`, which will likely cause your program to generate an easily
diagnosed error.

However, there is one class of operations where the same operation sometimes has different behaviors with different types: the augmented assignment operators. For example, `+=` mutates lists but not tuples or ints (a_list += [1, 2, 3] is equivalent to a_list.extend([1, 2, 3]) and mutates a_list, whereas some_tuple += (1, 2, 3) and some_int += 1 create new objects).

In other words:

- If we have a mutable object (list, dict, set, etc.), we can use some specific operations to mutate it and all the variables that refer to it will see the change.
- If we have an immutable object (str, int, tuple, etc.), all the variables that refer to it will always see the same value, but operations that transform that value into a new value always return a new object.

If you want to know if two variables refer to the same object or not, you can use the `is` operator, or the built-in function `id()`.

**How do I write a function with output parameters (call by reference)?**

Remember that arguments are passed by assignment in Python. Since assignment just creates references to objects, there's no alias between an argument name in the caller and callee, and so no call-by-reference per se. You can achieve the desired effect in a number of ways.

1. By returning a tuple of the results:
```python
def func2(a, b):
    a = 'new-value'  # a and b are local names
    b = b + 1  # assigned to new object
    return a, b  # return new values

x, y = 'old-value', 99
x, y = func2(x, y)
print(x, y)  # output: new-value 100
```

This is almost always the clearest solution.

2. By using global variables. This isn’t thread-safe, and is not recommended.

3. By passing a mutable (changeable in-place) object:

```python
def func1(a):
    a[0] = 'new-value'  # 'a' references a mutable list
    a[1] = a[1] + 1  # changes a shared object

args = ['old-value', 99]
func1(args)
print(args[0], args[1])  # output: new-value 100
```

4. By passing in a dictionary that gets mutated:

```python
def func3(args):
    args['a'] = 'new-value'  # args is a mutable dictionary
    args['b'] = args['b'] + 1  # change it in-place

args = {'a': 'old-value', 'b': 99}
func3(args)
print(args['a'], args['b'])
```
5. Or bundle up values in a class instance:

```python
class callByRef:
    def __init__(self, **args):
        for (key, value) in args.items():
            setattr(self, key, value)

def func4(args):
    args.a = 'new-value'  # args is a mutable
    args.b = args.b + 1   # change object in-place

args = callByRef(a='old-value', b=99)
func4(args)
print(args.a, args.b)
```

There's almost never a good reason to get this complicated.

Your best choice is to return a tuple containing the multiple results.

**How do you make a higher order function in Python?**

You have two choices: you can use nested scopes or you can use callable objects. For example, suppose you wanted to define `linear(a, b)` which returns a function `f(x)` that computes the value `a*x+b`. Using nested scopes:

```python
def linear(a, b):
    def result(x):
        return a * x + b
    return result
```

Or using a callable object:
class linear:
    
def __init__(self, a, b):
        self.a, self.b = a, b
    
def __call__(self, x):
        return self.a * x + self.b

In both cases,

taxes = linear(0.3, 2)

gives a callable object where taxes(10e6) == 0.3 * 10e6 + 2.

The callable object approach has the disadvantage that it is a bit slower and results in slightly longer code. However, note that a collection of callables can share their signature via inheritance:

class exponential(linear):
    # __init__ inherited
    def __call__(self, x):
        return self.a * (x ** self.b)

Object can encapsulate state for several methods:

class counter:
    
    value = 0
    
def set(self, x):
        self.value = x
    
def up(self):
        self.value = self.value + 1
    
def down(self):
self.value = self.value - 1

count = counter()
inc, dec, reset = count.up, count.down, count.set

Here inc(), dec() and reset() act like functions which share the same counting variable.

**How do I copy an object in Python?**

In general, try `copy.copy()` or `copy.deepcopy()` for the general case. Not all objects can be copied, but most can.

Some objects can be copied more easily. Dictionaries have a `copy()` method:

```python
newdict = olddict.copy()
```

Sequences can be copied by slicing:

```python
new_l = l[:]
```

**How can I find the methods or attributes of an object?**

For an instance `x` of a user-defined class, `dir(x)` returns an alphabetized list of the names containing the instance attributes and methods and attributes defined by its class.

**How can my code discover the name of an object?**
Generally speaking, it can’t, because objects don’t really have names. Essentially, assignment always binds a name to a value; The same is true of `def` and `class` statements, but in that case the value is a callable. Consider the following code:

```
>>> class A:
...     pass
...
>>> B = A
>>> a = B()
>>> b = a
>>> print(b)
<_main__.A object at 0x16D07CC>
>>> print(a)
<_main__.A object at 0x16D07CC>
```

Arguably the class has a name: even though it is bound to two names and invoked through the name B the created instance is still reported as an instance of class A. However, it is impossible to say whether the instance’s name is a or b, since both names are bound to the same value.

Generally speaking it should not be necessary for your code to “know the names” of particular values. Unless you are deliberately writing introspective programs, this is usually an indication that a change of approach might be beneficial.

In comp.lang.python, Fredrik Lundh once gave an excellent analogy in answer to this question:

The same way as you get the name of that cat you found on your porch: the cat (object) itself cannot tell you its name, and it doesn’t really care – so the only way to find out what it’s called is to ask all your neighbours (namespaces) if it’s their cat (object)…
...and don't be surprised if you'll find that it's known by many names, or no name at all!

**What's up with the comma operator's precedence?**

Comma is not an operator in Python. Consider this session:

```python
>>> "a" in "b", "a"
(False, 'a')
```

Since the comma is not an operator, but a separator between expressions the above is evaluated as if you had entered:

```python
("a" in "b"), "a"
```

not:

```python
"a" in ("b", "a")
```

The same is true of the various assignment operators (=, += etc). They are not truly operators but syntactic delimiters in assignment statements.

**Is there an equivalent of C's "?:" ternary operator?**

Yes, there is. The syntax is as follows:

```python
[on_true] if [expression] else [on_false]
```

```python
x, y = 50, 25
small = x if x < y else y
```
Before this syntax was introduced in Python 2.5, a common idiom was to use logical operators:

```
[expression] and [on_true] or [on_false]
```

However, this idiom is unsafe, as it can give wrong results when `on_true` has a false boolean value. Therefore, it is always better to use the `... if ... else ...` form.

Is it possible to write obfuscated one-liners in Python?

Yes. Usually this is done by nesting `lambda` within `lambda`. See the following three examples, due to Ulf Bartelt:

```python
from functools import reduce

# Primes < 1000
print(list(filter(None, map(lambda y: y*y*reduce(lambda map(lambda x, y=y:y%x, range(2, int(pow(y, 0.5)+1))), 1),
                          map(lambda x, y=x: y, range(2, int(pow(y, 0.5)+1))))))

# First 10 Fibonacci numbers
print(list(map(lambda x, f=lambda x: f(x-1, f)+f(x-2, f(x, f)), range(10))))

# Mandelbrot set
print((lambda Ru, Ro, Iu, Io, IM, Sx, Sy: reduce(lambda x, y: x*y, map(lambda x, y: x, range(2, int(pow(y, 0.5)+1))))))
```

Don’t try this at home, kids!
Numbers and strings

How do I specify hexadecimal and octal integers?

To specify an octal digit, precede the octal value with a zero, and then a lower or uppercase “o”. For example, to set the variable “a” to the octal value “10” (8 in decimal), type:

```python
>>> a = 0o10
>>> a
8
```

Hexadecimal is just as easy. Simply precede the hexadecimal number with a zero, and then a lower or uppercase “x”. Hexadecimal digits can be specified in lower or uppercase. For example, in the Python interpreter:

```python
>>> a = 0xa5
>>> a
165
>>> b = 0XB2
>>> b
178
```

Why does -22 // 10 return -3?

It’s primarily driven by the desire that \( i \ % \ j \) have the same sign as \( j \). If you want that, and also want:

\[
i == (i \ // \ j) * j + (i \ % \ j)
\]

then integer division has to return the floor. C also requires that identity
to hold, and then compilers that truncate $i \div j$ need to make $i \% j$ have the same sign as $i$.

There are few real use cases for $i \% j$ when $j$ is negative. When $j$ is positive, there are many, and in virtually all of them it's more useful for $i \% j$ to be $\geq 0$. If the clock says 10 now, what did it say 200 hours ago? $-190 \% 12 == 2$ is useful; $-190 \% 12 == -10$ is a bug waiting to bite.

**How do I convert a string to a number?**

For integers, use the built-in `int()` type constructor, e.g. `int('144') == 144`. Similarly, `float()` converts to floating-point, e.g. `float('144') == 144.0`.

By default, these interpret the number as decimal, so that `int('0144') == 144` and `int('0x144')` raises `ValueError`. `int(string, base)` takes the base to convert from as a second optional argument, so `int('0x144', 16) == 324`. If the base is specified as 0, the number is interpreted using Python's rules: a leading '0o' indicates octal, and '0x' indicates a hex number.

Do not use the built-in function `eval()` if all you need is to convert strings to numbers. `eval()` will be significantly slower and it presents a security risk: someone could pass you a Python expression that might have unwanted side effects. For example, someone could pass `__import__('os').system("rm -rf $HOME")` which would erase your home directory.

`eval()` also has the effect of interpreting numbers as Python expressions, so that e.g. `eval('09')` gives a syntax error because
Python does not allow leading ‘0’ in a decimal number (except ‘0’).

**How do I convert a number to a string?**

To convert, e.g., the number 144 to the string ‘144’, use the built-in type constructor `str()`. If you want a hexadecimal or octal representation, use the built-in functions `hex()` or `oct()`. For fancy formatting, see the Formatted string literals and Format String Syntax sections, e.g. `{:04d}`.format(144) yields '0144' and `{::.3f}`.format(1.0/3.0) yields '0.333'.

**How do I modify a string in place?**

You can’t, because strings are immutable. In most situations, you should simply construct a new string from the various parts you want to assemble it from. However, if you need an object with the ability to modify in-place unicode data, try using an `io.StringIO` object or the `array` module:

```python
>>> import io
>>> s = "Hello, world"
>>> sio = io.StringIO(s)
>>> sio.getvalue()
'Hello, world'
>>> sio.seek(7)
7
>>> sio.write("there!"
6
>>> sio.getvalue()
'Hello, there!'
```
How do I use strings to call functions/methods?

There are various techniques.

- The best is to use a dictionary that maps strings to functions. The primary advantage of this technique is that the strings do not need to match the names of the functions. This is also the primary technique used to emulate a case construct:

```python
def a():
    pass

def b():
    pass

dispatch = {'go': a, 'stop': b}  # Note lack of parens for funcs

dispatch[get_input()]()  # Note trailing parens to call function
```

- Use the built-in function `getattr()`:

```python
import foo
getattr(foo, 'bar')()
```

Note that `getattr()` works on any object, including classes, class instances, modules, and so on.
This is used in several places in the standard library, like this:

```python
class Foo:
    def do_foo(self):
        ...

    def do_bar(self):
        ...

f = getattr(foo_instance, 'do_' + opname)
f()
```

- Use `locals()` or `eval()` to resolve the function name:

```python
def myFunc():
    print("hello")

fname = "myFunc"

f = locals()[fname]
f()

f = eval(fname)
f()
```

Note: Using `eval()` is slow and dangerous. If you don’t have absolute control over the contents of the string, someone could pass a string that resulted in an arbitrary function being executed.

**Is there an equivalent to Perl’s chomp() for removing trailing newlines from strings?**

You can use `S.rstrip("\r\n")` to remove all occurrences of any line terminator from the end of the string `S` without removing other
trailing whitespace. If the string \$ represents more than one line, with several empty lines at the end, the line terminators for all the blank lines will be removed:

```python
>>> lines = ("line 1 \r\n"...
            "\r\n"...
            "\r\n")
>>> lines.rstrip("\n\r")
'line 1'
```

Since this is typically only desired when reading text one line at a time, using \$\_rstrip() this way works well.

**Is there a scanf() or sscanf() equivalent?**

Not as such.

For simple input parsing, the easiest approach is usually to split the line into whitespace-delimited words using the `split()` method of string objects and then convert decimal strings to numeric values using `int()` or `float()`. `split()` supports an optional “sep” parameter which is useful if the line uses something other than whitespace as a separator.

For more complicated input parsing, regular expressions are more powerful than C’s `sscanf()` and better suited for the task.

**What does ‘UnicodeDecodeError’ or ‘UnicodeEncodeError’ error mean?**

See the [Unicode HOWTO](https://docs.python.org/3/library/unicode.html).
Performance

My program is too slow. How do I speed it up?

That’s a tough one, in general. First, here are a list of things to remember before diving further:

- Performance characteristics vary across Python implementations. This FAQ focusses on CPython.
- Behaviour can vary across operating systems, especially when talking about I/O or multi-threading.
- You should always find the hot spots in your program before attempting to optimize any code (see the profile module).
- Writing benchmark scripts will allow you to iterate quickly when searching for improvements (see the timeit module).
- It is highly recommended to have good code coverage (through unit testing or any other technique) before potentially introducing regressions hidden in sophisticated optimizations.

That being said, there are many tricks to speed up Python code. Here are some general principles which go a long way towards reaching acceptable performance levels:

- Making your algorithms faster (or changing to faster ones) can yield much larger benefits than trying to sprinkle micro-optimization tricks all over your code.
- Use the right data structures. Study documentation for the Built-in Types and the collections module.
- When the standard library provides a primitive for doing something, it is likely (although not guaranteed) to be faster than any alternative you may come up with. This is doubly true for primitives written in C, such as builtins and some extension types. For example, be sure to use either the list.sort() built-in
method or the related \texttt{sorted()} function to do sorting (and see the \texttt{Sorting HOW TO} for examples of moderately advanced usage).

- Abstractions tend to create indirections and force the interpreter to work more. If the levels of indirection outweigh the amount of useful work done, your program will be slower. You should avoid excessive abstraction, especially under the form of tiny functions or methods (which are also often detrimental to readability).

If you have reached the limit of what pure Python can allow, there are tools to take you further away. For example, \texttt{Cython} can compile a slightly modified version of Python code into a C extension, and can be used on many different platforms. Cython can take advantage of compilation (and optional type annotations) to make your code significantly faster than when interpreted. If you are confident in your C programming skills, you can also write a C extension module yourself.

\textbf{See also: } The wiki page devoted to performance tips.

\textbf{What is the most efficient way to concatenate many strings together?}

\texttt{str} and \texttt{bytes} objects are immutable, therefore concatenating many strings together is inefficient as each concatenation creates a new object. In the general case, the total runtime cost is quadratic in the total string length.

To accumulate many \texttt{str} objects, the recommended idiom is to place them into a list and call \texttt{str.join()} at the end:

\begin{verbatim}
chunks = []
for s in my_strings:
    chunks.append(s)
\end{verbatim}
result = ''.join(chunks)

(another reasonably efficient idiom is to use `io.StringIO`)

To accumulate many `bytes` objects, the recommended idiom is to extend a `bytearray` object using in-place concatenation (the `+=` operator):

```python
result = bytearray()
for b in my_bytes_objects:
    result += b
```
Sequences (Tuples/Lists)

How do I convert between tuples and lists?

The type constructor `tuple(seq)` converts any sequence (actually, any iterable) into a tuple with the same items in the same order.

For example, `tuple([1, 2, 3])` yields `(1, 2, 3)` and `tuple('abc')` yields ('a', 'b', 'c'). If the argument is a tuple, it does not make a copy but returns the same object, so it is cheap to call `tuple()` when you aren't sure that an object is already a tuple.

The type constructor `list(seq)` converts any sequence or iterable into a list with the same items in the same order. For example, `list((1, 2, 3))` yields `[1, 2, 3]` and `list('abc')` yields ['a', 'b', 'c']. If the argument is a list, it makes a copy just like `seq[:]` would.

What's a negative index?

Python sequences are indexed with positive numbers and negative numbers. For positive numbers 0 is the first index 1 is the second index and so forth. For negative indices `-1` is the last index and `-2` is the penultimate (next to last) index and so forth. Think of `seq[-n]` as the same as `seq[len(seq)-n]`.

Using negative indices can be very convenient. For example `S[::1]` is all of the string except for its last character, which is useful for removing the trailing newline from a string.
How do I iterate over a sequence in reverse order?

Use the `reversed()` built-in function, which is new in Python 2.4:

```python
for x in reversed(sequence):
    ...  # do something with x ...
```

This won't touch your original sequence, but build a new copy with reversed order to iterate over.

With Python 2.3, you can use an extended slice syntax:

```python
for x in sequence[:::-1]:
    ...  # do something with x ...
```

How do you remove duplicates from a list?

See the Python Cookbook for a long discussion of many ways to do this:

https://code.activestate.com/recipes/52560/

If you don’t mind reordering the list, sort it and then scan from the end of the list, deleting duplicates as you go:

```python
if mylist:
    mylist.sort()
    last = mylist[-1]
    for i in range(len(mylist)-2, -1, -1):
        if last == mylist[i]:
            del mylist[i]
        else:
```
If all elements of the list may be used as set keys (i.e. they are all **hashable**) this is often faster

```python
mylist = list(set(mylist))
```
This converts the list into a set, thereby removing duplicates, and then back into a list.

**How do you make an array in Python?**

Use a list:

```python
["this", 1, "is", "an", "array"]
```
Lists are equivalent to C or Pascal arrays in their time complexity; the primary difference is that a Python list can contain objects of many different types.

The `array` module also provides methods for creating arrays of fixed types with compact representations, but they are slower to index than lists. Also note that the Numeric extensions and others define array-like structures with various characteristics as well.

To get Lisp-style linked lists, you can emulate cons cells using tuples:

```python
lisp_list = ("like", ("this", ("example", None)))
```
If mutability is desired, you could use lists instead of tuples. Here the analogue of lisp car is `lisp_list[0]` and the analogue of cdr is `lisp_list[1]`. Only do this if you're sure you really need to,
because it’s usually a lot slower than using Python lists.

**How do I create a multidimensional list?**

You probably tried to make a multidimensional array like this:

```python
>>> A = [[[None] * 2] * 3
```

This looks correct if you print it:

```python
>>> A
[[[None, None], [None, None], [None, None]]
```

But when you assign a value, it shows up in multiple places:

```python
>>> A[0][0] = 5
>>> A
[[[5, None], [5, None], [5, None]]
```

The reason is that replicating a list with `*` doesn’t create copies, it only creates references to the existing objects. The `*3` creates a list containing 3 references to the same list of length two. Changes to one row will show in all rows, which is almost certainly not what you want.

The suggested approach is to create a list of the desired length first and then fill in each element with a newly created list:

```python
A = [None] * 3
for i in range(3):
    A[i] = [None] * 2
```

This generates a list containing 3 different lists of length two. You can also use a list comprehension:
$$w, \ h = 2, \ 3$$

$$A = [[\text{None}] * w \ \text{for} \ i \ \text{in} \ \text{range}(h)]$$

Or, you can use an extension that provides a matrix datatype; NumPy is the best known.

**How do I apply a method to a sequence of objects?**

Use a list comprehension:

```python
result = [obj.method() \text{ for } obj \ \text{in} \ \text{mylist}]
```

**Why does a_tuple[i] += ['item'] raise an exception when the addition works?**

This is because of a combination of the fact that augmented assignment operators are *assignment* operators, and the difference between mutable and immutable objects in Python.

This discussion applies in general when augmented assignment operators are applied to elements of a tuple that point to mutable objects, but we’ll use a list and += as our exemplar.

If you wrote:

```bash
>>> a_tuple = (1, 2)
>>> a_tuple[0] += 1
Traceback (most recent call last):
...
TypeError: 'tuple' object does not support item assignment
```
The reason for the exception should be immediately clear: 1 is added to the object `a_tuple[0]` points to (1), producing the result object, 2, but when we attempt to assign the result of the computation, 2, to element 0 of the tuple, we get an error because we can’t change what an element of a tuple points to.

Under the covers, what this augmented assignment statement is doing is approximately this:

```python
>>> result = a_tuple[0] + 1
>>> a_tuple[0] = result
Traceback (most recent call last):
  ...  
TypeError: 'tuple' object does not support item assignment
```

It is the assignment part of the operation that produces the error, since a tuple is immutable.

When you write something like:

```python
>>> a_tuple = ([‘foo’], ‘bar’)
>>> a_tuple[0] += [‘item’]
Traceback (most recent call last):
  ...  
TypeError: 'tuple' object does not support item assignment
```

The exception is a bit more surprising, and even more surprising is the fact that even though there was an error, the append worked:

```python
>>> a_tuple[0]
[‘foo’, ‘item’]
```

To see why this happens, you need to know that (a) if an object
implements an \_\_iadd\_\_ magic method, it gets called when the += augmented assignment is executed, and its return value is what gets used in the assignment statement; and (b) for lists, \_\_iadd\_\_ is equivalent to calling \texttt{extend} on the list and returning the list. That's why we say that for lists, += is a “shorthand” for \texttt{list.extend}:

```python
>>> a_list = []
>>> a_list += [1]
>>> a_list
[1]
```

This is equivalent to:

```python
>>> result = a_list.\_\_iadd\_\_(\[1\])
>>> a_list = result
```

The object pointed to by \texttt{a_list} has been mutated, and the pointer to the mutated object is assigned back to \texttt{a_list}. The end result of the assignment is a no-op, since it is a pointer to the same object that \texttt{a_list} was previously pointing to, but the assignment still happens.

Thus, in our tuple example what is happening is equivalent to:

```python
>>> result = a_tuple[0].\_\_iadd\_\_(\[\text{'item'}\])
>>> a_tuple[0] = result
Traceback (most recent call last):
 ...
TypeError: 'tuple' object does not support item assignment
```

The \_\_iadd\_\_ succeeds, and thus the list is extended, but even though \texttt{result} points to the same object that \texttt{a_tuple[0]} already points to, that final assignment still results in an error, because tuples are immutable.
Dictionaries

How can I get a dictionary to store and display its keys in a consistent order?

Use `collections.OrderedDict`.

I want to do a complicated sort: can you do a Schwartzian Transform in Python?

The technique, attributed to Randal Schwartz of the Perl community, sorts the elements of a list by a metric which maps each element to its “sort value”. In Python, use the `key` argument for the `list.sort()` method:

```python
Isorted = L[:]
Isorted.sort(key=lambda s: int(s[10:15]))
```

How can I sort one list by values from another list?

Merge them into an iterator of tuples, sort the resulting list, and then pick out the element you want.

```python
>>> list1 = ['what', 'I'm', 'sorting', 'by']
>>> list2 = ['something', 'else', 'to', 'sort']
>>> pairs = zip(list1, list2)
>>> pairs = sorted(pairs)
>>> pairs
[('I'm', 'else'), ('by', 'sort'), ('sorting', 'to'), ('what', 'something')]
>>> result = [x[1] for x in pairs]
>>> result
['else', 'sort', 'to', 'something']
```
An alternative for the last step is:

```python
>>> result = []
>>> for p in pairs: result.append(p[1])
```

If you find this more legible, you might prefer to use this instead of the final list comprehension. However, it is almost twice as slow for long lists. Why? First, the `append()` operation has to reallocate memory, and while it uses some tricks to avoid doing that each time, it still has to do it occasionally, and that costs quite a bit. Second, the expression “`result.append`” requires an extra attribute lookup, and third, there's a speed reduction from having to make all those function calls.
Objects

What is a class?

A class is the particular object type created by executing a class statement. Class objects are used as templates to create instance objects, which embody both the data (attributes) and code (methods) specific to a datatype.

A class can be based on one or more other classes, called its base class(es). It then inherits the attributes and methods of its base classes. This allows an object model to be successively refined by inheritance. You might have a generic Mailbox class that provides basic accessor methods for a mailbox, and subclasses such as MboxMailbox, MaildirMailbox, OutlookMailbox that handle various specific mailbox formats.

What is a method?

A method is a function on some object $x$ that you normally call as $x$.name(arguments...). Methods are defined as functions inside the class definition:

```python
class C:
    def meth(self, arg):
        return arg * 2 + self.attribute
```

What is self?

Self is merely a conventional name for the first argument of a method. A method defined as `meth(self, a, b, c)` should be called as
for some instance $x$ of the class in which the definition occurs; the called method will think it is called as \( \text{meth}(x, a, b, c) \).

See also Why must ‘self’ be used explicitly in method definitions and calls?

**How do I check if an object is an instance of a given class or of a subclass of it?**

Use the built-in function `isinstance(obj, cls)`. You can check if an object is an instance of any of a number of classes by providing a tuple instead of a single class, e.g. `isinstance(obj, (class1, class2, ...))`, and can also check whether an object is one of Python’s built-in types, e.g. `isinstance(obj, str)` or `isinstance(obj, (int, float, complex))`.

Note that most programs do not use `isinstance()` on user-defined classes very often. If you are developing the classes yourself, a more proper object-oriented style is to define methods on the classes that encapsulate a particular behaviour, instead of checking the object’s class and doing a different thing based on what class it is. For example, if you have a function that does something:

```python
def search(obj):
    if isinstance(obj, Mailbox):
        ...  # code to search a mailbox
    elif isinstance(obj, Document):
        ...  # code to search a document
    elif ...
```

A better approach is to define a `search()` method on all the classes
and just call it:

```python
class Mailbox:
    def search(self):
        ...  # code to search a mailbox

class Document:
    def search(self):
        ...  # code to search a document

obj.search()
```

**What is delegation?**

Delegation is an object oriented technique (also called a design pattern). Let's say you have an object `x` and want to change the behaviour of just one of its methods. You can create a new class that provides a new implementation of the method you’re interested in changing and delegates all other methods to the corresponding method of `x`.

Python programmers can easily implement delegation. For example, the following class implements a class that behaves like a file but converts all written data to uppercase:

```python
class UpperOut:

    def __init__(self, outfile):
        self._outfile = outfile

    def write(self, s):
        self._outfile.write(s.upper())

    def __getattr__(self, name):
```
Here the UpperOut class redefines the `write()` method to convert the argument string to uppercase before calling the underlying `self.__outfile.write()` method. All other methods are delegated to the underlying `self.__outfile` object. The delegation is accomplished via the `__getattr__` method; consult the language reference for more information about controlling attribute access.

Note that for more general cases delegation can get trickier. When attributes must be set as well as retrieved, the class must define a `__setattr__()` method too, and it must do so carefully. The basic implementation of `__setattr__()` is roughly equivalent to the following:

```python
class X:
    ...
    def __setattr__(self, name, value):
        self.__dict__[name] = value
    ...
```

Most `__setattr__()` implementations must modify `self.__dict__` to store local state for `self` without causing an infinite recursion.

**How do I call a method defined in a base class from a derived class that overrides it?**

Use the built-in `super()` function:

```python
class Derived(Base):
    def meth(self):
```
For version prior to 3.0, you may be using classic classes: For a class definition such as `class Derived(Base): ...` you can call method `meth()` defined in `Base` (or one of `Base`'s base classes) as `Base.meth(self, arguments...)`. Here, `Base.meth` is an unbound method, so you need to provide the `self` argument.

**How can I organize my code to make it easier to change the base class?**

You could define an alias for the base class, assign the real base class to it before your class definition, and use the alias throughout your class. Then all you have to change is the value assigned to the alias. Incidentally, this trick is also handy if you want to decide dynamically (e.g. depending on availability of resources) which base class to use. Example:

```python
BaseAlias = <real base class>

class Derived(BaseAlias):
    def meth(self):
        BaseAlias.meth(self)
    ...
```

**How do I create static class data and static class methods?**

Both static data and static methods (in the sense of C++ or Java) are supported in Python.

For static data, simply define a class attribute. To assign a new value
to the attribute, you have to explicitly use the class name in the assignment:

```python
class C:
    count = 0  # number of times C.__init__ called

    def __init__(self):
        C.count = C.count + 1

    def getcount(self):
        return C.count  # or return self.count
```

c.count also refers to C.count for any c such that isinstance(c, C) holds, unless overridden by c itself or by some class on the base-class search path from c.__class__ back to C.

Caution: within a method of C, an assignment like `self.count = 42` creates a new and unrelated instance named “count” in self’s own dict. Rebinding of a class-static data name must always specify the class whether inside a method or not:

```python
C.count = 314
```

Static methods are possible:

```python
class C:
    @staticmethod
    def static(arg1, arg2, arg3):
        # No 'self' parameter!
        ...
```

However, a far more straightforward way to get the effect of a static method is via a simple module-level function:
def getcount():
    return C.count

If your code is structured so as to define one class (or tightly related class hierarchy) per module, this supplies the desired encapsulation.

How can I overload constructors (or methods) in Python?

This answer actually applies to all methods, but the question usually comes up first in the context of constructors.

In C++ you’d write

class C {
    C() { cout << "No arguments\n"; }
    C(int i) { cout << "Argument is " << i << "\n";
}

In Python you have to write a single constructor that catches all cases using default arguments. For example:

class C:
    def __init__(self, i=None):
        if i is None:
            print("No arguments")
        else:
            print("Argument is", i)

This is not entirely equivalent, but close enough in practice.

You could also try a variable-length argument list, e.g.
def __init__(self, *args):
...

The same approach works for all method definitions.

I try to use __spam and I get an error about _SomeClassName__spam.

Variable names with double leading underscores are “mangled” to provide a simple but effective way to define class private variables. Any identifier of the form __spam (at least two leading underscores, at most one trailing underscore) is textually replaced with _classname__spam, where classname is the current class name with any leading underscores stripped.

This doesn't guarantee privacy: an outside user can still deliberately access the "_classname__spam" attribute, and private values are visible in the object's __dict__. Many Python programmers never bother to use private variable names at all.

My class defines __del__ but it is not called when I delete the object.

There are several possible reasons for this.

The del statement does not necessarily call __del__() – it simply decrements the object's reference count, and if this reaches zero __del__() is called.

If your data structures contain circular links (e.g. a tree where each child has a parent reference and each parent has a list of children) the reference counts will never go back to zero. Once in a while Python
runs an algorithm to detect such cycles, but the garbage collector might run some time after the last reference to your data structure vanishes, so your \_del\_() method may be called at an inconvenient and random time. This is inconvenient if you're trying to reproduce a problem. Worse, the order in which object's \_del\_() methods are executed is arbitrary. You can run gc\_collect() to force a collection, but there are pathological cases where objects will never be collected.

Despite the cycle collector, it's still a good idea to define an explicit close() method on objects to be called whenever you're done with them. The close() method can then remove attributes that refer to subobjects. Don't call \_del\_() directly – \_del\_() should call close() and close() should make sure that it can be called more than once for the same object.

Another way to avoid cyclical references is to use the weakref module, which allows you to point to objects without incrementing their reference count. Tree data structures, for instance, should use weak references for their parent and sibling references (if they need them!).

Finally, if your \_del\_() method raises an exception, a warning message is printed to sys\_stderr.

**How do I get a list of all instances of a given class?**

Python does not keep track of all instances of a class (or of a built-in type). You can program the class's constructor to keep track of all instances by keeping a list of weak references to each instance.
Why does the result of \texttt{id()} appear to be not unique?

The \texttt{id()} builtin returns an integer that is guaranteed to be unique during the lifetime of the object. Since in CPython, this is the object's memory address, it happens frequently that after an object is deleted from memory, the next freshly created object is allocated at the same position in memory. This is illustrated by this example:

\begin{verbatim}
>>> id(1000)
13901272
>>> id(2000)
13901272
\end{verbatim}

The two ids belong to different integer objects that are created before, and deleted immediately after execution of the \texttt{id()} call. To be sure that objects whose id you want to examine are still alive, create another reference to the object:

\begin{verbatim}
>>> a = 1000; b = 2000
>>> id(a)
13901272
>>> id(b)
13891296
\end{verbatim}
Modules

How do I create a .pyc file?

When a module is imported for the first time (or when the source file has changed since the current compiled file was created) a .pyc file containing the compiled code should be created in a __pycache__ subdirectory of the directory containing the .py file. The .pyc file will have a filename that starts with the same name as the .py file, and ends with .pyc, with a middle component that depends on the particular python binary that created it. (See PEP 3147 for details.)

One reason that a .pyc file may not be created is a permissions problem with the directory containing the source file, meaning that the __pycache__ subdirectory cannot be created. This can happen, for example, if you develop as one user but run as another, such as if you are testing with a web server.

Unless the PYTHONDONTWRITEBYTECODE environment variable is set, creation of a .pyc file is automatic if you're importing a module and Python has the ability (permissions, free space, etc…) to create a __pycache__ subdirectory and write the compiled module to that subdirectory.

Running Python on a top level script is not considered an import and no .pyc will be created. For example, if you have a top-level module foo.py that imports another module xyz.py, when you run foo (by typing python foo.py as a shell command), a .pyc will be created for xyz because xyz is imported, but no .pyc file will be created for foo since foo.py isn't being imported.
If you need to create a .pyc file for foo – that is, to create a .pyc file for a module that is not imported – you can, using the py_compile and compileall modules.

The py_compile module can manually compile any module. One way is to use the compile() function in that module interactively:

```python
>>> import py_compile
>>> py_compile.compile('foo.py')
```

This will write the .pyc to a __pycache__ subdirectory in the same location as foo.py (or you can override that with the optional parameter cfile).

You can also automatically compile all files in a directory or directories using the compileall module. You can do it from the shell prompt by running compileall.py and providing the path of a directory containing Python files to compile:

```
python -m compileall .
```

How do I find the current module name?

A module can find out its own module name by looking at the predefined global variable __name__. If this has the value '__main__', the program is running as a script. Many modules that are usually used by importing them also provide a command-line interface or a self-test, and only execute this code after checking __name__:

```python
def main():
    print('Running test...')
```
How can I have modules that mutually import each other?

Suppose you have the following modules:

foo.py:

```python
from bar import bar_var
foo_var = 1
```

bar.py:

```python
from foo import foo_var
bar_var = 2
```

The problem is that the interpreter will perform the following steps:

- main imports foo
- Empty globals for foo are created
- foo is compiled and starts executing
- foo imports bar
- Empty globals for bar are created
- bar is compiled and starts executing
- bar imports foo (which is a no-op since there already is a module named foo)
- bar.foo_var = foo.foo_var

The last step fails, because Python isn’t done with interpreting foo yet and the global symbol dictionary for foo is still empty.
The same thing happens when you use `import foo`, and then try to access `foo.foo_var` in global code.

There are (at least) three possible workarounds for this problem.

Guido van Rossum recommends avoiding all uses of `from <module> import ...`, and placing all code inside functions. Initializations of global variables and class variables should use constants or built-in functions only. This means everything from an imported module is referenced as `<module>.<name>`.

Jim Roskind suggests performing steps in the following order in each module:

- exports (globals, functions, and classes that don't need imported base classes)
- `import` statements
- active code (including globals that are initialized from imported values).

van Rossum doesn't like this approach much because the imports appear in a strange place, but it does work.

Matthias Urlichs recommends restructuring your code so that the recursive import is not necessary in the first place.

These solutions are not mutually exclusive.

`__import__('x.y.z')` returns `<module 'x'>`; how do I get `z`?

Consider using the convenience function `import_module()` from `importlib` instead:
When I edit an imported module and reimport it, the changes don’t show up. Why does this happen?

For reasons of efficiency as well as consistency, Python only reads the module file on the first time a module is imported. If it didn't, in a program consisting of many modules where each one imports the same basic module, the basic module would be parsed and re-parsed many times. To force re-reading of a changed module, do this:

```python
import importlib
import modname
importlib.reload(modname)
```

Warning: this technique is not 100% fool-proof. In particular, modules containing statements like

```python
from modname import some_objects
```

will continue to work with the old version of the imported objects. If the module contains class definitions, existing class instances will not be updated to use the new class definition. This can result in the following paradoxical behaviour:

```python
>>> import importlib
>>> import cls
>>> c = cls.C()     # Create an instance
>>> importlib.reload(cls)
<module 'cls' from 'cls.py'>
>>> isinstance(c, cls.C)     # isinstance is false
False
```
The nature of the problem is made clear if you print out the “identity” of the class objects:

```python
>>> hex(id(c.__class__))
'0x7352a0'
>>> hex(id(cls.C))
'0x4198d0'
```
Why does Python use indentation for grouping of statements?

Guido van Rossum believes that using indentation for grouping is extremely elegant and contributes a lot to the clarity of the average Python program. Most people learn to love this feature after a while.

Since there are no begin/end brackets there cannot be a disagreement between grouping perceived by the parser and the human reader. Occasionally C programmers will encounter a fragment of code like this:

```python
if (x <= y)
    x++;  # Indentation leads you to believe that this is a separate block.
    y--;  # Even though there's no explicit block, it seems like it's here.
z++;   # But only the x++ statement is executed if the condition is true.
```

Only the `x++` statement is executed if the condition is true, but the indentation leads you to believe otherwise. Even experienced C programmers will sometimes stare at it a long time wondering why `y` is being decremented even for `x > y`.

Because there are no begin/end brackets, Python is much less prone to coding-style conflicts. In C there are many different ways to place the braces. If you’re used to reading and writing code that uses one style, you will feel at least slightly uneasy when reading (or being required to write) another style.

Many coding styles place begin/end brackets on a line by themselves. This makes programs considerably longer and wastes valuable screen space, making it harder to get a good overview of a program. Ideally, a function should fit on one screen (say, 20–30 lines). 20 lines of Python
can do a lot more work than 20 lines of C. This is not solely due to the lack of begin/end brackets – the lack of declarations and the high-level data types are also responsible – but the indentation-based syntax certainly helps.
Why am I getting strange results with simple arithmetic operations?

See the next question.
Why are floating-point calculations so inaccurate?

Users are often surprised by results like this:

```
>>> 1.2 - 1.0
0.19999999999999996
```

and think it is a bug in Python. It's not. This has little to do with Python, and much more to do with how the underlying platform handles floating-point numbers.

The float type in CPython uses a C double for storage. A float object's value is stored in binary floating-point with a fixed precision (typically 53 bits) and Python uses C operations, which in turn rely on the hardware implementation in the processor, to perform floating-point operations. This means that as far as floating-point operations are concerned, Python behaves like many popular languages including C and Java.

Many numbers that can be written easily in decimal notation cannot be expressed exactly in binary floating-point. For example, after:

```
>>> x = 1.2
```

the value stored for \( x \) is a (very good) approximation to the decimal value \( 1.2 \), but is not exactly equal to it. On a typical machine, the actual stored value is:

```
1.0011001100110011001100110011001100110011001100110011
```
which is exactly:

```
1.19999999999999995559107901499373838305473327636718
```

The typical precision of 53 bits provides Python floats with 15–16 decimal digits of accuracy.

For a fuller explanation, please see the floating point arithmetic chapter in the Python tutorial.
Why are Python strings immutable?

There are several advantages.

One is performance: knowing that a string is immutable means we can allocate space for it at creation time, and the storage requirements are fixed and unchanging. This is also one of the reasons for the distinction between tuples and lists.

Another advantage is that strings in Python are considered as “elemental” as numbers. No amount of activity will change the value 8 to anything else, and in Python, no amount of activity will change the string “eight” to anything else.
Why must ‘self’ be used explicitly in method definitions and calls?

The idea was borrowed from Modula-3. It turns out to be very useful, for a variety of reasons.

First, it's more obvious that you are using a method or instance attribute instead of a local variable. Reading `self.x` or `self.meth()` makes it absolutely clear that an instance variable or method is used even if you don’t know the class definition by heart. In C++, you can sort of tell by the lack of a local variable declaration (assuming globals are rare or easily recognizable) – but in Python, there are no local variable declarations, so you’d have to look up the class definition to be sure. Some C++ and Java coding standards call for instance attributes to have an `m_` prefix, so this explicitness is still useful in those languages, too.

Second, it means that no special syntax is necessary if you want to explicitly reference or call the method from a particular class. In C++, if you want to use a method from a base class which is overridden in a derived class, you have to use the `::` operator – in Python you can write `baseclass.methodname(self, <argument list>).` This is particularly useful for `__init__()` methods, and in general in cases where a derived class method wants to extend the base class method of the same name and thus has to call the base class method somehow.

Finally, for instance variables it solves a syntactic problem with assignment: since local variables in Python are (by definition!) those variables to which a value is assigned in a function body (and that aren’t explicitly declared global), there has to be some way to tell the
interpreter that an assignment was meant to assign to an instance variable instead of to a local variable, and it should preferably be syntactic (for efficiency reasons). C++ does this through declarations, but Python doesn’t have declarations and it would be a pity having to introduce them just for this purpose. Using the explicit `self.var` solves this nicely. Similarly, for using instance variables, having to write `self.var` means that references to unqualified names inside a method don’t have to search the instance’s directories. To put it another way, local variables and instance variables live in two different namespaces, and you need to tell Python which namespace to use.
Why can’t I use an assignment in an expression?

Many people used to C or Perl complain that they want to use this C idiom:

```c
while (line = readline(f)) {
    // do something with line
}
```

where in Python you’re forced to write this:

```python
while True:
    line = f.readline()
    if not line:
        break
    ... # do something with line
```

The reason for not allowing assignment in Python expressions is a common, hard-to-find bug in those other languages, caused by this construct:

```c
if (x = 0) {
    // error handling
}
else {
    // code that only works for nonzero x
}
```

The error is a simple typo: ```x = 0``` which assigns 0 to the variable ```x``` was written while the comparison ```x == 0``` is certainly what was intended.
Many alternatives have been proposed. Most are hacks that save some typing but use arbitrary or cryptic syntax or keywords, and fail the simple criterion for language change proposals: it should intuitively suggest the proper meaning to a human reader who has not yet been introduced to the construct.

An interesting phenomenon is that most experienced Python programmers recognize the `while True` idiom and don’t seem to be missing the assignment in expression construct much; it’s only newcomers who express a strong desire to add this to the language.

There’s an alternative way of spelling this that seems attractive but is generally less robust than the “while True” solution:

```python
line = f.readline()
while line:
    ... # do something with line...
    line = f.readline()
```

The problem with this is that if you change your mind about exactly how you get the next line (e.g. you want to change it into `sys.stdin.readline()`) you have to remember to change two places in your program – the second occurrence is hidden at the bottom of the loop.

The best approach is to use iterators, making it possible to loop through objects using the `for` statement. For example, file objects support the iterator protocol, so you can write simply:

```python
for line in f:
    ... # do something with line...
```
Why does Python use methods for some functionality (e.g. list.index()) but functions for other (e.g. len(list))? 

The major reason is history. Functions were used for those operations that were generic for a group of types and which were intended to work even for objects that didn’t have methods at all (e.g. tuples). It is also convenient to have a function that can readily be applied to an amorphous collection of objects when you use the functional features of Python (map(), zip() et al).

In fact, implementing len(), max(), min() as a built-in function is actually less code than implementing them as methods for each type. One can quibble about individual cases but it’s a part of Python, and it’s too late to make such fundamental changes now. The functions have to remain to avoid massive code breakage.

**Note:** For string operations, Python has moved from external functions (the string module) to methods. However, len() is still a function.
Why is `join()` a string method instead of a list or tuple method?

Strings became much more like other standard types starting in Python 1.6, when methods were added which give the same functionality that has always been available using the functions of the string module. Most of these new methods have been widely accepted, but the one which appears to make some programmers feel uncomfortable is:

```
", ".join(['1', '2', '4', '8', '16'])
```

which gives the result:

```
"1, 2, 4, 8, 16"
```

There are two common arguments against this usage.

The first runs along the lines of: “It looks really ugly using a method of a string literal (string constant)”, to which the answer is that it might, but a string literal is just a fixed value. If the methods are to be allowed on names bound to strings there is no logical reason to make them unavailable on literals.

The second objection is typically cast as: “I am really telling a sequence to join its members together with a string constant”. Sadly, you aren’t. For some reason there seems to be much less difficulty with having `split()` as a string method, since in that case it is easy to see that

```
"1, 2, 4, 8, 16".split("", ")
```
is an instruction to a string literal to return the substrings delimited by the given separator (or, by default, arbitrary runs of white space).

`join()` is a string method because in using it you are telling the separator string to iterate over a sequence of strings and insert itself between adjacent elements. This method can be used with any argument which obeys the rules for sequence objects, including any new classes you might define yourself. Similar methods exist for bytes and bytearray objects.
How fast are exceptions?

A try/except block is extremely efficient if no exceptions are raised. Actually catching an exception is expensive. In versions of Python prior to 2.0 it was common to use this idiom:

```python
try:
    value = mydict[key]
except KeyError:
    mydict[key] = getvalue(key)
    value = mydict[key]
```

This only made sense when you expected the dict to have the key almost all the time. If that wasn’t the case, you coded it like this:

```python
if key in mydict:
    value = mydict[key]
else:
    value = mydict[key] = getvalue(key)
```

For this specific case, you could also use `value = dict.setdefault(key, getvalue(key))`, but only if the `getvalue()` call is cheap enough because it is evaluated in all cases.
Why isn’t there a switch or case statement in Python?

You can do this easily enough with a sequence of `if...elif...elif...else`. There have been some proposals for switch statement syntax, but there is no consensus (yet) on whether and how to do range tests. See PEP 275 for complete details and the current status.

For cases where you need to choose from a very large number of possibilities, you can create a dictionary mapping case values to functions to call. For example:

```python
def function_1(...):
    ...

functions = {'a': function_1,
             'b': function_2,
             'c': self.method_1, ...
}

func = functions[value]
func()
```

For calling methods on objects, you can simplify yet further by using the `getattr()` built-in to retrieve methods with a particular name:

```python
def visit_a(self, ...):
    ...
    ...

def dispatch(self, value):
    method_name = 'visit_' + str(value)
    method = getattr(self, method_name)
```
It's suggested that you use a prefix for the method names, such as `visit_` in this example. Without such a prefix, if values are coming from an untrusted source, an attacker would be able to call any method on your object.
Can’t you emulate threads in the interpreter instead of relying on an OS-specific thread implementation?

Answer 1: Unfortunately, the interpreter pushes at least one C stack frame for each Python stack frame. Also, extensions can call back into Python at almost random moments. Therefore, a complete threads implementation requires thread support for C.

Answer 2: Fortunately, there is Stackless Python, which has a completely redesigned interpreter loop that avoids the C stack.
Why can’t lambda expressions contain statements?

Python lambda expressions cannot contain statements because Python's syntactic framework can’t handle statements nested inside expressions. However, in Python, this is not a serious problem. Unlike lambda forms in other languages, where they add functionality, Python lambdas are only a shorthand notation if you’re too lazy to define a function.

Functions are already first class objects in Python, and can be declared in a local scope. Therefore the only advantage of using a lambda instead of a locally-defined function is that you don’t need to invent a name for the function – but that’s just a local variable to which the function object (which is exactly the same type of object that a lambda expression yields) is assigned!
Can Python be compiled to machine code, C or some other language?

**Cython** compiles a modified version of Python with optional annotations into C extensions. **Nuitka** is an up-and-coming compiler of Python into C++ code, aiming to support the full Python language. For compiling to Java you can consider **VOC**.
How does Python manage memory?

The details of Python memory management depend on the implementation. The standard implementation of Python, CPython, uses reference counting to detect inaccessible objects, and another mechanism to collect reference cycles, periodically executing a cycle detection algorithm which looks for inaccessible cycles and deletes the objects involved. The `gc` module provides functions to perform a garbage collection, obtain debugging statistics, and tune the collector's parameters.

Other implementations (such as Jython or PyPy), however, can rely on a different mechanism such as a full-blown garbage collector. This difference can cause some subtle porting problems if your Python code depends on the behavior of the reference counting implementation.

In some Python implementations, the following code (which is fine in CPython) will probably run out of file descriptors:

```python
for file in very_long_list_of_files:
    f = open(file)
    c = f.read(1)
```

Indeed, using CPython's reference counting and destructor scheme, each new assignment to `f` closes the previous file. With a traditional GC, however, those file objects will only get collected (and closed) at varying and possibly long intervals.

If you want to write code that will work with any Python implementation, you should explicitly close the file or use the `with` statement; this will work regardless of memory management scheme:
for file in very_long_list_of_files:
    with open(file) as f:
        c = f.read(1)
Why doesn’t CPython use a more traditional garbage collection scheme?

For one thing, this is not a C standard feature and hence it’s not portable. (Yes, we know about the Boehm GC library. It has bits of assembler code for most common platforms, not for all of them, and although it is mostly transparent, it isn’t completely transparent; patches are required to get Python to work with it.)

Traditional GC also becomes a problem when Python is embedded into other applications. While in a standalone Python it’s fine to replace the standard malloc() and free() with versions provided by the GC library, an application embedding Python may want to have its own substitute for malloc() and free(), and may not want Python’s. Right now, CPython works with anything that implements malloc() and free() properly.
Why isn’t all memory freed when CPython exits?

Objects referenced from the global namespaces of Python modules are not always deallocated when Python exits. This may happen if there are circular references. There are also certain bits of memory that are allocated by the C library that are impossible to free (e.g. a tool like Purify will complain about these). Python is, however, aggressive about cleaning up memory on exit and does try to destroy every single object.

If you want to force Python to delete certain things on deallocation use the `atexit` module to run a function that will force those deletions.
Why are there separate tuple and list data types?

Lists and tuples, while similar in many respects, are generally used in fundamentally different ways. Tuples can be thought of as being similar to Pascal records or C structs; they're small collections of related data which may be of different types which are operated on as a group. For example, a Cartesian coordinate is appropriately represented as a tuple of two or three numbers.

Lists, on the other hand, are more like arrays in other languages. They tend to hold a varying number of objects all of which have the same type and which are operated on one-by-one. For example, `os.listdir('.')` returns a list of strings representing the files in the current directory. Functions which operate on this output would generally not break if you added another file or two to the directory.

Tuples are immutable, meaning that once a tuple has been created, you can’t replace any of its elements with a new value. Lists are mutable, meaning that you can always change a list's elements. Only immutable elements can be used as dictionary keys, and hence only tuples and not lists can be used as keys.
How are lists implemented?

Python’s lists are really variable-length arrays, not Lisp-style linked lists. The implementation uses a contiguous array of references to other objects, and keeps a pointer to this array and the array’s length in a list head structure.

This makes indexing a list \( a[i] \) an operation whose cost is independent of the size of the list or the value of the index.

When items are appended or inserted, the array of references is resized. Some cleverness is applied to improve the performance of appending items repeatedly; when the array must be grown, some extra space is allocated so the next few times don’t require an actual resize.
How are dictionaries implemented?

Python's dictionaries are implemented as resizable hash tables. Compared to B-trees, this gives better performance for lookup (the most common operation by far) under most circumstances, and the implementation is simpler.

Dictionaries work by computing a hash code for each key stored in the dictionary using the `hash()` built-in function. The hash code varies widely depending on the key and a per-process seed; for example, “Python” could hash to -539294296 while “python”, a string that differs by a single bit, could hash to 1142331976. The hash code is then used to calculate a location in an internal array where the value will be stored. Assuming that you're storing keys that all have different hash values, this means that dictionaries take constant time – O(1), in computer science notation – to retrieve a key. It also means that no sorted order of the keys is maintained, and traversing the array as the `.keys()` and `.items()` do will output the dictionary's content in some arbitrary jumbled order that can change with every invocation of a program.
Why must dictionary keys be immutable?

The hash table implementation of dictionaries uses a hash value calculated from the key value to find the key. If the key were a mutable object, its value could change, and thus its hash could also change. But since whoever changes the key object can’t tell that it was being used as a dictionary key, it can’t move the entry around in the dictionary. Then, when you try to look up the same object in the dictionary it won’t be found because its hash value is different. If you tried to look up the old value it wouldn’t be found either, because the value of the object found in that hash bin would be different.

If you want a dictionary indexed with a list, simply convert the list to a tuple first; the function \texttt{tuple(L)} creates a tuple with the same entries as the list \texttt{L}. Tuples are immutable and can therefore be used as dictionary keys.

Some unacceptable solutions that have been proposed:

- Hash lists by their address (object ID). This doesn’t work because if you construct a new list with the same value it won’t be found; e.g.:

```python
mydict = {[1, 2]: '12'}
print(mydict[[1, 2]])
```

would raise a KeyError exception because the id of the \texttt{[1, 2]} used in the second line differs from that in the first line. In other words, dictionary keys should be compared using \texttt{==}, not using \texttt{is}.

- Make a copy when using a list as a key. This doesn’t work
because the list, being a mutable object, could contain a reference to itself, and then the copying code would run into an infinite loop.

- Allow lists as keys but tell the user not to modify them. This would allow a class of hard-to-track bugs in programs when you forgot or modified a list by accident. It also invalidates an important invariant of dictionaries: every value in `d.keys()` is usable as a key of the dictionary.

- Mark lists as read-only once they are used as a dictionary key. The problem is that it’s not just the top-level object that could change its value; you could use a tuple containing a list as a key. Entering anything as a key into a dictionary would require marking all objects reachable from there as read-only – and again, self-referential objects could cause an infinite loop.

There is a trick to get around this if you need to, but use it at your own risk: You can wrap a mutable structure inside a class instance which has both a `__eq__()` and a `__hash__()` method. You must then make sure that the hash value for all such wrapper objects that reside in a dictionary (or other hash based structure), remain fixed while the object is in the dictionary (or other structure).

class ListWrapper:
    def __init__(self, the_list):
        self.the_list = the_list

    def __eq__(self, other):
        return self.the_list == other.the_list

    def __hash__(self):
        l = self.the_list
        result = 98767 - len(l)*555
```python
for i, el in enumerate(l):
    try:
        result = result + (hash(el) % 999999)
    except Exception:
        result = (result % 7777777) + i * 33

return result
```

Note that the hash computation is complicated by the possibility that some members of the list may be unhashable and also by the possibility of arithmetic overflow.

Furthermore it must always be the case that if `o1 == o2` (ie `o1.__eq__(o2)` is True) then `hash(o1) == hash(o2)` (ie, `o1.__hash__() == o2.__hash__()`, regardless of whether the object is in a dictionary or not. If you fail to meet these restrictions dictionaries and other hash based structures will misbehave.

In the case of ListWrapper, whenever the wrapper object is in a dictionary the wrapped list must not change to avoid anomalies. Don't do this unless you are prepared to think hard about the requirements and the consequences of not meeting them correctly. Consider yourself warned.
Why doesn’t list.sort() return the sorted list?

In situations where performance matters, making a copy of the list just to sort it would be wasteful. Therefore, `list.sort()` sorts the list in place. In order to remind you of that fact, it does not return the sorted list. This way, you won’t be fooled into accidentally overwriting a list when you need a sorted copy but also need to keep the unsorted version around.

If you want to return a new list, use the built-in `sorted()` function instead. This function creates a new list from a provided iterable, sorts it and returns it. For example, here’s how to iterate over the keys of a dictionary in sorted order:

```python
for key in sorted(mydict):
    ... # do whatever with mydict[key]...
```
How do you specify and enforce an interface spec in Python?

An interface specification for a module as provided by languages such as C++ and Java describes the prototypes for the methods and functions of the module. Many feel that compile-time enforcement of interface specifications helps in the construction of large programs.

Python 2.6 adds an `abc` module that lets you define Abstract Base Classes (ABCs). You can then use `isinstance()` and `issubclass()` to check whether an instance or a class implements a particular ABC. The `collections.abc` module defines a set of useful ABCs such as `Iterable`, `Container`, and `MutableMapping`.

For Python, many of the advantages of interface specifications can be obtained by an appropriate test discipline for components. There is also a tool, PyChecker, which can be used to find problems due to subclassing.

A good test suite for a module can both provide a regression test and serve as a module interface specification and a set of examples. Many Python modules can be run as a script to provide a simple “self test.” Even modules which use complex external interfaces can often be tested in isolation using trivial “stub” emulations of the external interface. The `doctest` and `unittest` modules or third-party test frameworks can be used to construct exhaustive test suites that exercise every line of code in a module.

An appropriate testing discipline can help build large complex applications in Python as well as having interface specifications would.
In fact, it can be better because an interface specification cannot test certain properties of a program. For example, the `append()` method is expected to add new elements to the end of some internal list; an interface specification cannot test that your `append()` implementation will actually do this correctly, but it’s trivial to check this property in a test suite.

Writing test suites is very helpful, and you might want to design your code with an eye to making it easily tested. One increasingly popular technique, test-directed development, calls for writing parts of the test suite first, before you write any of the actual code. Of course Python allows you to be sloppy and not write test cases at all.
Why is there no goto?

You can use exceptions to provide a “structured goto” that even works across function calls. Many feel that exceptions can conveniently emulate all reasonable uses of the “go” or “goto” constructs of C, Fortran, and other languages. For example:

```python
class label(Exception): pass  # declare a label
try:
    ...
    if condition: raise label()  # goto label
    ...
except label:  # where to goto
    pass
    ...
```

This doesn't allow you to jump into the middle of a loop, but that's usually considered an abuse of goto anyway. Use sparingly.
Why can’t raw strings (r-strings) end with a backslash?

More precisely, they can’t end with an odd number of backslashes: the unpaired backslash at the end escapes the closing quote character, leaving an unterminated string.

Raw strings were designed to ease creating input for processors (chiefly regular expression engines) that want to do their own backslash escape processing. Such processors consider an unmatched trailing backslash to be an error anyway, so raw strings disallow that. In return, they allow you to pass on the string quote character by escaping it with a backslash. These rules work well when r-strings are used for their intended purpose.

If you’re trying to build Windows pathnames, note that all Windows system calls accept forward slashes too:

```python
f = open("/mydir/file.txt")  # works fine!
```

If you're trying to build a pathname for a DOS command, try e.g. one of

```python
dir = r"\this\is\my\dos\dir" "\\"
dir = r"\this\is\my\dos\dir\ "[\:-1]
dir = "\\this\\is\\my\\dos\\dir\\"
```
Why doesn’t Python have a “with” statement for attribute assignments?

Python has a ‘with’ statement that wraps the execution of a block, calling code on the entrance and exit from the block. Some language have a construct that looks like this:

```python
with obj:
    a = 1  # equivalent to obj.a = 1
    total = total + 1  # obj.total = obj.total + 1
```

In Python, such a construct would be ambiguous.

Other languages, such as Object Pascal, Delphi, and C++, use static types, so it’s possible to know, in an unambiguous way, what member is being assigned to. This is the main point of static typing – the compiler always knows the scope of every variable at compile time.

Python uses dynamic types. It is impossible to know in advance which attribute will be referenced at runtime. Member attributes may be added or removed from objects on the fly. This makes it impossible to know, from a simple reading, what attribute is being referenced: a local one, a global one, or a member attribute?

For instance, take the following incomplete snippet:

```python
def foo(a):
    with a:
        print(x)
```

The snippet assumes that “a” must have a member attribute called “x”. However, there is nothing in Python that tells the interpreter this. What
should happen if “a” is, let us say, an integer? If there is a global
variable named “x”, will it be used inside the with block? As you see,
the dynamic nature of Python makes such choices much harder.

The primary benefit of “with” and similar language features (reduction
of code volume) can, however, easily be achieved in Python by
assignment. Instead of:

```python
function(args).mydict[index][index].a = 21
function(args).mydict[index][index].b = 42
function(args).mydict[index][index].c = 63
```

write this:

```python
ref = function(args).mydict[index][index]
ref.a = 21
ref.b = 42
ref.c = 63
```

This also has the side-effect of increasing execution speed because
name bindings are resolved at run-time in Python, and the second
version only needs to perform the resolution once.
Why are colons required for the if/while/def/class statements?

The colon is required primarily to enhance readability (one of the results of the experimental ABC language). Consider this:

```python
if a == b
    print(a)
```

versus

```python
if a == b:
    print(a)
```

Notice how the second one is slightly easier to read. Notice further how a colon sets off the example in this FAQ answer; it's a standard usage in English.

Another minor reason is that the colon makes it easier for editors with syntax highlighting; they can look for colons to decide when indentation needs to be increased instead of having to do a more elaborate parsing of the program text.
Why does Python allow commas at the end of lists and tuples?

Python lets you add a trailing comma at the end of lists, tuples, and dictionaries:

```python
[1, 2, 3,]
('a', 'b', 'c',)
d = {
    "A": [1, 5],
    "B": [6, 7],  # last trailing comma is optional
}
```

There are several reasons to allow this.

When you have a literal value for a list, tuple, or dictionary spread across multiple lines, it's easier to add more elements because you don't have to remember to add a comma to the previous line. The lines can also be reordered without creating a syntax error.

Accidentally omitting the comma can lead to errors that are hard to diagnose. For example:

```python
x = [
    "fee",
    "fie",
    "foo",
    "fum"
]
```

This list looks like it has four elements, but it actually contains three: “fee”, “fiefoo” and “fum”. Always adding the comma avoids this source
of error.

Allowing the trailing comma may also make programmatic code generation easier.

General Library Questions

How do I find a module or application to perform task X?

Check the Library Reference to see if there's a relevant standard library module. (Eventually you'll learn what's in the standard library and will be able to skip this step.)

For third-party packages, search the Python Package Index or try Google or another Web search engine. Searching for “Python” plus a keyword or two for your topic of interest will usually find something helpful.

Where is the math.py (socket.py, regex.py, etc.) source file?

If you can't find a source file for a module it may be a built-in or dynamically loaded module implemented in C, C++ or other compiled language. In this case you may not have the source file or it may be something like mathmodule.c, somewhere in a C source directory (not on the Python Path).

There are (at least) three kinds of modules in Python:

1. modules written in Python (.py);

2. modules written in C and dynamically loaded (.dll, .pyd, .so, .sl, etc);

3. modules written in C and linked with the interpreter; to get a list of these, type:
How do I make a Python script executable on Unix?

You need to do two things: the script file’s mode must be executable and the first line must begin with `#!` followed by the path of the Python interpreter.

The first is done by executing `chmod +x scriptfile` or perhaps `chmod 755 scriptfile`.

The second can be done in a number of ways. The most straightforward way is to write

```
#!/usr/local/bin/python
```

as the very first line of your file, using the pathname for where the Python interpreter is installed on your platform.

If you would like the script to be independent of where the Python interpreter lives, you can use the `env` program. Almost all Unix variants support the following, assuming the Python interpreter is in a directory on the user’s PATH:

```
#!/usr/bin/env python
```

Don't do this for CGI scripts. The PATH variable for CGI scripts is often very minimal, so you need to use the actual absolute pathname of the interpreter.
Occasionally, a user’s environment is so full that the `usr/bin/env` program fails; or there’s no env program at all. In that case, you can try the following hack (due to Alex Rezinsky):

```bash
#!/bin/sh
"":"
exec python $0 ${1+"$@"}
"
```

The minor disadvantage is that this defines the script’s `__doc__` string. However, you can fix that by adding

```python
__doc__ = """"...Whatever..."""
```

**Is there a curses/termcap package for Python?**

For Unix variants: The standard Python source distribution comes with a curses module in the `Modules` subdirectory, though it’s not compiled by default. (Note that this is not available in the Windows distribution – there is no curses module for Windows.)

The `curses` module supports basic curses features as well as many additional functions from ncurses and SYSV curses such as colour, alternative character set support, pads, and mouse support. This means the module isn't compatible with operating systems that only have BSD curses, but there don't seem to be any currently maintained OSes that fall into this category.

For Windows: use the `consolelib` module.

**Is there an equivalent to C’s onexit() in Python?**
The `atexit` module provides a register function that is similar to C's `onexit()`.

**Why don’t my signal handlers work?**

The most common problem is that the signal handler is declared with the wrong argument list. It is called as

```
handler(signum, frame)
```

so it should be declared with two arguments:

```
def handler(signum, frame):
    ...
```
Common tasks

How do I test a Python program or component?

Python comes with two testing frameworks. The doctest module finds examples in the docstrings for a module and runs them, comparing the output with the expected output given in the docstring.

The unittest module is a fancier testing framework modelled on Java and Smalltalk testing frameworks.

To make testing easier, you should use good modular design in your program. Your program should have almost all functionality encapsulated in either functions or class methods – and this sometimes has the surprising and delightful effect of making the program run faster (because local variable accesses are faster than global accesses). Furthermore the program should avoid depending on mutating global variables, since this makes testing much more difficult to do.

The “global main logic” of your program may be as simple as

```python
if __name__ == "__main__":
    main_logic()
```

at the bottom of the main module of your program.

Once your program is organized as a tractable collection of functions and class behaviours you should write test functions that exercise the behaviours. A test suite that automates a sequence of tests can be associated with each module. This sounds like a lot of work, but since Python is so terse and flexible it’s surprisingly easy. You can make
coding much more pleasant and fun by writing your test functions in parallel with the “production code”, since this makes it easy to find bugs and even design flaws earlier.

“Support modules” that are not intended to be the main module of a program may include a self-test of the module.

```python
if __name__ == '__main__':
    self_test()
```

Even programs that interact with complex external interfaces may be tested when the external interfaces are unavailable by using “fake” interfaces implemented in Python.

How do I create documentation from doc strings?

The `pydoc` module can create HTML from the doc strings in your Python source code. An alternative for creating API documentation purely from docstrings is `epydoc`. `Sphinx` can also include docstring content.

How do I get a single keypress at a time?

For Unix variants there are several solutions. It’s straightforward to do this using `curses`, but `curses` is a fairly large module to learn.
Threads

How do I program using threads?

Be sure to use the `threading` module and not the `_thread` module. The `threading` module builds convenient abstractions on top of the low-level primitives provided by the `_thread` module.

Aahz has a set of slides from his threading tutorial that are helpful; see [http://www.pythoncraft.com/OSCON2001/](http://www.pythoncraft.com/OSCON2001/).

None of my threads seem to run: why?

As soon as the main thread exits, all threads are killed. Your main thread is running too quickly, giving the threads no time to do any work.

A simple fix is to add a sleep to the end of the program that's long enough for all the threads to finish:

```python
import threading, time

def thread_task(name, n):
    for i in range(n):
        print(name, i)

for i in range(10):
    T = threading.Thread(target=thread_task, args=(str(T.start())

time.sleep(10)  # <-----------------------------!
```
But now (on many platforms) the threads don’t run in parallel, but appear to run sequentially, one at a time! The reason is that the OS thread scheduler doesn’t start a new thread until the previous thread is blocked.

A simple fix is to add a tiny sleep to the start of the run function:

```python
def thread_task(name, n):
    time.sleep(0.001)  # <------------------------!
    for i in range(n):
        print(name, i)

for i in range(10):
    T = threading.Thread(target=thread_task, args=(s,))
    T.start()

time.sleep(10)
```

Instead of trying to guess a good delay value for `time.sleep()`, it’s better to use some kind of semaphore mechanism. One idea is to use the `queue` module to create a queue object, let each thread append a token to the queue when it finishes, and let the main thread read as many tokens from the queue as there are threads.

**How do I parcel out work among a bunch of worker threads?**

The easiest way is to use the new `concurrent.futures` module, especially the `ThreadPoolExecutor` class.

Or, if you want fine control over the dispatching algorithm, you can write your own logic manually. Use the `queue` module to create a
queue containing a list of jobs. The Queue class maintains a list of objects and has a .put(obj) method that adds items to the queue and a .get() method to return them. The class will take care of the locking necessary to ensure that each job is handed out exactly once.

Here's a trivial example:

```python
import threading, queue, time

# The worker thread gets jobs off the queue. When the queue is empty,
# it assumes there will be no more work and exits. (Realistically workers will run until terminated.)
def worker():
    print('Running worker')
    time.sleep(0.1)
    while True:
        try:
            arg = q.get(block=False)
        except queue.Empty:
            print('Worker', threading.currentThread(), 'queue empty')
            break
        else:
            print('Worker', threading.currentThread(), 'running with argument', arg)
            time.sleep(0.5)

# Create queue
q = queue.Queue()

# Start a pool of 5 workers
for i in range(5):
    t = threading.Thread(target=worker, name='worker' + str(i))
    t.start()

# Begin adding work to the queue
```
for i in range(50):
    q.put(i)

# Give threads time to run
print('Main thread sleeping')
time.sleep(5)

When run, this will produce the following output:

Running worker
Running worker
Running worker
Running worker
Running worker
Main thread sleeping
Worker <Thread(worker 1, started 130283832797456)> running with argument 0
Worker <Thread(worker 2, started 130283824404752)> running with argument 1
Worker <Thread(worker 3, started 130283816012048)> running with argument 2
Worker <Thread(worker 4, started 130283807619344)> running with argument 3
Worker <Thread(worker 5, started 130283799226640)> running with argument 4
Worker <Thread(worker 1, started 130283832797456)> running with argument 5
...

Consult the module's documentation for more details; the Queue class provides a featureful interface.

**What kinds of global value mutation are thread-safe?**

A global interpreter lock (GIL) is used internally to ensure that only one thread runs in the Python VM at a time. In general, Python offers to switch among threads only between bytecode instructions; how frequently it switches can be set via `sys.setswitchinterval()`.
Each bytecode instruction and therefore all the C implementation code reached from each instruction is therefore atomic from the point of view of a Python program.

In theory, this means an exact accounting requires an exact understanding of the PVM bytecode implementation. In practice, it means that operations on shared variables of built-in data types (ints, lists, dicts, etc) that “look atomic” really are.

For example, the following operations are all atomic (L, L1, L2 are lists, D, D1, D2 are dicts, x, y are objects, i, j are ints):

```python
L.append(x)
L1.extend(L2)
x = L[i]
x = L.pop()
L1[i:j] = L2
L.sort()
x = y
x.field = y
D[x] = y
D1.update(D2)
D.keys()
```

These aren’t:

```python
i = i+1
L.append(L[-1])
L[i] = L[j]
D[x] = D[x] + 1
```

Operations that replace other objects may invoke those other objects’ `__del__()` method when their reference count reaches zero, and that can affect things. This is especially true for the mass updates to dictionaries and lists. When in doubt, use a mutex!
Can't we get rid of the Global Interpreter Lock?

The global interpreter lock (GIL) is often seen as a hindrance to Python's deployment on high-end multiprocessor server machines, because a multi-threaded Python program effectively only uses one CPU, due to the insistence that (almost) all Python code can only run while the GIL is held.

Back in the days of Python 1.5, Greg Stein actually implemented a comprehensive patch set (the “free threading” patches) that removed the GIL and replaced it with fine-grained locking. Adam Olsen recently did a similar experiment in his python-safethread project. Unfortunately, both experiments exhibited a sharp drop in single-thread performance (at least 30% slower), due to the amount of fine-grained locking necessary to compensate for the removal of the GIL.

This doesn’t mean that you can’t make good use of Python on multi-CPU machines! You just have to be creative with dividing the work up between multiple processes rather than multiple threads. The ProcessPoolExecutor class in the new concurrent.futures module provides an easy way of doing so; the multiprocessing module provides a lower-level API in case you want more control over dispatching of tasks.

Judicious use of C extensions will also help; if you use a C extension to perform a time-consuming task, the extension can release the GIL while the thread of execution is in the C code and allow other threads to get some work done. Some standard library modules such as zlib and hashlib already do this.

It has been suggested that the GIL should be a per-interpreter-state lock rather than truly global; interpreters then wouldn’t be able to share
objects. Unfortunately, this isn’t likely to happen either. It would be a tremendous amount of work, because many object implementations currently have global state. For example, small integers and short strings are cached; these caches would have to be moved to the interpreter state. Other object types have their own free list; these free lists would have to be moved to the interpreter state. And so on.

And I doubt that it can even be done in finite time, because the same problem exists for 3rd party extensions. It is likely that 3rd party extensions are being written at a faster rate than you can convert them to store all their global state in the interpreter state.

And finally, once you have multiple interpreters not sharing any state, what have you gained over running each interpreter in a separate process?
How do I delete a file? (And other file questions...)

Use `os.remove(filename)` or `os.unlink(filename)`; for documentation, see the `os` module. The two functions are identical; `unlink()` is simply the name of the Unix system call for this function.

To remove a directory, use `os.rmdir()`; use `os.mkdir()` to create one. `os.makedirs(path)` will create any intermediate directories in `path` that don't exist. `os.removedirs(path)` will remove intermediate directories as long as they're empty; if you want to delete an entire directory tree and its contents, use `shutil.rmtree()`.

To rename a file, use `os.rename(old_path, new_path)`.

To truncate a file, open it using `f = open(filename, "rb+")`, and use `f.truncate(offset)`: offset defaults to the current seek position. There's also `os.ftruncate(fd, offset)` for files opened with `os.open()`, where `fd` is the file descriptor (a small integer).

The `shutil` module also contains a number of functions to work on files including `copyfile()`, `copytree()`, and `rmtree()`.

How do I copy a file?

The `shutil` module contains a `copyfile()` function. Note that on MacOS 9 it doesn’t copy the resource fork and Finder info.

How do I read (or write) binary data?
To read or write complex binary data formats, it's best to use the `struct` module. It allows you to take a string containing binary data (usually numbers) and convert it to Python objects; and vice versa.

For example, the following code reads two 2-byte integers and one 4-byte integer in big-endian format from a file:

```python
import struct

with open(filename, "rb") as f:
    s = f.read(8)
    x, y, z = struct.unpack(">hhl", s)
```

The ‘>’ in the format string forces big-endian data; the letter ‘h’ reads one “short integer” (2 bytes), and ‘l’ reads one “long integer” (4 bytes) from the string.

For data that is more regular (e.g. a homogeneous list of ints or floats), you can also use the `array` module.

**Note:** To read and write binary data, it is mandatory to open the file in binary mode (here, passing "rb" to `open()`). If you use "r" instead (the default), the file will be open in text mode and `f.read()` will return `str` objects rather than `bytes` objects.

I can’t seem to use `os.read()` on a pipe created with `os.popen();` why?

`os.read()` is a low-level function which takes a file descriptor, a small integer representing the opened file. `os.popen()` creates a high-level file object, the same type returned by the built-in `open()`
function. Thus, to read $n$ bytes from a pipe $p$ created with `os.popen()`, you need to use `p.read(n)`.

**How do I access the serial (RS232) port?**

For Win32, POSIX (Linux, BSD, etc.), Jython:

```python
http://pyserial.sourceforge.net
```

For Unix, see a Usenet post by Mitch Chapman:

```python
https://groups.google.com/groups?selm=34A04430.CF9@ohioee.com
```

**Why doesn’t closing `sys.stdout` (stdin, stderr) really close it?**

Python file objects are a high-level layer of abstraction on low-level C file descriptors.

For most file objects you create in Python via the built-in `open()` function, `f.close()` marks the Python file object as being closed from Python’s point of view, and also arranges to close the underlying C file descriptor. This also happens automatically in `f`’s destructor, when `f` becomes garbage.

But stdin, stdout and stderr are treated specially by Python, because of the special status also given to them by C. Running `sys.stdout.close()` marks the Python-level file object as being closed, but does not close the associated C file descriptor.

To close the underlying C file descriptor for one of these three, you should first be sure that’s what you really want to do (e.g., you may
confuse extension modules trying to do I/O). If it is, use `os.close()`:

```python
os.close(stdin.fileno())
os.close(stdout.fileno())
os.close(stderr.fileno())
```

Or you can use the numeric constants 0, 1 and 2, respectively.
Network/Internet Programming

What WWW tools are there for Python?

See the chapters titled Internet Protocols and Support and Internet Data Handling in the Library Reference Manual. Python has many modules that will help you build server-side and client-side web systems.

A summary of available frameworks is maintained by Paul Boddie at https://wiki.python.org/moin/WebProgramming.

How can I mimic CGI form submission (METHOD=POST)?

I would like to retrieve web pages that are the result of POSTing a form. Is there existing code that would let me do this easily?

Yes. Here’s a simple example that uses urllib.request:

```
#!/usr/local/bin/python

import urllib.request

# build the query string
qs = "First=Josephine&MI=Q&Last=Public"

# connect and send the server a path
req = urllib.request.urlopen('http://www.some-server.out-there' './cgi-bin/some-cgi-script')
```
Note that in general for percent-encoded POST operations, query strings must be quoted using `urllib.parse.urlencode()`. For example, to send `name=Guy Steele, Jr.`:

```python
>>> import urllib.parse
>>> urllib.parse.urlencode({'name': 'Guy Steele, Jr.', 'name'=Guy+Steele%2C+Jr.'})
```

See also: HOWTO Fetch Internet Resources Using The `urllib` Package for extensive examples.

What module should I use to help with generating HTML?

You can find a collection of useful links on the Web Programming wiki page.

How do I send mail from a Python script?

Use the standard library module `smtplib`.

Here's a very simple interactive mail sender that uses it. This method will work on any host that supports an SMTP listener.

```python
import sys, smtplib
fromaddr = input("From: ")
toaddrs = input("To: ").split(',')
```
print("Enter message, end with ^D:")
msg = ''
while True:
    line = sys.stdin.readline()
    if not line:
        break
    msg += line

# The actual mail send
server = smtplib.SMTP('localhost')
server.sendmail(fromaddr, toaddrs, msg)
server.quit()

A Unix-only alternative uses sendmail. The location of the sendmail program varies between systems; sometimes it is /usr/lib/sendmail, sometimes /usr/sbin/sendmail. The sendmail manual page will help you out. Here's some sample code:

```python
import os
SENDMAIL = "/usr/sbin/sendmail"  # sendmail location
p = os.popen("%s -t -i" % SENDMAIL, "w")
p.write("To: receiver@example.com\n")
p.write("Subject: test\n")
p.write("\n")  # blank line separating headers from
p.write("Some text\n")
p.write("some more text\n")
sts = p.close()
if sts != 0:
    print("Sendmail exit status", sts)
```

How do I avoid blocking in the connect() method of a socket?
The `select` module is commonly used to help with asynchronous I/O on sockets.

To prevent the TCP connect from blocking, you can set the socket to non-blocking mode. Then when you do the `connect()`, you will either connect immediately (unlikely) or get an exception that contains the error number as `.errno`. `errno.EINPROGRESS` indicates that the connection is in progress, but hasn't finished yet. Different OSes will return different values, so you're going to have to check what's returned on your system.

You can use the `connect_ex()` method to avoid creating an exception. It will just return the errno value. To poll, you can call `connect_ex()` again later – `0` or `errno.EISCONN` indicate that you're connected – or you can pass this socket to `select` to check if it's writable.

**Note:** The `asyncore` module presents a framework-like approach to the problem of writing non-blocking networking code. The third-party `Twisted` library is a popular and feature-rich alternative.
Databases

Are there any interfaces to database packages in Python?

Yes.

Interfaces to disk-based hashes such as DBM and GDBM are also included with standard Python. There is also the sqlite3 module, which provides a lightweight disk-based relational database.

Support for most relational databases is available. See the DatabaseProgramming wiki page for details.

How do you implement persistent objects in Python?

The pickle library module solves this in a very general way (though you still can’t store things like open files, sockets or windows), and the shelf library module uses pickle and (g)dbm to create persistent mappings containing arbitrary Python objects.
Mathematics and Numerics

How do I generate random numbers in Python?

The standard module `random` implements a random number generator. Usage is simple:

```python
import random
random.random()
```

This returns a random floating point number in the range [0, 1).

There are also many other specialized generators in this module, such as:

- `randrange(a, b)` chooses an integer in the range [a, b).
- `uniform(a, b)` chooses a floating point number in the range [a, b).
- `normalvariate(mean, sdev)` samples the normal (Gaussian) distribution.

Some higher-level functions operate on sequences directly, such as:

- `choice(S)` chooses random element from a given sequence
- `shuffle(L)` shuffles a list in-place, i.e. permutes it randomly

There's also a `Random` class you can instantiate to create independent multiple random number generators.
Extending/Embedding FAQ

  - Can I create an object class with some methods implemented in C and others in Python (e.g. through inheritance)?
Can I create my own functions in C?

Yes, you can create built-in modules containing functions, variables, exceptions and even new types in C. This is explained in the document *Extending and Embedding the Python Interpreter*.

Most intermediate or advanced Python books will also cover this topic.
Can I create my own functions in C++?

Yes, using the C compatibility features found in C++. Place `extern "C"` `{ ... }` around the Python include files and put `extern "C"` before each function that is going to be called by the Python interpreter. Global or static C++ objects with constructors are probably not a good idea.
Writing C is hard; are there any alternatives?

There are a number of alternatives to writing your own C extensions, depending on what you're trying to do.

Cython and its relative Pyrex are compilers that accept a slightly modified form of Python and generate the corresponding C code. Cython and Pyrex make it possible to write an extension without having to learn Python's C API.

If you need to interface to some C or C++ library for which no Python extension currently exists, you can try wrapping the library's data types and functions with a tool such as SWIG. SIP, CXX Boost, or Weave are also alternatives for wrapping C++ libraries.
How can I execute arbitrary Python statements from C?

The highest-level function to do this is `PyRun_SimpleString()` which takes a single string argument to be executed in the context of the module `__main__` and returns 0 for success and -1 when an exception occurred (including `SyntaxError`). If you want more control, use `PyRun_String()`; see the source for `PyRun_SimpleString()` in `Python/pythonrun.c`. 
How can I evaluate an arbitrary Python expression from C?

Call the function `PyRun_String()` from the previous question with the start symbol `Py_eval_input`; it parses an expression, evaluates it and returns its value.
How do I extract C values from a Python object?

That depends on the object's type. If it's a tuple, `PyTuple_Size()` returns its length and `PyTuple_GetItem()` returns the item at a specified index. Lists have similar functions, `PyList_Size()` and `PyList_GetItem()`.

For bytes, `PyBytes_Size()` returns its length and `PyBytes_AsStringAndSize()` provides a pointer to its value and its length. Note that Python bytes objects may contain null bytes so C’s `strlen()` should not be used.

To test the type of an object, first make sure it isn't `NULL`, and then use `PyBytes_Check()`, `PyTuple_Check()`, `PyList_Check()`, etc.

There is also a high-level API to Python objects which is provided by the so-called ‘abstract’ interface – read `Include/abstract.h` for further details. It allows interfacing with any kind of Python sequence using calls like `PySequence_Length()`, `PySequence_GetItem()`, etc. as well as many other useful protocols such as numbers (`PyNumber_Index()` et al.) and mappings in the PyMapping APIs.
How do I use Py_BuildValue() to create a tuple of arbitrary length?

You can't. Use PyTuple_Pack() instead.
How do I call an object’s method from C?

The `PyObject_CallMethod()` function can be used to call an arbitrary method of an object. The parameters are the object, the name of the method to call, a format string like that used with `Py_BuildValue()`, and the argument values:

```c
PyObject *
PyObject_CallMethod(PyObject *object, const char *method_name, const char *arg_format, ...);
```

This works for any object that has methods – whether built-in or user-defined. You are responsible for eventually `Py_DECREF()`’ing the return value.

To call, e.g., a file object’s “seek” method with arguments 10, 0 (assuming the file object pointer is “f”):

```c
res = PyObject_CallMethod(f, "seek", "(ii)", 10, 0);
if (res == NULL) {
    ... an exception occurred ...
} else {
    Py_DECREF(res);
}
```

Note that since `PyObject_CallObject()` always wants a tuple for the argument list, to call a function without arguments, pass “()” for the format, and to call a function with one argument, surround the argument in parentheses, e.g. “(i)”.
How do I catch the output from `PyErr_Print()` (or anything that prints to stdout/stderr)?

In Python code, define an object that supports the `write()` method. Assign this object to `sys.stdout` and `sys.stderr`. Call `print_error`, or just allow the standard traceback mechanism to work. Then, the output will go wherever your `write()` method sends it.

The easiest way to do this is to use the `io.StringIO` class:

```python
>>> import io, sys
>>> sys.stdout = io.StringIO()
>>> print('foo')
>>> print('hello world!')
>>> sys.stderr.write(sys.stdout.getvalue())
foo
hello world!
```

A custom object to do the same would look like this:

```python
>>> import io, sys
>>> class StdoutCatcher(io.TextIOBase):
...    def __init__(self):
...        self.data = []
...    def write(self, stuff):
...        self.data.append(stuff)
...>>> import sys
>>> sys.stdout = StdoutCatcher()
>>> print('foo')
>>> print('hello world!')
>>> sys.stderr.write(''.join(sys.stdout.data))
```
foo
hello world!
How do I access a module written in Python from C?

You can get a pointer to the module object as follows:

```python
module = PyImport_ImportModule("<modulename>" loaded at 0x1b5e470);
```

If the module hasn't been imported yet (i.e. it is not yet present in `sys.modules`), this initializes the module; otherwise it simply returns the value of `sys.modules["<modulename>"]`. Note that it doesn't enter the module into any namespace – it only ensures it has been initialized and is stored in `sys.modules`.

You can then access the module's attributes (i.e. any name defined in the module) as follows:

```python
attr = PyObject_GetAttrString(module, "<attrname>");
```

Calling `PyObject_SetAttrString()` to assign to variables in the module also works.
How do I interface to C++ objects from Python?

Depending on your requirements, there are many approaches. To do this manually, begin by reading the “Extending and Embedding” document. Realize that for the Python run-time system, there isn’t a whole lot of difference between C and C++ – so the strategy of building a new Python type around a C structure (pointer) type will also work for C++ objects.

For C++ libraries, see Writing C is hard; are there any alternatives?.
I added a module using the Setup file and the make fails; why?

Setup must end in a newline, if there is no newline there, the build process fails. (Fixing this requires some ugly shell script hackery, and this bug is so minor that it doesn't seem worth the effort.)
How do I debug an extension?

When using GDB with dynamically loaded extensions, you can’t set a breakpoint in your extension until your extension is loaded.

In your `.gdbinit` file (or interactively), add the command:

```
br _PyImport_LoadDynamicModule
```

Then, when you run GDB:

```
$ gdb /local/bin/python
gdb) run myscript.py
gdb) continue # repeat until your extension is loaded
gdb) finish       # so that your extension is loaded
gdb) br myfunction.c:50
gdb) continue
```
I want to compile a Python module on my Linux system, but some files are missing. Why?

Most packaged versions of Python don’t include the /usr/lib/python2.x/config/ directory, which contains various files required for compiling Python extensions.

For Red Hat, install the python-devel RPM to get the necessary files.

For Debian, run `apt-get install python-dev`. 
How do I tell “incomplete input” from “invalid input”?

Sometimes you want to emulate the Python interactive interpreter’s behavior, where it gives you a continuation prompt when the input is incomplete (e.g. you typed the start of an “if” statement or you didn’t close your parentheses or triple string quotes), but it gives you a syntax error message immediately when the input is invalid.

In Python you can use the codeop module, which approximates the parser’s behavior sufficiently. IDLE uses this, for example.

The easiest way to do it in C is to call PyRun_InteractiveLoop() (perhaps in a separate thread) and let the Python interpreter handle the input for you. You can also set the PyOS_ReadlineFunctionPointer() to point at your custom input function. See Modules/readline.c and Parser/myreadline.c for more hints.

However sometimes you have to run the embedded Python interpreter in the same thread as your rest application and you can’t allow the PyRun_InteractiveLoop() to stop while waiting for user input. The one solution then is to call PyParser_ParseString() and test for e.error equal to E_EOF, which means the input is incomplete. Here’s a sample code fragment, untested, inspired by code from Alex Farber:

```c
#include <Python.h>
#include <node.h>
#include <errcode.h>
#include <grammar.h>
#include <parsetok.h>
```
```c
#include <compile.h>

int testcomplete(char *code)
/* code should end in \n */
/* return -1 for error, 0 for incomplete, 1 for complete */
{
    node *n;
    perrdetail e;

    n = PyParser_ParseString(code, &_PyParser_Grammar,
                            Py_file_input, &e);
    if (n == NULL) {
        if (e.error == E_EOF)
            return 0;
        return -1;
    }
    PyNode_Free(n);
    return 1;
}
```

Another solution is trying to compile the received string with `Py_CompileString()`. If it compiles without errors, try to execute the returned code object by calling `PyEval_EvalCode()`. Otherwise save the input for later. If the compilation fails, find out if it’s an error or just more input is required - by extracting the message string from the exception tuple and comparing it to the string “unexpected EOF while parsing”. Here is a complete example using the GNU readline library (you may want to ignore `SIGINT` while calling readline()):

```c
#include <stdio.h>
#include <readline.h>

#include <Python.h>
#include <object.h>
```
#include <compile.h>
#include <eval.h>

int main (int argc, char* argv[]) {
    int i, j, done = 0; /* length of line, code */
    char ps1[] = ">>> ";
    char ps2[] = "... ";
    char *prompt = ps1;
    char *msg, *line, *code = NULL;
    PyObject *src, *glb, *loc;

    Py_Initialize ();
    loc = PyDict_New ();
    glb = PyDict_New ();
    PyDict_SetItemString (glb, "__builtins__", PyEval_
code = realloc (code, i + j + 2);
if (NULL == code) /* out
    exit (1);

if (0 == j) /* co
code[0] = '\0'; /* ke
strncat (code, line, i); /* ap
code[i + j] = '\n'; /* ap
code[i + j + 1] = '\0';

src = Py_CompileString (code, "<stdin>", Py_single_input
if (NULL != src) /* co
{
    if (ps1 == prompt | |
        '\n' == code[i + j - 1]) /* ".
        {
            dum = PyEval_EvalCode (src, glb, loc);
            Py_XDECREF (dum);
            Py_XDECREF (src);
            free (code);
            code = NULL;
            if (PyErr_Occurred ())
                PyErr_Print ();
                prompt = ps1;
        }
    } /* sys
else if (PyErr_ExceptionMatches (PyExc_SyntaxError
    {       
        PyErr_FETCH (&exc, &val, &trb); /* cl

        if (PyArg_ParseTuple (val, "sO", &msg, &obj)
            !=strcmp (msg, "unexpected EOF while par
            {     
                Py_XDECREF (exc);
Py_XDECREF (val);
Py_XDECREF (trb);
prompt = ps2;
}
else
{
    PyErr_Restore (exc, val, trb);
    PyErr_Print ();
    free (code);
    code = NULL;
    prompt = ps1;
}
}
else
{
    PyErr_Print ();
    free (code);
    code = NULL;
    prompt = ps1;
}
free (line);
}

Py_XDECREF(glb);
Py_XDECREF(loc);
Py_Finalize();
exit(0);
How do I find undefined g++ symbols __builtin_new or __pure_virtual?

To dynamically load g++ extension modules, you must recompile Python, relink it using g++ (change LINKCC in the Python Modules Makefile), and link your extension module using g++ (e.g., g++ -shared -o mymodule.so mymodule.o).
Can I create an object class with some methods implemented in C and others in Python (e.g. through inheritance)?

Yes, you can inherit from built-in classes such as `int`, `list`, `dict`, etc.

The Boost Python Library (BPL, http://www.boost.org/libs/python/doc/index.html) provides a way of doing this from C++ (i.e. you can inherit from an extension class written in C++ using the BPL).

How do I run a Python program under Windows?

This is not necessarily a straightforward question. If you are already familiar with running programs from the Windows command line then everything will seem obvious; otherwise, you might need a little more guidance.

Unless you use some sort of integrated development environment, you will end up typing Windows commands into what is variously referred to as a “DOS window” or “Command prompt window”. Usually you can create such a window from your Start menu; under Windows 7 the menu selection is Start ‣ Programs ‣ Accessories ‣ Command Prompt. You should be able to recognize when you have started such a window because you will see a Windows “command prompt”, which usually looks like this:

C:\>

The letter may be different, and there might be other things after it, so you might just as easily see something like:

D:\YourName\Projects\Python>
depending on how your computer has been set up and what else you have recently done with it. Once you have started such a window, you are well on the way to running Python programs.

You need to realize that your Python scripts have to be processed by another program called the Python interpreter. The interpreter reads your script, compiles it into bytecodes, and then executes the bytecodes to run your program. So, how do you arrange for the interpreter to handle your Python?

First, you need to make sure that your command window recognises the word “python” as an instruction to start the interpreter. If you have opened a command window, you should try entering the command python and hitting return.:

```
C:\Users\YourName> python
```

You should then see something like:

```
Python 3.3.0 (v3.3.0:bd8afb90ebf2, Sep 29 2012, 10:55:09) [GCC 4.2.1 (Apple Inc. build 5666) ( revised)]
Type "help", "copyright", "credits" or "license" for more information.
>>> print("Hello")
Hello
>>> "Hello" * 3
'HelloHelloHello'
```

You have started the interpreter in “interactive mode”. That means you can enter Python statements or expressions interactively and have them executed or evaluated while you wait. This is one of Python's strongest features. Check it by entering a few expressions of your choice and seeing the results:
Many people use the interactive mode as a convenient yet highly programmable calculator. When you want to end your interactive Python session, hold the Ctrl key down while you enter a Z, then hit the “Enter” key to get back to your Windows command prompt.

You may also find that you have a Start-menu entry such as Start ▶ Programs ▶ Python 3.3 ▶ Python (command line) that results in you seeing the >>> prompt in a new window. If so, the window will disappear after you enter the Ctrl-Z character; Windows is running a single “python” command in the window, and closes it when you terminate the interpreter.

If the python command, instead of displaying the interpreter prompt >>>, gives you a message like:

```
'python' **is not** recognized as an internal or external
```

or:

```
Bad command or filename
```

then you need to make sure that your computer knows where to find the Python interpreter. To do this you will have to modify a setting called PATH, which is a list of directories where Windows will look for programs.

You should arrange for Python’s installation directory to be added to the PATH of every command window as it starts. If you installed Python

---

**VIDEO**

Adding Python to DOS Path

Python is not added to the DOS path by default. This screencast will walk you through the steps to add the correct entry to the **System Path**, allowing Python to be executed from the command-line by all users.
fairly recently then the command

```
dir C:\py*
```

will probably tell you where it is installed; the usual location is something like `C:\Python33`. Otherwise you will be reduced to a search of your whole disk ... use Tools ▶ Find or hit the Search button and look for “python.exe”. Supposing you discover that Python is installed in the `C:\Python33` directory (the default at the time of writing), you should make sure that entering the command

```
c:\Python33\python
```

starts up the interpreter as above (and don’t forget you’ll need a “Ctrl-Z” and an “Enter” to get out of it). Once you have verified the directory, you can add it to the system path to make it easier to start Python by just running the `python` command. This is currently an option in the installer as of CPython 3.3.

More information about environment variables can be found on the Using Python on Windows page.
How do I make Python scripts executable?

On Windows, the standard Python installer already associates the .py extension with a file type (Python.File) and gives that file type an open command that runs the interpreter (D:\Program Files\Python\python.exe "%1" %*). This is enough to make scripts executable from the command prompt as ‘foo.py’. If you’d rather be able to execute the script by simple typing ‘foo’ with no extension you need to add .py to the PATH\EXT environment variable.
Why does Python sometimes take so long to start?

Usually Python starts very quickly on Windows, but occasionally there are bug reports that Python suddenly begins to take a long time to start up. This is made even more puzzling because Python will work fine on other Windows systems which appear to be configured identically.

The problem may be caused by a misconfiguration of virus checking software on the problem machine. Some virus scanners have been known to introduce startup overhead of two orders of magnitude when the scanner is configured to monitor all reads from the filesystem. Try checking the configuration of virus scanning software on your systems to ensure that they are indeed configured identically. McAfee, when configured to scan all file system read activity, is a particular offender.
How do I make an executable from a Python script?

See [http://cx-freeze.sourceforge.net/](http://cx-freeze.sourceforge.net/) for a distutils extension that allows you to create console and GUI executables from Python code. `py2exe`, the most popular extension for building Python 2.x-based executables, does not yet support Python 3 but a version that does is in development.
Is a *.pyd file the same as a DLL?

Yes, .pyd files are dll's, but there are a few differences. If you have a DLL named foo.pyd, then it must have a function PyInit_foo(). You can then write Python “import foo”, and Python will search for foo.pyd (as well as foo.py, foo.pyc) and if it finds it, will attempt to call PyInit_foo() to initialize it. You do not link your .exe with foo.lib, as that would cause Windows to require the DLL to be present.

Note that the search path for foo.pyd is PYTHONPATH, not the same as the path that Windows uses to search for foo.dll. Also, foo.pyd need not be present to run your program, whereas if you linked your program with a dll, the dll is required. Of course, foo.pyd is required if you want to say import foo. In a DLL, linkage is declared in the source code with __declspec(dllexport). In a .pyd, linkage is defined in a list of available functions.
How can I embed Python into a Windows application?

Embedding the Python interpreter in a Windows app can be summarized as follows:

1. Do _not_ build Python into your .exe file directly. On Windows, Python must be a DLL to handle importing modules that are themselves DLL's. (This is the first key undocumented fact.) Instead, link to `pythonNN.dll`; it is typically installed in `C:\Windows\System`. `NN` is the Python version, a number such as “33” for Python 3.3.

You can link to Python in two different ways. Load-time linking means linking against `pythonNN.lib`, while run-time linking means linking against `pythonNN.dll`. (General note: `pythonNN.lib` is the so-called “import lib” corresponding to `pythonNN.dll`. It merely defines symbols for the linker.)

Run-time linking greatly simplifies link options; everything happens at run time. Your code must load `pythonNN.dll` using the Windows `LoadLibraryEx()` routine. The code must also use access routines and data in `pythonNN.dll` (that is, Python’s C API’s) using pointers obtained by the Windows `GetProcAddress()` routine. Macros can make using these pointers transparent to any C code that calls routines in Python’s C API.

Borland note: convert `pythonNN.lib` to OMF format using `Coff2Omf.exe` first.
2. If you use SWIG, it is easy to create a Python “extension module” that will make the app’s data and methods available to Python. SWIG will handle just about all the grungy details for you. The result is C code that you link into your .exe file (!) You do _not_ have to create a DLL file, and this also simplifies linking.

3. SWIG will create an init function (a C function) whose name depends on the name of the extension module. For example, if the name of the module is leo, the init function will be called initleo(). If you use SWIG shadow classes, as you should, the init function will be called initleoc(). This initializes a mostly hidden helper class used by the shadow class.

The reason you can link the C code in step 2 into your .exe file is that calling the initialization function is equivalent to importing the module into Python! (This is the second key undocumented fact.)

4. In short, you can use the following code to initialize the Python interpreter with your extension module.

```c
#include "python.h"
...
Py_Initialize(); // Initialize Python.
initmyAppc();  // Initialize (import) the helper
PyRun_SimpleString("import myApp"); // Import the
```

5. There are two problems with Python’s C API which will become apparent if you use a compiler other than MSVC, the compiler used to build pythonNN.dll.

Problem 1: The so-called “Very High Level” functions that take FILE * arguments will not work in a multi-compiler environment because each compiler’s notion of a struct FILE will be different.
From an implementation standpoint these are very _low_ level functions.

Problem 2: SWIG generates the following code when generating wrappers to void functions:

```c
Py_INCREF(Py_None);
_resultobj = Py_None;
return _resultobj;
```

Alas, Py_None is a macro that expands to a reference to a complex data structure called _Py_NoneStruct inside pythonNN.dll. Again, this code will fail in a mult-compiler environment. Replace such code by:

```c
return Py_BuildValue(""");
```

It may be possible to use SWIG’s `%typemap` command to make the change automatically, though I have not been able to get this to work (I’m a complete SWIG newbie).

6. Using a Python shell script to put up a Python interpreter window from inside your Windows app is not a good idea; the resulting window will be independent of your app’s windowing system. Rather, you (or the wxPythonWindow class) should create a “native” interpreter window. It is easy to connect that window to the Python interpreter. You can redirect Python’s i/o to _any_ object that supports read and write, so all you need is a Python object (defined in your extension module) that contains read() and write() methods.
How do I keep editors from inserting tabs into my Python source?

The FAQ does not recommend using tabs, and the Python style guide, PEP 8, recommends 4 spaces for distributed Python code; this is also the Emacs python-mode default.

Under any editor, mixing tabs and spaces is a bad idea. MSVC is no different in this respect, and is easily configured to use spaces: Take Tools ▸ Options ▸ Tabs, and for file type “Default” set “Tab size” and “Indent size” to 4, and select the “Insert spaces” radio button.

Python raises `IndentationError` or `TabError` if mixed tabs and spaces are causing problems in leading whitespace. You may also run the tabnanny module to check a directory tree in batch mode.
How do I check for a keypress without blocking?

Use the msvcrt module. This is a standard Windows-specific extension module. It defines a function `kbhit()` which checks whether a keyboard hit is present, and `getch()` which gets one character without echoing it.
How do I emulate os.kill() in Windows?

Prior to Python 2.7 and 3.2, to terminate a process, you can use ctypes:

```python
import ctypes

def kill(pid):
    """kill function for Win32""
    kernel32 = ctypes.windll.kernel32
    handle = kernel32.OpenProcess(1, 0, pid)
    return (0 != kernel32.TerminateProcess(handle, 0))
```

In 2.7 and 3.2, `os.kill()` is implemented similar to the above function, with the additional feature of being able to send Ctrl+C and Ctrl+Break to console subprocesses which are designed to handle those signals. See `os.kill()` for further details.
How do I extract the downloaded documentation on Windows?

Sometimes, when you download the documentation package to a Windows machine using a web browser, the file extension of the saved file ends up being .EXE. This is a mistake; the extension should be .TGZ.

Simply rename the downloaded file to have the .TGZ extension, and WinZip will be able to handle it. (If your copy of WinZip doesn’t, get a newer one from https://www.winzip.com.)

General GUI Questions
What platform-independent GUI toolkits exist for Python?

Depending on what platform(s) you are aiming at, there are several. Some of them haven’t been ported to Python 3 yet. At least Tkinter and Qt are known to be Python 3-compatible.

**Tkinter**

Standard builds of Python include an object-oriented interface to the Tcl/Tk widget set, called tkinter. This is probably the easiest to install (since it comes included with most binary distributions of Python) and use. For more info about Tk, including pointers to the source, see the Tcl/Tk home page. Tcl/Tk is fully portable to the Mac OS X, Windows, and Unix platforms.

**wxWidgets**

wxWidgets ([https://www.wxwidgets.org](https://www.wxwidgets.org)) is a free, portable GUI class library written in C++ that provides a native look and feel on a number of platforms, with Windows, Mac OS X, GTK, X11, all listed as current stable targets. Language bindings are available for a number of languages including Python, Perl, Ruby, etc.

wxPython ([http://www.wxpython.org](http://www.wxpython.org)) is the Python binding for wxwidgets. While it often lags slightly behind the official wxWidgets releases, it also offers a number of features via pure Python extensions that are not available in other language bindings. There is an active wxPython user and developer community.

Both wxWidgets and wxPython are free, open source, software with
permissive licences that allow their use in commercial products as well as in freeware or shareware.

**Qt**

There are bindings available for the Qt toolkit (using either **PyQt** or **PySide**) and for KDE (**PyKDE4**). PyQt is currently more mature than PySide, but you must buy a PyQt license from Riverbank Computing if you want to write proprietary applications. PySide is free for all applications.

Qt 4.5 upwards is licensed under the LGPL license; also, commercial licenses are available from The Qt Company.

**Gtk+**

The **GObject introspection bindings** for Python allow you to write GTK+ 3 applications. There is also a Python GTK+ 3 Tutorial.

The older PyGtk bindings for the **Gtk+ 2 toolkit** have been implemented by James Henstridge; see <http://www.pygtk.org>.

**Kivy**

**Kivy** is a cross-platform GUI library supporting both desktop operating systems (Windows, macOS, Linux) and mobile devices (Android, iOS). It is written in Python and Cython, and can use a range of windowing backends.

Kivy is free and open source software distributed under the MIT license.
FLTK

Python bindings for the FLTK toolkit, a simple yet powerful and mature cross-platform windowing system, are available from the PyFLTK project.

OpenGL

For OpenGL bindings, see PyOpenGL.
What platform-specific GUI toolkits exist for Python?

By installing the **PyObjc Objective-C bridge**, Python programs can use Mac OS X's Cocoa libraries.

**Pythonwin** by Mark Hammond includes an interface to the Microsoft Foundation Classes and a Python programming environment that's written mostly in Python using the MFC classes.
Tkinter questions

How do I freeze Tkinter applications?

Freeze is a tool to create stand-alone applications. When freezing Tkinter applications, the applications will not be truly stand-alone, as the application will still need the Tcl and Tk libraries.

One solution is to ship the application with the Tcl and Tk libraries, and point to them at run-time using the TCL_LIBRARY and TK_LIBRARY environment variables.

To get truly stand-alone applications, the Tcl scripts that form the library have to be integrated into the application as well. One tool supporting that is SAM (stand-alone modules), which is part of the Tix distribution (http://tix.sourceforge.net/).

Build Tix with SAM enabled, perform the appropriate call to Tclsam_init(), etc. inside Python's Modules/tkappinit.c, and link with libtcltsam and libtksam (you might include the Tix libraries as well).

Can I have Tk events handled while waiting for I/O?

On platforms other than Windows, yes, and you don’t even need threads! But you’ll have to restructure your I/O code a bit. Tk has the equivalent of Xt’s XtAddInput() call, which allows you to register a callback function which will be called from the Tk mainloop when I/O is possible on a file descriptor. See File Handlers.
I can’t get key bindings to work in Tkinter: why?

An often-heard complaint is that event handlers bound to events with the `bind()` method don’t get handled even when the appropriate key is pressed.

The most common cause is that the widget to which the binding applies doesn’t have “keyboard focus”. Check out the Tk documentation for the focus command. Usually a widget is given the keyboard focus by clicking in it (but not for labels; see the takefocus option).

</pre>
“Why is Python Installed on my Computer?” FAQ
What is Python?

Python is a programming language. It’s used for many different applications. It’s used in some high schools and colleges as an introductory programming language because Python is easy to learn, but it’s also used by professional software developers at places such as Google, NASA, and Lucasfilm Ltd.

If you wish to learn more about Python, start with the Beginner’s Guide to Python.
Why is Python installed on my machine?

If you find Python installed on your system but don’t remember installing it, there are several possible ways it could have gotten there.

- Perhaps another user on the computer wanted to learn programming and installed it; you'll have to figure out who’s been using the machine and might have installed it.
- A third-party application installed on the machine might have been written in Python and included a Python installation. There are many such applications, from GUI programs to network servers and administrative scripts.
- Some Windows machines also have Python installed. At this writing we’re aware of computers from Hewlett-Packard and Compaq that include Python. Apparently some of HP/Compaq's administrative tools are written in Python.
- Many Unix-compatible operating systems, such as Mac OS X and some Linux distributions, have Python installed by default; it’s included in the base installation.
Can I delete Python?

That depends on where Python came from.

If someone installed it deliberately, you can remove it without hurting anything. On Windows, use the Add/Remove Programs icon in the Control Panel.

If Python was installed by a third-party application, you can also remove it, but that application will no longer work. You should use that application's uninstaller rather than removing Python directly.

If Python came with your operating system, removing it is not recommended. If you remove it, whatever tools were written in Python will no longer run, and some of them might be important to you. Reinstalling the whole system would then be required to fix things again.
Glossary

>>> The default Python prompt of the interactive shell. Often seen for code examples which can be executed interactively in the interpreter.

... The default Python prompt of the interactive shell when entering code for an indented code block or within a pair of matching left and right delimiters (parentheses, square brackets or curly braces).

2to3

A tool that tries to convert Python 2.x code to Python 3.x code by handling most of the incompatibilities which can be detected by parsing the source and traversing the parse tree.

2to3 is available in the standard library as `lib2to3`; a standalone entry point is provided as `Tools/scripts/2to3`. See 2to3 - Automated Python 2 to 3 code translation.

abstract base class

Abstract base classes complement duck-typing by providing a way to define interfaces when other techniques like `hasattr()` would be clumsy or subtly wrong (for example with magic methods). ABCs introduce virtual subclasses, which are classes that don't inherit from a class but are still recognized by `isinstance()` and `issubclass()`; see the `abc` module documentation. Python comes with many built-in ABCs for data structures (in the `collections.abc` module), numbers (in the `numbers` module), streams (in the `io` module), import finders and loaders (in the `importlib.abc` module). You can create your own ABCs with the `abc` module.
**argument**

A value passed to a function (or method) when calling the function. There are two kinds of argument:

- *keyword argument*: an argument preceded by an identifier (e.g. `name=`) in a function call or passed as a value in a dictionary preceded by `**`. For example, `3` and `5` are both keyword arguments in the following calls to `complex()`:

  ```python
  complex(real=3, imag=5)
  complex(**{'real': 3, 'imag': 5})
  ```

- *positional argument*: an argument that is not a keyword argument. Positional arguments can appear at the beginning of an argument list and/or be passed as elements of an iterable preceded by `*`. For example, `3` and `5` are both positional arguments in the following calls:

  ```python
  complex(3, 5)
  complex(*(3, 5))
  ```

Arguments are assigned to the named local variables in a function body. See the Calls section for the rules governing this assignment. Syntactically, any expression can be used to represent an argument; the evaluated value is assigned to the local variable.

See also the parameter glossary entry, the FAQ question on the difference between arguments and parameters, and PEP 362.

**asynchronous context manager**

An object which controls the environment seen in an async with statement by defining `__aenter__()` and `__aexit__()` methods. Introduced by PEP 492.
asynchronous generator
A function which returns an asynchronous generator iterator. It looks like a coroutine function defined with async def except that it contains yield expressions for producing a series of values usable in an async for loop.

Usually refers to a asynchronous generator function, but may refer to an asynchronous generator iterator in some contexts. In cases where the intended meaning isn’t clear, using the full terms avoids ambiguity.

An asynchronous generator function may contain await expressions as well as async for, and async with statements.

asynchronous generator iterator
An object created by a asynchronous generator function.

This is an asynchronous iterator which when called using the __anext__() method returns an awaitable object which will execute that the body of the asynchronous generator function until the next yield expression.

Each yield temporarily suspends processing, remembering the location execution state (including local variables and pending try-statements). When the asynchronous generator iterator effectively resumes with another awaitable returned by __anext__(), it picks-up where it left-off. See PEP 492 and PEP 525.

asynchronous iterable
An object, that can be used in an async for statement. Must return an asynchronous iterator from its __aiter__() method. Introduced by PEP 492.
asynchronous iterator
An object that implements __aiter__() and __anext__() methods. __anext__ must return an awaitable object. async for resolves awaitable returned from asynchronous iterator’s __anext__() method until it raises StopAsyncIteration exception. Introduced by PEP 492.

attribute
A value associated with an object which is referenced by name using dotted expressions. For example, if an object o has an attribute a it would be referenced as o.a.

awaitable
An object that can be used in an await expression. Can be a coroutine or an object with an __await__() method. See also PEP 492.

BDFL
Benevolent Dictator For Life, a.k.a. Guido van Rossum, Python’s creator.

binary file
A file object able to read and write bytes-like objects. Examples of binary files are files opened in binary mode ('rb', 'wb' or 'rb+'), sys.stdin.buffer, sys.stdout.buffer, and instances of io.BytesIO and gzip.GzipFile.

See also: A text file reads and writes str objects.

bytes-like object
An object that supports the Buffer Protocol and can export a C-contiguous buffer. This includes all bytes, bytearray, and array.array objects, as well as many common memoryview objects. Bytes-like objects can be used for various operations that
work with binary data; these include compression, saving to a binary file, and sending over a socket.

Some operations need the binary data to be mutable. The documentation often refers to these as “read-write bytes-like objects”. Example mutable buffer objects include `bytearray` and a `memoryview` of a `bytearray`. Other operations require the binary data to be stored in immutable objects (“read-only bytes-like objects”); examples of these include `bytes` and a `memoryview` of a `bytes` object.

**bytecode**

Python source code is compiled into bytecode, the internal representation of a Python program in the CPython interpreter. The bytecode is also cached in `.pyc` files so that executing the same file is faster the second time (recompilation from source to bytecode can be avoided). This “intermediate language” is said to run on a virtual machine that executes the machine code corresponding to each bytecode. Do note that bytecodes are not expected to work between different Python virtual machines, nor to be stable between Python releases.

A list of bytecode instructions can be found in the documentation for the `dis` module.

**class**

A template for creating user-defined objects. Class definitions normally contain method definitions which operate on instances of the class.

**coercion**

The implicit conversion of an instance of one type to another during an operation which involves two arguments of the same type. For
example, \texttt{int(3.15)} converts the floating point number to the integer 3, but in \texttt{3+4.5}, each argument is of a different type (one int, one float), and both must be converted to the same type before they can be added or it will raise a \texttt{TypeError}. Without coercion, all arguments of even compatible types would have to be normalized to the same value by the programmer, e.g., \texttt{float(3)+4.5} rather than just \texttt{3+4.5}.

**complex number**

An extension of the familiar real number system in which all numbers are expressed as a sum of a real part and an imaginary part. Imaginary numbers are real multiples of the imaginary unit (the square root of \(-1\)), often written \texttt{i} in mathematics or \texttt{j} in engineering. Python has built-in support for complex numbers, which are written with this latter notation; the imaginary part is written with a \texttt{j} suffix, e.g., \texttt{3+1j}. To get access to complex equivalents of the \texttt{math} module, use \texttt{cmath}. Use of complex numbers is a fairly advanced mathematical feature. If you're not aware of a need for them, it's almost certain you can safely ignore them.

**context manager**

An object which controls the environment seen in a \texttt{with} statement by defining \texttt{__enter__()} and \texttt{__exit__()} methods. See \texttt{PEP 343}.

**contiguous**

A buffer is considered contiguous exactly if it is either \texttt{C-contiguous} or \texttt{Fortran contiguous}. Zero-dimensional buffers are C and Fortran contiguous. In one-dimensional arrays, the items must be laid out in memory next to each other, in order of increasing indexes starting from zero. In multidimensional C-contiguous arrays, the last index varies the fastest when visiting items in order of memory address. However, in Fortran contiguous arrays, the first index
varies the fastest.

**coroutine**

Coroutines is a more generalized form of subroutines. Subroutines are entered at one point and exited at another point. Coroutines can be entered, exited, and resumed at many different points. They can be implemented with the `async def` statement. See also [PEP 492](https://www.python.org/peps/pep-0492/).

**coroutine function**

A function which returns a coroutine object. A coroutine function may be defined with the `async def` statement, and may contain `await`, `async for`, and `async with` keywords. These were introduced by [PEP 492](https://www.python.org/peps/pep-0492/).

**CPython**

The canonical implementation of the Python programming language, as distributed on [python.org](https://www.python.org). The term “CPython” is used when necessary to distinguish this implementation from others such as Jython or IronPython.

**decorator**

A function returning another function, usually applied as a function transformation using the `@wrapper` syntax. Common examples for decorators are `classmethod()` and `staticmethod()`.

The decorator syntax is merely syntactic sugar, the following two function definitions are semantically equivalent:

```python
def f(...):
    ...
f = staticmethod(f)

@staticmethod
def f(...):
    ...
```

```
The same concept exists for classes, but is less commonly used there. See the documentation for function definitions and class definitions for more about decorators.

**descriptor**

Any object which defines the methods `__get__`, `__set__`, or `__delete__`. When a class attribute is a descriptor, its special binding behavior is triggered upon attribute lookup. Normally, using `a.b` to get, set or delete an attribute looks up the object named `b` in the class dictionary for `a`, but if `b` is a descriptor, the respective descriptor method gets called. Understanding descriptors is a key to a deep understanding of Python because they are the basis for many features including functions, methods, properties, class methods, static methods, and reference to super classes.

For more information about descriptors’ methods, see Implementing Descriptors.

**dictionary**

An associative array, where arbitrary keys are mapped to values. The keys can be any object with `__hash__()` and `__eq__()` methods. Called a hash in Perl.

**dictionary view**

The objects returned from `dict.keys()`, `dict.values()`, and `dict.items()` are called dictionary views. They provide a dynamic view on the dictionary’s entries, which means that when the dictionary changes, the view reflects these changes. To force the dictionary view to become a full list use `list(dictview)`. See Dictionary view objects.

**docstring**
A string literal which appears as the first expression in a class, function or module. While ignored when the suite is executed, it is recognized by the compiler and put into the __doc__ attribute of the enclosing class, function or module. Since it is available via introspection, it is the canonical place for documentation of the object.

**duck-typing**
A programming style which does not look at an object's type to determine if it has the right interface; instead, the method or attribute is simply called or used (“If it looks like a duck and quacks like a duck, it must be a duck.”) By emphasizing interfaces rather than specific types, well-designed code improves its flexibility by allowing polymorphic substitution. Duck-typing avoids tests using `type()` or `isinstance()`. (Note, however, that duck-typing can be complemented with abstract base classes.) Instead, it typically employs `hasattr()` tests or EAFP programming.

**EAFP**
Easier to ask for forgiveness than permission. This common Python coding style assumes the existence of valid keys or attributes and catches exceptions if the assumption proves false. This clean and fast style is characterized by the presence of many `try` and `except` statements. The technique contrasts with the LBYL style common to many other languages such as C.

**expression**
A piece of syntax which can be evaluated to some value. In other words, an expression is an accumulation of expression elements like literals, names, attribute access, operators or function calls which all return a value. In contrast to many other languages, not all language constructs are expressions. There are also statements which cannot be used as expressions, such as `if`. Assignments are also statements, not expressions.

**extension module**
A module written in C or C++, using Python's C API to interact with the core and with user code.

f-string
String literals prefixed with `'f'` or `'F'` are commonly called “f-strings” which is short for formatted string literals. See also PEP 498.

file object
An object exposing a file-oriented API (with methods such as `read()` or `write()`) to an underlying resource. Depending on the way it was created, a file object can mediate access to a real on-disk file or to another type of storage or communication device (for example standard input/output, in-memory buffers, sockets, pipes, etc.). File objects are also called file-like objects or streams.

There are actually three categories of file objects: raw binary files, buffered binary files and text files. Their interfaces are defined in the `io` module. The canonical way to create a file object is by using the `open()` function.

file-like object
A synonym for file object.

finder
An object that tries to find the loader for a module that is being imported.

Since Python 3.3, there are two types of finder: meta path finders for use with `sys.meta_path`, and path entry finders for use with `sys.path_hooks`.

See PEP 302, PEP 420 and PEP 451 for much more detail.

floor division
Mathematical division that rounds down to nearest integer. The floor division operator is `//`. For example, the expression `11 // 4` evaluates to 2 in contrast to the 2.75 returned by float true division. Note that `(-11) // 4` is -3 because that is -2.75 rounded *downward*. See PEP 238.

**function**

A series of statements which returns some value to a caller. It can also be passed zero or more arguments which may be used in the execution of the body. See also parameter, method, and the Function definitions section.

**function annotation**

An arbitrary metadata value associated with a function parameter or return value. Its syntax is explained in section Function definitions. Annotations may be accessed via the `__annotations__` special attribute of a function object.

Python itself does not assign any particular meaning to function annotations. They are intended to be interpreted by third-party libraries or tools. See PEP 3107, which describes some of their potential uses.

**__future__**

A pseudo-module which programmers can use to enable new language features which are not compatible with the current interpreter.

By importing the `__future__` module and evaluating its variables, you can see when a new feature was first added to the language and when it becomes the default:

```python
>>> import __future__
>>> __future__.division
```
garbage collection
The process of freeing memory when it is not used anymore. Python performs garbage collection via reference counting and a cyclic garbage collector that is able to detect and break reference cycles.

generator
A function which returns a generator iterator. It looks like a normal function except that it contains yield expressions for producing a series of values usable in a for-loop or that can be retrieved one at a time with the next() function.

Usually refers to a generator function, but may refer to a generator iterator in some contexts. In cases where the intended meaning isn’t clear, using the full terms avoids ambiguity.

generator iterator
An object created by a generator function.

Each yield temporarily suspends processing, remembering the location execution state (including local variables and pending try-statements). When the generator iterator resumes, it picks-up where it left-off (in contrast to functions which start fresh on every invocation).

generator expression
An expression that returns an iterator. It looks like a normal expression followed by a for expression defining a loop variable, range, and an optional if expression. The combined expression generates values for an enclosing function:
generic function
A function composed of multiple functions implementing the same operation for different types. Which implementation should be used during a call is determined by the dispatch algorithm.

See also the single dispatch glossary entry, the functools.singledispatch() decorator, and PEP 443.

GIL
See global interpreter lock.

global interpreter lock
The mechanism used by the CPython interpreter to assure that only one thread executes Python bytecode at a time. This simplifies the CPython implementation by making the object model (including critical built-in types such as dict) implicitly safe against concurrent access. Locking the entire interpreter makes it easier for the interpreter to be multi-threaded, at the expense of much of the parallelism afforded by multi-processor machines.

However, some extension modules, either standard or third-party, are designed so as to release the GIL when doing computationally-intensive tasks such as compression or hashing. Also, the GIL is always released when doing I/O.

Past efforts to create a “free-threaded” interpreter (one which locks shared data at a much finer granularity) have not been successful because performance suffered in the common single-processor case. It is believed that overcoming this performance issue would make the implementation much more complicated and therefore
costlier to maintain.

**hashable**

An object is *hashable* if it has a hash value which never changes during its lifetime (it needs a `__hash__()` method), and can be compared to other objects (it needs an `__eq__()` method). Hashable objects which compare equal must have the same hash value.

Hashability makes an object usable as a dictionary key and a set member, because these data structures use the hash value internally.

All of Python’s immutable built-in objects are hashable; mutable containers (such as lists or dictionaries) are not. Objects which are instances of user-defined classes are hashable by default. They all compare unequal (except with themselves), and their hash value is derived from their `id()`.

**IDLE**

An Integrated Development Environment for Python. IDLE is a basic editor and interpreter environment which ships with the standard distribution of Python.

**immutable**

An object with a fixed value. Immutable objects include numbers, strings and tuples. Such an object cannot be altered. A new object has to be created if a different value has to be stored. They play an important role in places where a constant hash value is needed, for example as a key in a dictionary.

**import path**

A list of locations (or *path entries*) that are searched by the *path based finder* for modules to import. During import, this list of
locations usually comes from \texttt{sys.path}, but for subpackages it may also come from the parent package's \texttt{__path__} attribute.

**importing**
The process by which Python code in one module is made available to Python code in another module.

**importer**
An object that both finds and loads a module; both a \texttt{finder} and \texttt{loader} object.

**interactive**
Python has an interactive interpreter which means you can enter statements and expressions at the interpreter prompt, immediately execute them and see their results. Just launch \texttt{python} with no arguments (possibly by selecting it from your computer's main menu). It is a very powerful way to test out new ideas or inspect modules and packages (remember \texttt{help(x)}).

**interpreted**
Python is an interpreted language, as opposed to a compiled one, though the distinction can be blurry because of the presence of the bytecode compiler. This means that source files can be run directly without explicitly creating an executable which is then run. Interpreted languages typically have a shorter development/debug cycle than compiled ones, though their programs generally also run more slowly. See also \texttt{interactive}.

**interpreter shutdown**
When asked to shut down, the Python interpreter enters a special phase where it gradually releases all allocated resources, such as modules and various critical internal structures. It also makes several calls to the \texttt{garbage collector}. This can trigger the execution of code in user-defined destructors or weakref callbacks. Code executed during the shutdown phase can encounter various exceptions as the resources it relies on may not function anymore
(common examples are library modules or the warnings machinery).

The main reason for interpreter shutdown is that the `__main__` module or the script being run has finished executing.

**iterable**

An object capable of returning its members one at a time. Examples of iterables include all sequence types (such as `list`, `str`, and `tuple`) and some non-sequence types like `dict`, `file objects`, and objects of any classes you define with an `__iter__()` or `__getitem__()` method. Iterables can be used in a `for` loop and in many other places where a sequence is needed (`zip()`, `map()`, …). When an iterable object is passed as an argument to the built-in function `iter()`, it returns an iterator for the object. This iterator is good for one pass over the set of values. When using iterables, it is usually not necessary to call `iter()` or deal with iterator objects yourself. The `for` statement does that automatically for you, creating a temporary unnamed variable to hold the iterator for the duration of the loop. See also `iterator`, `sequence`, and `generator`.

**iterator**

An object representing a stream of data. Repeated calls to the iterator’s `__next__()` method (or passing it to the built-in function `next()`) return successive items in the stream. When no more data are available a `StopIteration` exception is raised instead. At this point, the iterator object is exhausted and any further calls to its `__next__()` method just raise `StopIteration` again. Iterators are required to have an `__iter__()` method that returns the iterator object itself so every iterator is also iterable and may be used in most places where other iterables are accepted. One notable exception is code which attempts multiple iteration passes.
A container object (such as a list) produces a fresh new iterator each time you pass it to the \texttt{iter()} function or use it in a \texttt{for} loop. Attempting this with an iterator will just return the same exhausted iterator object used in the previous iteration pass, making it appear like an empty container.

More information can be found in \textit{Iterator Types}.

**key function**

A key function or collation function is a callable that returns a value used for sorting or ordering. For example, \texttt{locale.strxfrm()} is used to produce a sort key that is aware of locale specific sort conventions.

A number of tools in Python accept key functions to control how elements are ordered or grouped. They include \texttt{min()}, \texttt{max()}, \texttt{sorted()}, \texttt{list.sort()}, \texttt{heapq.merge()}, \texttt{heapq.nsmallest()}, \texttt{heapq.nlargest()}, \texttt{and itertools.groupby()}.

There are several ways to create a key function. For example, the \texttt{str.lower()} method can serve as a key function for case insensitive sorts. Alternatively, a key function can be built from a \texttt{lambda} expression such as \texttt{lambda r: (r[0], r[2])}. Also, the \texttt{operator} module provides three key function constructors: \texttt{attrgetter()}, \texttt{itemgetter()}, and \texttt{methodcaller()}. See the \textit{Sorting HOW TO} for examples of how to create and use key functions.

**keyword argument**

See \textit{argument}.

**lambda**
An anonymous inline function consisting of a single expression which is evaluated when the function is called. The syntax to create a lambda function is \texttt{lambda [arguments]: expression}

\textbf{LBYL}

Look before you leap. This coding style explicitly tests for preconditions before making calls or lookups. This style contrasts with the \texttt{EAFP} approach and is characterized by the presence of many \texttt{if} statements.

In a multi-threaded environment, the LBYL approach can risk introducing a race condition between “the looking” and “the leaping”. For example, the code, \texttt{if key in mapping: return mapping[key]} can fail if another thread removes \texttt{key} from \texttt{mapping} after the test, but before the lookup. This issue can be solved with locks or by using the EAFP approach.

\textbf{list}

A built-in Python sequence. Despite its name it is more akin to an array in other languages than to a linked list since access to elements are $O(1)$.

\textbf{list comprehension}

A compact way to process all or part of the elements in a sequence and return a list with the results. \texttt{result = ['{:04x}'.format(x) for x in range(256) if x \% 2 == 0]} generates a list of strings containing even hex numbers (0x..) in the range from 0 to 255. The \texttt{if} clause is optional. If omitted, all elements in \texttt{range(256)} are processed.

\textbf{loader}

An object that loads a module. It must define a method named \texttt{load_module()}. A loader is typically returned by a \texttt{finder}. See \texttt{PEP 302} for details and \texttt{importlib.abc.Loader} for an abstract
**base class.**

**mapping**
A container object that supports arbitrary key lookups and implements the methods specified in the `Mapping` or `MutableMapping` abstract base classes. Examples include `dict`, `collections.defaultdict`, `collections.OrderedDict` and `collections.Counter`.

**meta path finder**
A finder returned by a search of `sys.meta_path`. Meta path finders are related to, but different from path entry finders.

See `importlib.abc.MetaPathFinder` for the methods that meta path finders implement.

**metaclass**
The class of a class. Class definitions create a class name, a class dictionary, and a list of base classes. The metaclass is responsible for taking those three arguments and creating the class. Most object oriented programming languages provide a default implementation. What makes Python special is that it is possible to create custom metaclasses. Most users never need this tool, but when the need arises, metaclasses can provide powerful, elegant solutions. They have been used for logging attribute access, adding thread-safety, tracking object creation, implementing singletons, and many other tasks.

More information can be found in [Metaclasses](#).

**method**
A function which is defined inside a class body. If called as an attribute of an instance of that class, the method will get the instance object as its first argument (which is usually called `self`).
See function and nested scope.

**method resolution order**
Method Resolution Order is the order in which base classes are searched for a member during lookup. See The Python 2.3 Method Resolution Order for details of the algorithm used by the Python interpreter since the 2.3 release.

**module**
An object that serves as an organizational unit of Python code. Modules have a namespace containing arbitrary Python objects. Modules are loaded into Python by the process of importing.

See also package.

**module spec**
A namespace containing the import-related information used to load a module. An instance of `importlib.machinery.ModuleSpec`.

**MRO**
See method resolution order.

**mutable**
Mutable objects can change their value but keep their `id()`. See also immutable.

**named tuple**
Any tuple-like class whose indexable elements are also accessible using named attributes (for example, `time.localtime()` returns a tuple-like object where the `year` is accessible either with an index such as `t[0]` or with a named attribute like `t.tm_year`).

A named tuple can be a built-in type such as `time.struct_time`, or it can be created with a regular class definition. A full featured named tuple can also be created with the
factory function `collections.namedtuple()`. The latter approach automatically provides extra features such as a self-documenting representation like `Employee(name='jones', title='programmer')`.

**namespace**

The place where a variable is stored. Namespaces are implemented as dictionaries. There are the local, global and built-in namespaces as well as nested namespaces in objects (in methods). Namespaces support modularity by preventing naming conflicts. For instance, the functions `builtins.open` and `os.open()` are distinguished by their namespaces. Namespaces also aid readability and maintainability by making it clear which module implements a function. For instance, writing `random.seed()` or `itertools.islice()` makes it clear that those functions are implemented by the `random` and `itertools` modules, respectively.

**namespace package**

A [PEP 420](https://www.python.org/dev/peps/pep-0420/) package which serves only as a container for subpackages. Namespace packages may have no physical representation, and specifically are not like a regular package because they have no `__init__.py` file.

See also [module](https://docs.python.org/3/library/module.html).

**nested scope**

The ability to refer to a variable in an enclosing definition. For instance, a function defined inside another function can refer to variables in the outer function. Note that nested scopes by default work only for reference and not for assignment. Local variables both read and write in the innermost scope. Likewise, global variables read and write to the global namespace. The `nonlocal` allows writing to outer scopes.
**new-style class**
Old name for the flavor of classes now used for all class objects. In earlier Python versions, only new-style classes could use Python's newer, versatile features like `__slots__`, descriptors, properties, `__getattribute__()`, class methods, and static methods.

**object**
Any data with state (attributes or value) and defined behavior (methods). Also the ultimate base class of any new-style class.

**package**
A Python module which can contain submodules or recursively, subpackages. Technically, a package is a Python module with an `__path__` attribute.

See also regular package and namespace package.

**parameter**
A named entity in a function (or method) definition that specifies an argument (or in some cases, arguments) that the function can accept. There are five kinds of parameter:

- **positional-or-keyword**: specifies an argument that can be passed either positionally or as a keyword argument. This is the default kind of parameter, for example `foo` and `bar` in the following:

  ```python
def func(foo, bar=None): ...
  ```

- **positional-only**: specifies an argument that can be supplied only by position. Python has no syntax for defining positional-only parameters. However, some built-in functions have positional-only parameters (e.g. `abs()`).

- **keyword-only**: specifies an argument that can be supplied only
by keyword. Keyword-only parameters can be defined by including a single var-positional parameter or bare * in the parameter list of the function definition before them, for example *kw_only1 and *kw_only2 in the following:

```python
def func(arg, *, kw_only1, kw_only2): ...
```

- **var-positional**: specifies that an arbitrary sequence of positional arguments can be provided (in addition to any positional arguments already accepted by other parameters). Such a parameter can be defined by prepending the parameter name with *, for example *args in the following:

```python
def func(*args, **kwargs): ...
```

- **var-keyword**: specifies that arbitrarily many keyword arguments can be provided (in addition to any keyword arguments already accepted by other parameters). Such a parameter can be defined by prepending the parameter name with **, for example **kwargs in the example above.

Parameters can specify both optional and required arguments, as well as default values for some optional arguments.

See also the argument glossary entry, the FAQ question on the difference between arguments and parameters, the `inspect.Parameter` class, the Function definitions section, and PEP 362.

**path entry**

A single location on the import path which the path based finder consults to find modules for importing.

**path entry finder**
A **finder** returned by a callable on `sys.path_hooks` (i.e. a **path entry hook**) which knows how to locate modules given a **path entry**.

See `importlib.abc.PathEntryFinder` for the methods that path entry finders implement.

**path entry hook**
A callable on the `sys.path_hook` list which returns a **path entry finder** if it knows how to find modules on a specific **path entry**.

**path based finder**
One of the default **meta path finders** which searches an **import path** for modules.

**path-like object**
An object representing a file system path. A path-like object is either a `str` or `bytes` object representing a path, or an object implementing the `os.PathLike` protocol. An object that supports the `os.PathLike` protocol can be converted to a `str` or `bytes` file system path by calling the `os.fspath()` function; `os.fsdecode()` and `os.fsencode()` can be used to guarantee a `str` or `bytes` result instead, respectively. Introduced by **PEP 519**.

**portion**
A set of files in a single directory (possibly stored in a zip file) that contribute to a namespace package, as defined in **PEP 420**.

**positional argument**
See argument.

**provisional API**
A provisional API is one which has been deliberately excluded from the standard library’s backwards compatibility guarantees. While major changes to such interfaces are not expected, as long as they
are marked provisional, backwards incompatible changes (up to and including removal of the interface) may occur if deemed necessary by core developers. Such changes will not be made gratuitously – they will occur only if serious fundamental flaws are uncovered that were missed prior to the inclusion of the API.

Even for provisional APIs, backwards incompatible changes are seen as a “solution of last resort” - every attempt will still be made to find a backwards compatible resolution to any identified problems.

This process allows the standard library to continue to evolve over time, without locking in problematic design errors for extended periods of time. See PEP 411 for more details.

**provisional package**

See provisional API.

**Python 3000**

Nickname for the Python 3.x release line (coined long ago when the release of version 3 was something in the distant future.) This is also abbreviated “Py3k”.

**Pythonic**

An idea or piece of code which closely follows the most common idioms of the Python language, rather than implementing code using concepts common to other languages. For example, a common idiom in Python is to loop over all elements of an iterable using a `for` statement. Many other languages don’t have this type of construct, so people unfamiliar with Python sometimes use a numerical counter instead:

```python
for i in range(len(food)):
    print(food[i])
```
As opposed to the cleaner, Pythonic method:

```python
for piece in food:
    print(piece)
```

**qualified name**

A dotted name showing the “path” from a module’s global scope to a class, function or method defined in that module, as defined in [PEP 3155](https://www.python.org/dev/peps/pep-0315/). For top-level functions and classes, the qualified name is the same as the object’s name:

```python
>>> class C:
    ...
    class D:
    ...
    def meth(self):
    ...
    pass
...
>>> C.__qualname__
'C'
>>> C.D.__qualname__
'C.D'
>>> C.D.meth.__qualname__
'C.D.meth'
```

When used to refer to modules, the *fully qualified name* means the entire dotted path to the module, including any parent packages, e.g. `email.mime.text`:

```python
>>> import email.mime.text
>>> email.mime.text.__name__
'email.mime.text'
```

**reference count**

The number of references to an object. When the reference count of an object drops to zero, it is deallocated. Reference counting is
generally not visible to Python code, but it is a key element of the CPython implementation. The `sys` module defines a `getrefcount()` function that programmers can call to return the reference count for a particular object.

**regular package**

A traditional package, such as a directory containing an `__init__.py` file.

See also namespace package.

**__slots__**

A declaration inside a class that saves memory by pre-declaring space for instance attributes and eliminating instance dictionaries. Though popular, the technique is somewhat tricky to get right and is best reserved for rare cases where there are large numbers of instances in a memory-critical application.

**sequence**

An iterable which supports efficient element access using integer indices via the `__getitem__()` special method and defines a `__len__()` method that returns the length of the sequence. Some built-in sequence types are `list`, `str`, `tuple`, and `bytes`. Note that `dict` also supports `__getitem__()` and `__len__()`, but is considered a mapping rather than a sequence because the lookups use arbitrary immutable keys rather than integers.

The `collections.abc.Sequence` abstract base class defines a much richer interface that goes beyond just `__getitem__()` and `__len__()`, adding `count()`, `index()`, `__contains__()`, and `__reversed__()`. Types that implement this expanded interface can be registered explicitly using `register()`.

**single dispatch**
A form of **generic function** dispatch where the implementation is chosen based on the type of a single argument.

**slice**

An object usually containing a portion of a **sequence**. A slice is created using the subscript notation, `[]` with colons between numbers when several are given, such as in `variable_name[1:3:5]`. The bracket (subscript) notation uses **slice** objects internally.

**special method**

A method that is called implicitly by Python to execute a certain operation on a type, such as addition. Such methods have names starting and ending with double underscores. Special methods are documented in **Special method names**.

**statement**

A statement is part of a suite (a “block” of code). A statement is either an **expression** or one of several constructs with a keyword, such as `if`, `while` or `for`.

**struct sequence**

A tuple with named elements. Struct sequences expose an interface similar to **named tuple** in that elements can either be accessed either by index or as an attribute. However, they do not have any of the named tuple methods like `_make()` or `_asdict()`. Examples of struct sequences include `sys.float_info` and the return value of `os.stat()`.

**text encoding**

A codec which encodes Unicode strings to bytes.

**text file**

A **file object** able to read and write **str** objects. Often, a text file actually accesses a byte-oriented datastream and handles the **text encoding** automatically. Examples of text files are files opened in
text mode ('r' or 'w'), `sys.stdin`, `sys.stdout`, and instances of `io.StringIO`.

See also: A binary file reads and write bytes objects.

**triple-quoted string**

A string which is bound by three instances of either a quotation mark (") or an apostrophe ('). While they don't provide any functionality not available with single-quoted strings, they are useful for a number of reasons. They allow you to include unescaped single and double quotes within a string and they can span multiple lines without the use of the continuation character, making them especially useful when writing docstrings.

**type**

The type of a Python object determines what kind of object it is; every object has a type. An object's type is accessible as its `__class__` attribute or can be retrieved with `type(obj)`.

**universal newlines**

A manner of interpreting text streams in which all of the following are recognized as ending a line: the Unix end-of-line convention '\n', the Windows convention '\r\n', and the old Macintosh convention '\r'. See PEP 278 and PEP 3116, as well as `bytes.splitlines()` for an additional use.

**variable annotation**

A type metadata value associated with a module global variable or a class attribute. Its syntax is explained in section Annotated assignment statements. Annotations are stored in the `__annotations__` special attribute of a class or module object and can be accessed using `typing.get_type_hints()`.

Python itself does not assign any particular meaning to variable
annotations. They are intended to be interpreted by third-party libraries or type checking tools. See PEP 526, PEP 484 which describe some of their potential uses.

**virtual environment**
A cooperatively isolated runtime environment that allows Python users and applications to install and upgrade Python distribution packages without interfering with the behaviour of other Python applications running on the same system.

See also **venv**.

**virtual machine**
A computer defined entirely in software. Python’s virtual machine executes the bytecode emitted by the bytecode compiler.

**Zen of Python**
Listing of Python design principles and philosophies that are helpful in understanding and using the language. The listing can be found by typing “```import this```” at the interactive prompt.
About these documents

These documents are generated from reStructuredText sources by Sphinx, a document processor specifically written for the Python documentation.

Development of the documentation and its toolchain is an entirely volunteer effort, just like Python itself. If you want to contribute, please take a look at the Dealing with Bugs page for information on how to do so. New volunteers are always welcome!

Many thanks go to:

- Fred L. Drake, Jr., the creator of the original Python documentation toolset and writer of much of the content;
- the Docutils project for creating reStructuredText and the Docutils suite;
- Fredrik Lundh for his Alternative Python Reference project from which Sphinx got many good ideas.
Contributors to the Python Documentation

Many people have contributed to the Python language, the Python standard library, and the Python documentation. See Misc/ACKS in the Python source distribution for a partial list of contributors.

It is only with the input and contributions of the Python community that Python has such wonderful documentation – Thank You!
Dealing with Bugs

Python is a mature programming language which has established a reputation for stability. In order to maintain this reputation, the developers would like to know of any deficiencies you find in Python.

It can be sometimes faster to fix bugs yourself and contribute patches to Python as it streamlines the process and involves less people. Learn how to contribute.
Documentation bugs

If you find a bug in this documentation or would like to propose an improvement, please submit a bug report on the tracker. If you have a suggestion how to fix it, include that as well.

If you’re short on time, you can also email documentation bug reports to docs@python.org (behavioral bugs can be sent to python-list@python.org). ‘docs@’ is a mailing list run by volunteers; your request will be noticed, though it may take a while to be processed.

See also: Documentation bugs on the Python issue tracker
Using the Python issue tracker

Bug reports for Python itself should be submitted via the Python Bug Tracker (https://bugs.python.org/). The bug tracker offers a Web form which allows pertinent information to be entered and submitted to the developers.

The first step in filing a report is to determine whether the problem has already been reported. The advantage in doing so, aside from saving the developers time, is that you learn what has been done to fix it; it may be that the problem has already been fixed for the next release, or additional information is needed (in which case you are welcome to provide it if you can!). To do this, search the bug database using the search box on the top of the page.

If the problem you’re reporting is not already in the bug tracker, go back to the Python Bug Tracker and log in. If you don’t already have a tracker account, select the “Register” link or, if you use OpenID, one of the OpenID provider logos in the sidebar. It is not possible to submit a bug report anonymously.

Being now logged in, you can submit a bug. Select the “Create New” link in the sidebar to open the bug reporting form.

The submission form has a number of fields. For the “Title” field, enter a very short description of the problem; less than ten words is good. In the “Type” field, select the type of your problem; also select the “Component” and “Versions” to which the bug relates.

In the “Comment” field, describe the problem in detail, including what you expected to happen and what did happen. Be sure to include whether any extension modules were involved, and what hardware
and software platform you were using (including version information as appropriate).

Each bug report will be assigned to a developer who will determine what needs to be done to correct the problem. You will receive an update each time action is taken on the bug.

**See also:**

**How to Report Bugs Effectively**

Article which goes into some detail about how to create a useful bug report. This describes what kind of information is useful and why it is useful.

**Bug Writing Guidelines**

Information about writing a good bug report. Some of this is specific to the Mozilla project, but describes general good practices.
Getting started contributing to Python yourself

Beyond just reporting bugs that you find, you are also welcome to submit patches to fix them. You can find more information on how to get started patching Python in the Python Developer’s Guide. If you have questions, the core-mentorship mailing list is a friendly place to get answers to any and all questions pertaining to the process of fixing issues in Python.

History and License
History of the software

Python was created in the early 1990s by Guido van Rossum at Stichting Mathematisch Centrum (CWI, see https://www.cwi.nl/) in the Netherlands as a successor of a language called ABC. Guido remains Python’s principal author, although it includes many contributions from others.

In 1995, Guido continued his work on Python at the Corporation for National Research Initiatives (CNRI, see https://www.cnri.reston.va.us/) in Reston, Virginia where he released several versions of the software.

In May 2000, Guido and the Python core development team moved to BeOpen.com to form the BeOpen PythonLabs team. In October of the same year, the PythonLabs team moved to Digital Creations (now Zope Corporation; see http://www.zope.com/). In 2001, the Python Software Foundation (PSF, see https://www.python.org/psf/) was formed, a non-profit organization created specifically to own Python-related Intellectual Property. Zope Corporation is a sponsoring member of the PSF.

All Python releases are Open Source (see https://opensource.org/ for the Open Source Definition). Historically, most, but not all, Python releases have also been GPL-compatible; the table below summarizes the various releases.

</table>

**Note:** GPL-compatible doesn't mean that we're distributing Python under the GPL. All Python licenses, unlike the GPL, let you distribute a modified version without making your changes open source. The GPL-compatible licenses make it possible to combine Python with other software that is released under the GPL; the others don't.

Thanks to the many outside volunteers who have worked under Guido's direction to make these releases possible.
Terms and conditions for accessing or otherwise using Python

PSF LICENSE AGREEMENT FOR PYTHON 3.6.3

1. This LICENSE AGREEMENT is between the Python Software Foundation ("PSF"), and the Individual or Organization ("Licensee") accessing and otherwise using Python 3.6.3 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, PSF hereby grants Licensee a nonexclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 3.6.3 alone or in any derivative version, provided, however, that PSF's License Agreement and PSF's notice of copyright, i.e., "Copyright © 2001-2017 Python Software Foundation; All Rights Reserved" are retained in Python 3.6.3 alone or in any derivative version prepared by Licensee.

3. In the event Licensee prepares a derivative work that is based on or incorporates Python 3.6.3 or any part thereof, and any derivative work available to others as provided hereunder, Licensee agrees to include in any such work a brief summary of the changes made to Python 3.6.3.

4. PSF is making Python 3.6.3 available to Licensee on an "AS IS" basis. PSF MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, PSF MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 3.6.3 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. PSF SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 3.6.3, OR ANY DERIVATIVE VERSION THEREOF.
6. This License Agreement will automatically terminate upon its terms and conditions.

7. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between BeOpen and Licensee. This License Agreement does not grant permission to use PSF trademarks or trade name in a trademark sense to endorse or promote products of third party.

8. By copying, installing or otherwise using Python, Licensee agrees to be bound by the terms and conditions of this License Agreement.

BEOPEN.COM LICENSE AGREEMENT FOR PYTHON 2.0

BEOPEN PYTHON OPEN SOURCE LICENSE AGREEMENT VERSION 1

1. This LICENSE AGREEMENT is between BeOpen.com ("BeOpen") and the Individual or Organization ("Licensee") accessing and otherwise using this software in source or binary form and its associated documentation ("the Software").

2. Subject to the terms and conditions of this BeOpen Python License Agreement, BeOpen hereby grants Licensee a non-exclusive, royalty-free, world-wide license to reproduce, analyze, test, perform and/or display, prepare derivative works, distribute, and otherwise use the Software alone or in any derivative version, provided, however, that the BeOpen Python License is retained in the Software, alone or in any derivative version prepared by Licensee.

3. BeOpen is making the Software available to Licensee on an "AS IS" basis. BEOPEN MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED, BY WAY OF EXAMPLE, BUT NOT LIMITATION, BEOPEN MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR A PARTICULAR PURPOSE.
WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF THE SOFTWARE WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

4. BEOPEN SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER PERSON FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF USING, MODIFYING OR DISTRIBUTING THE SOFTWARE, OR ANY DERIVATIVE THEREOF, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

5. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

6. This License Agreement shall be governed by and interpreted in all respects by the law of the State of California, excluding conflict of law provisions. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between BeOpen and Licensee. This License Agreement does not grant permission to use BeOpen trademarks in a trademark sense to endorse or promote products of Licensee or any third party. As an exception, the "BeOpen Python" logos available at http://www.pythonlabs.com/logos.html may be used granted on that web page.

7. By copying, installing or otherwise using the software, Licensee agrees to be bound by the terms and conditions of this License Agreement.

CNRI LICENSE AGREEMENT FOR PYTHON 1.6.1

1. This LICENSE AGREEMENT is between the Corporation for National Research Initiatives, having an office at 1895 Preston White Drive, Reston, VA 20191 ("CNRI"), and the Individual or Organization ("Licensee") accessing and otherwise using Python 1.6.1 software in source or binary form and its associated documentation.

2. Subject to the terms and conditions of this License Agreement, CNRI grants Licensee a nonexclusive, royalty-free, worldwide license to reproduce,

3. Use of the software is subject to the Terms and Conditions of this License Agreement. The software is provided "as is", without warranty of any kind, express or implied, including but not limited to the warranties of merchantability, fitness for a particular purpose and noninfringement. In no event shall CNRI be liable for any claims, damages, losses, or costs in excess of the fee paid for the software.

4. This License Agreement will automatically terminate upon a material breach of its terms and conditions.
analyze, test, perform and/or display publicly, prepare derivative works, distribute, and otherwise use Python 1.6.1 alone or in any derivative version, provided, however, that CNRI's License Agreement and notice of copyright, i.e., "Copyright © 1995-2001 Corporation for National Research Initiatives; All Rights Reserved" are retained in Python 1.6.1 alone or in any derivative version prepared by Licensee. Alternately, in lieu of CNRI's License Agreement, Licensee may substitute the following text (omitting the quotes): "Python 1.6.1 is made available subject to the terms and conditions in CNRI's License Agreement. This Agreement together with Python 1.6.1 may be located on the Internet using the following unique, persistent identifier (known as a handle): 1895.22/1013. This Agreement may also be obtained from a proxy server on the Internet using the following URL: http://hdl.handle.net/1895.22/1013."

3. In the event Licensee prepares a derivative work that incorporates Python 1.6.1 or any part thereof, and is making the derivative work available to others as provided herein, then Licensee will include in any such work a brief summary of the changes made to Python 1.6.1.

4. CNRI is making Python 1.6.1 available to Licensee on an "AS IS" basis. CNRI MAKES NO REPRESENTATIONS OR WARRANTIES, EXPRESS OR IMPLIED. BY WAY OF EXAMPLE, BUT NOT LIMITATION, CNRI MAKES NO AND DISCLAIMS ANY REPRESENTATION OR WARRANTY OF MERCHANTABILITY OR FITNESS FOR ANY PARTICULAR PURPOSE OR THAT THE USE OF PYTHON 1.6.1 WILL NOT INFRINGE ANY THIRD PARTY RIGHTS.

5. CNRI SHALL NOT BE LIABLE TO LICENSEE OR ANY OTHER USERS OF PYTHON 1.6.1 FOR ANY INCIDENTAL, SPECIAL, OR CONSEQUENTIAL DAMAGES OR LOSS AS A RESULT OF MODIFYING, DISTRIBUTING, OR OTHERWISE USING PYTHON 1.6.1, EVEN IF ADVISED OF THE POSSIBILITY THEREOF.

6. This License Agreement will automatically terminate upon a material breach of its terms and conditions.

7. This License Agreement shall be governed by the federal intellectual property law of the United States, including without limitation the federal copyright law, and, to the extent such U.S. federal law does not apply, by the law of the Commonwealth of Virginia, excluding Virginia's conflict of law provisions. Notwithstanding the foregoing, with regard to derivative works based on Python 1.6.1
1.6.1 that incorporate non-separable material that was previously distributed under the GNU General Public License (GPL), the law of the Commonwealth of Virginia shall govern this License Agreement only with respect to Paragraphs 4, 5, and 7 of this License Agreement. This License Agreement shall be deemed to create no relationship of agency, partnership, or joint venture between CNRI and Licensee. Nothing in this License Agreement shall be deemed to create any relationship of agency, partnership, or joint venture between CNRI and Licensee. This License Agreement does not grant permission to use CNRI trademarks or trade name in a trademark sense to endorse or promote products or services of Licensee or any third party.

8. By clicking on the "ACCEPT" button where indicated or otherwise using Python 1.6.1, Licensee agrees to be bound by the terms and conditions of this License Agreement.

CWI LICENSE AGREEMENT FOR PYTHON 0.9.0 THROUGH 1.2

Copyright © 1991 - 1995, Stichting Mathematisch Centrum, Amsterdam, The Netherlands. All rights reserved.

Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Stichting Mathematisch Centrum or CWI not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.

STICHTING MATHEMATISCH CENTRUM DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS. Copyright 1991-1995, Stichting Mathematisch Centrum,

Permission to use, copy, modify, and distribute this and its associated documentation for any purpose without granted, provided that the above copyright notice appears and that both that copyright notice and this permission supporting documentation, and that the name of neither Bioreason or Mojam Media be used in advertising or p
distribution of the software without specific, written, prior permission.

UUencode and UUdecode functions

The uu module contains the following notice:

Copyright 1994 by Lance Ellinghouse
Cathedral City, California Republic, United States of America.
All Rights Reserved
Permission to use, copy, modify, and distribute this software and its documentation for any purpose and without fee is hereby granted, provided that the above copyright notice appear in all copies and that both that copyright notice and this permission notice appear in supporting documentation, and that the name of Lance Ellinghouse not be used in advertising or publicity pertaining to distribution of the software without specific, written prior permission.
LANCE ELLINGHOUSE DISCLAIMS ALL WARRANTIES WITH REGARD TO THIS SOFTWARE, INCLUDING ALL IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS, IN NO EVENT SHALL LANCE ELLINGHOUSE CENTRUM BE LIABLE FOR ANY SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES OR ANY DAMAGES WHATSOEVER RESULTING FROM LOSS OF USE, DATA OR PROFITS, WHETHER IN AN ACTION OF CONTRACT, NEGLIGENCE OR OTHER TORTIOUS ACTION, ARISING OUT OF OR IN CONNECTION WITH THE USE OR PERFORMANCE OF THIS SOFTWARE.

Modified by Jack Jansen, CWI, July 1995:
- Use binascii module to do the actual line-by-line conversion between ascii and binary. This results in a 1000-fold speedup.
- Arguments more compliant with Python standard.

XML Remote Procedure Calls

The xmlrpc.client module contains the following notice:
The XML-RPC client interface is

Copyright (c) 1999-2002 by Secret Labs AB

Solution inspired by code from:
strtod and dtoa

The file Python/dtoa.c, which supplies C functions dtoa and strtod for conversion of C doubles to and from strings, is derived from the file of the same name by David M. Gay, currently available from http://www.netlib.org/fp/. The original file, as retrieved on March 16, 2009, contains the following copyright and licensing notice:
The modules `hashlib`, `posix`, `ssl`, `crypt` use the OpenSSL library for added performance if made available by the operating system. Additionally, the Windows and Mac OS X installers for Python may include a copy of the OpenSSL libraries, so we include a copy of the OpenSSL license here:

**LICENSE ISSUES**

The OpenSSL toolkit stays under a dual license, i.e., the OpenSSL License and the original SSLeay license. See below for the actual license texts. Actually both licenses are BSD-style Open Source licenses. In case of any license issues related to OpenSSL please contact openssl-core@openssl.org.

**OpenSSL License**

What’s New in Python

The “What’s New in Python” series of essays takes tours through the most important changes between major Python versions. They are a “must read” for anyone wishing to stay up-to-date after a new release.

- What’s New In Python 3.6
  - Summary – Release highlights
  - New Features
  - Other Language Changes
  - New Modules
  - Improved Modules
  - Optimizations
  - Build and C API Changes
  - Other Improvements
  - Deprecated
  - Removed
  - Porting to Python 3.6
  - Notable changes in Python 3.6.2
- What’s New In Python 3.5
  - Summary – Release highlights
  - New Features
  - Other Language Changes
  - New Modules
  - Improved Modules
  - Other module-level changes
  - Optimizations
  - Build and C API Changes
  - Deprecated
  - Removed
  - Porting to Python 3.5
- What’s New In Python 3.4
  - Summary – Release Highlights
• New Features
• New Modules
• Improved Modules
• CPython Implementation Changes
• Deprecated
• Removed
• Porting to Python 3.4
• Changed in 3.4.3

• What's New In Python 3.3
  • Summary – Release highlights
  • PEP 405: Virtual Environments
  • PEP 420: Implicit Namespace Packages
  • PEP 3118: New memoryview implementation and buffer protocol documentation
  • PEP 393: Flexible String Representation
  • PEP 397: Python Launcher for Windows
  • PEP 3151: Reworking the OS and IO exception hierarchy
  • PEP 380: Syntax for Delegating to a Subgenerator
  • PEP 409: Suppressing exception context
  • PEP 414: Explicit Unicode literals
  • PEP 3155: Qualified name for classes and functions
  • PEP 412: Key-Sharing Dictionary
  • PEP 362: Function Signature Object
  • PEP 421: Adding sys.implementation
  • Using importlib as the Implementation of Import
  • Other Language Changes
  • A Finer-Grained Import Lock
  • Built in functions and types
  • New Modules
  • Improved Modules
  • Optimizations
  • Build and C API Changes
  • Deprecated
  • Porting to Python 3.3
• What's New In Python 3.2
  ○ PEP 384: Defining a Stable ABI
  ○ PEP 389: Argparse Command Line Parsing Module
  ○ PEP 391: Dictionary Based Configuration for Logging
  ○ PEP 3148: The concurrent.futures module
  ○ PEP 3147: PYC Repository Directories
  ○ PEP 3149: ABI Version Tagged .so Files
  ○ PEP 3333: Python Web Server Gateway Interface v1.0.1
  ○ Other Language Changes
  ○ New, Improved, and Deprecated Modules
  ○ Multi-threading
  ○ Optimizations
  ○ Unicode
  ○ Codecs
  ○ Documentation
  ○ IDLE
  ○ Code Repository
  ○ Build and C API Changes
  ○ Porting to Python 3.2

• What's New In Python 3.1
  ○ PEP 372: Ordered Dictionaries
  ○ PEP 378: Format Specifier for Thousands Separator
  ○ Other Language Changes
  ○ New, Improved, and Deprecated Modules
  ○ Optimizations
  ○ IDLE
  ○ Build and C API Changes
  ○ Porting to Python 3.1

• What's New In Python 3.0
  ○ Common Stumbling Blocks
  ○ Overview Of Syntax Changes
  ○ Changes Already Present In Python 2.6
  ○ Library Changes
  ○ PEP 3101: A New Approach To String Formatting
• Changes To Exceptions
• Miscellaneous Other Changes
• Build and C API Changes
• Performance
• Porting To Python 3.0

• What’s New in Python 2.7
  • The Future for Python 2.x
  • Changes to the Handling of Deprecation Warnings
  • Python 3.1 Features
  • PEP 372: Adding an Ordered Dictionary to collections
  • PEP 378: Format Specifier for Thousands Separator
  • PEP 389: The argparse Module for Parsing Command Lines
  • PEP 391: Dictionary-Based Configuration For Logging
  • PEP 3106: Dictionary Views
  • PEP 3137: The memoryview Object
  • Other Language Changes
  • New and Improved Modules
  • Build and C API Changes
  • Other Changes and Fixes
  • Porting to Python 2.7
  • New Features Added to Python 2.7 Maintenance Releases
  • Acknowledgements

• What’s New in Python 2.6
  • Python 3.0
  • Changes to the Development Process
  • PEP 343: The ‘with’ statement
  • PEP 366: Explicit Relative Imports From a Main Module
  • PEP 370: Per-user site-packages Directory
  • PEP 371: The multiprocessing Package
  • PEP 3101: Advanced String Formatting
  • PEP 3105: print As a Function
  • PEP 3110: Exception-Handling Changes
  • PEP 3112: Byte Literals
  • PEP 3116: New I/O Library
• PEP 3118: Revised Buffer Protocol
• PEP 3119: Abstract Base Classes
• PEP 3127: Integer Literal Support and Syntax
• PEP 3129: Class Decorators
• PEP 3141: A Type Hierarchy for Numbers
• Other Language Changes
• New and Improved Modules
• Deprecations and Removals
• Build and C API Changes
• Porting to Python 2.6
• Acknowledgements

• What’s New in Python 2.5
  • PEP 308: Conditional Expressions
  • PEP 309: Partial Function Application
  • PEP 314: Metadata for Python Software Packages v1.1
  • PEP 328: Absolute and Relative Imports
  • PEP 338: Executing Modules as Scripts
  • PEP 341: Unified try/except/finally
  • PEP 342: New Generator Features
  • PEP 343: The ‘with’ statement
  • PEP 352: Exceptions as New-Style Classes
  • PEP 353: Using ssize_t as the index type
  • PEP 357: The ‘__index__’ method
• Other Language Changes
• New, Improved, and Removed Modules
• Build and C API Changes
• Porting to Python 2.5
• Acknowledgements

• What’s New in Python 2.4
  • PEP 218: Built-In Set Objects
  • PEP 237: Unifying Long Integers and Integers
  • PEP 289: Generator Expressions
  • PEP 292: Simpler String Substitutions
  • PEP 318: Decorators for Functions and Methods
- PEP 322: Reverse Iteration
- PEP 324: New subprocess Module
- PEP 327: Decimal Data Type
- PEP 328: Multi-line Imports
- PEP 331: Locale-Independent Float/String Conversions
- Other Language Changes
  - New, Improved, and Deprecated Modules
  - Build and C API Changes
  - Porting to Python 2.4
  - Acknowledgements
- **What's New in Python 2.3**
  - PEP 218: A Standard Set Datatype
  - PEP 255: Simple Generators
  - PEP 263: Source Code Encodings
  - PEP 273: Importing Modules from ZIP Archives
  - PEP 277: Unicode file name support for Windows NT
  - PEP 278: Universal Newline Support
  - PEP 279: enumerate()
  - PEP 282: The logging Package
  - PEP 285: A Boolean Type
  - PEP 293: Codec Error Handling Callbacks
  - PEP 301: Package Index and Metadata for Distutils
  - PEP 302: New Import Hooks
  - PEP 305: Comma-separated Files
  - PEP 307: Pickle Enhancements
  - Extended Slices
  - Other Language Changes
  - New, Improved, and Deprecated Modules
  - Pymalloc: A Specialized Object Allocator
  - Build and C API Changes
  - Other Changes and Fixes
  - Porting to Python 2.3
  - Acknowledgements

- Python 3.5.0 beta 3?
- Python 3.5.0 beta 2?
- Python 3.5.0 beta 1?
- Python 3.5.0 alpha 4?
- Python 3.5.0 alpha 3?
- Python 3.5.0 alpha 2?
- Python 3.5.0 alpha 1?
The Python Tutorial

Python is an easy to learn, powerful programming language. It has efficient high-level data structures and a simple but effective approach to object-oriented programming. Python’s elegant syntax and dynamic typing, together with its interpreted nature, make it an ideal language for scripting and rapid application development in many areas on most platforms.

The Python interpreter and the extensive standard library are freely available in source or binary form for all major platforms from the Python Web site, https://www.python.org/, and may be freely distributed. The same site also contains distributions of and pointers to many free third party Python modules, programs and tools, and additional documentation.

The Python interpreter is easily extended with new functions and data types implemented in C or C++ (or other languages callable from C). Python is also suitable as an extension language for customizable applications.

This tutorial introduces the reader informally to the basic concepts and features of the Python language and system. It helps to have a Python interpreter handy for hands-on experience, but all examples are self-contained, so the tutorial can be read off-line as well.

For a description of standard objects and modules, see The Python Standard Library. The Python Language Reference gives a more formal definition of the language. To write extensions in C or C++, read Extending and Embedding the Python Interpreter and Python/C API Reference Manual. There are also several books covering Python in depth.
This tutorial does not attempt to be comprehensive and cover every single feature, or even every commonly used feature. Instead, it introduces many of Python’s most noteworthy features, and will give you a good idea of the language’s flavor and style. After reading it, you will be able to read and write Python modules and programs, and you will be ready to learn more about the various Python library modules described in The Python Standard Library.

The Glossary is also worth going through.

Python Setup and Usage

This part of the documentation is devoted to general information on the setup of the Python environment on different platforms, the invocation of the interpreter and things that make working with Python easier.

- **1. Command line and environment**
  - 1.1. Command line
    - 1.1.1. Interface options
    - 1.1.2. Generic options
    - 1.1.3. Miscellaneous options
    - 1.1.4. Options you shouldn’t use
  - 1.2. Environment variables
    - 1.2.1. Debug-mode variables

- **2. Using Python on Unix platforms**
  - 2.1. Getting and installing the latest version of Python
    - 2.1.1. On Linux
    - 2.1.2. On FreeBSD and OpenBSD
    - 2.1.3. On OpenSolaris
  - 2.2. Building Python
  - 2.3. Python-related paths and files
  - 2.4. Miscellaneous
  - 2.5. Editors and IDEs

- **3. Using Python on Windows**
  - 3.1. Installing Python
    - 3.1.1. Supported Versions
    - 3.1.2. Installation Steps
    - 3.1.3. Removing the MAX_PATH Limitation
    - 3.1.4. Installing Without UI
    - 3.1.5. Installing Without Downloading
    - 3.1.6. Modifying an install
    - 3.1.7. Other Platforms
3.2. Alternative bundles
3.3. Configuring Python
  - 3.3.1. Excursus: Setting environment variables
  - 3.3.2. Finding the Python executable
3.4. Python Launcher for Windows
  - 3.4.1. Getting started
    - 3.4.1.1. From the command-line
    - 3.4.1.2. Virtual environments
    - 3.4.1.3. From a script
    - 3.4.1.4. From file associations
  - 3.4.2. Shebang Lines
  - 3.4.3. Arguments in shebang lines
  - 3.4.4. Customization
    - 3.4.4.1. Customization via INI files
    - 3.4.4.2. Customizing default Python versions
  - 3.4.5. Diagnostics
3.5. Finding modules
3.6. Additional modules
  - 3.6.1. PyWin32
  - 3.6.2. cx_Freeze
  - 3.6.3. WConio
3.7. Compiling Python on Windows
3.8. Embedded Distribution
  - 3.8.1. Python Application
  - 3.8.2. Embedding Python
3.9. Other resources
4. Using Python on a Macintosh
  - 4.1. Getting and Installing MacPython
    - 4.1.1. How to run a Python script
    - 4.1.2. Running scripts with a GUI
    - 4.1.3. Configuration
  - 4.2. The IDE
  - 4.3. Installing Additional Python Packages
  - 4.4. GUI Programming on the Mac
4.5. Distributing Python Applications on the Mac

4.6. Other Resources
The Python Language Reference

This reference manual describes the syntax and “core semantics” of the language. It is terse, but attempts to be exact and complete. The semantics of non-essential built-in object types and of the built-in functions and modules are described in The Python Standard Library. For an informal introduction to the language, see The Python Tutorial. For C or C++ programmers, two additional manuals exist: Extending and Embedding the Python Interpreter describes the high-level picture of how to write a Python extension module, and the Python/C API Reference Manual describes the interfaces available to C/C++ programmers in detail.

- 1. Introduction
  - 1.1. Alternate Implementations

  • 9.1. Complete Python programs
  • 9.2. File input
  • 9.3. Interactive input
  • 9.4. Expression input

• 10. Full Grammar specification
The Python Standard Library

While The Python Language Reference describes the exact syntax and semantics of the Python language, this library reference manual describes the standard library that is distributed with Python. It also describes some of the optional components that are commonly included in Python distributions.

Python’s standard library is very extensive, offering a wide range of facilities as indicated by the long table of contents listed below. The library contains built-in modules (written in C) that provide access to system functionality such as file I/O that would otherwise be inaccessible to Python programmers, as well as modules written in Python that provide standardized solutions for many problems that occur in everyday programming. Some of these modules are explicitly designed to encourage and enhance the portability of Python programs by abstracting away platform-specifics into platform-neutral APIs.

The Python installers for the Windows platform usually include the entire standard library and often also include many additional components. For Unix-like operating systems Python is normally provided as a collection of packages, so it may be necessary to use the packaging tools provided with the operating system to obtain some or all of the optional components.

In addition to the standard library, there is a growing collection of several thousand components (from individual programs and modules to packages and entire application development frameworks), available from the Python Package Index.

- 1. Introduction
2. Built-in Functions
3. Built-in Constants
  3.1. Constants added by the site module
4. Built-in Types
  4.1. Truth Value Testing
  4.2. Boolean Operations — and, or, not
  4.3. Comparisons
  4.4. Numeric Types — int, float, complex
  4.5. Iterator Types
  4.6. Sequence Types — list, tuple, range
  4.7. Text Sequence Type — str
  4.8. Binary Sequence Types — bytes, bytearray, memoryview
  4.9. Set Types — set, frozenset
  4.10. Mapping Types — dict
  4.11. Context Manager Types
  4.12. Other Built-in Types
  4.13. Special Attributes
5. Built-in Exceptions
  5.1. Base classes
  5.2. Concrete exceptions
  5.3. Warnings
  5.4. Exception hierarchy
6. Text Processing Services
  6.1. string — Common string operations
  6.2. re — Regular expression operations
  6.3. difflib — Helpers for computing deltas
  6.4. textwrap — Text wrapping and filling
  6.5. unicodedata — Unicode Database
  6.6. stringprep — Internet String Preparation
  6.7. readline — GNU readline interface
  6.8. rlcompleter — Completion function for GNU readline
7. Binary Data Services
- 7.1. struct — Interpret bytes as packed binary data
- 7.2. codecs — Codec registry and base classes

8. Data Types
- 8.1. datetime — Basic date and time types
- 8.2. calendar — General calendar-related functions
- 8.3. collections — Container datatypes
- 8.4. collections.abc — Abstract Base Classes for Containers
- 8.5. heapq — Heap queue algorithm
- 8.6. bisect — Array bisection algorithm
- 8.7. array — Efficient arrays of numeric values
- 8.8. weakref — Weak references
- 8.9. types — Dynamic type creation and names for built-in types
- 8.10. copy — Shallow and deep copy operations
- 8.11. pprint — Data pretty printer
- 8.12. reprlib — Alternate repr() implementation
- 8.13. enum — Support for enumerations

9. Numeric and Mathematical Modules
- 9.1. numbers — Numeric abstract base classes
- 9.2. math — Mathematical functions
- 9.3. cmath — Mathematical functions for complex numbers
- 9.4. decimal — Decimal fixed point and floating point arithmetic
- 9.5. fractions — Rational numbers
- 9.6. random — Generate pseudo-random numbers
- 9.7. statistics — Mathematical statistics functions

10. Functional Programming Modules
- 10.1. itertools — Functions creating iterators for efficient looping
- 10.2. functools — Higher-order functions and operations on callable objects
10.3. operator — Standard operators as functions

11. File and Directory Access
   - 11.1. pathlib — Object-oriented filesystem paths
   - 11.2. os.path — Common pathname manipulations
   - 11.3. fileinput — Iterate over lines from multiple input streams
   - 11.4. stat — Interpreting stat() results
   - 11.5. filecmp — File and Directory Comparisons
   - 11.6. tempfile — Generate temporary files and directories
   - 11.7. glob — Unix style pathname pattern expansion
   - 11.8. fnmatch — Unix filename pattern matching
   - 11.9. linecache — Random access to text lines
   - 11.10. shutil — High-level file operations
   - 11.11. macpath — Mac OS 9 path manipulation functions

12. Data Persistence
   - 12.1. pickle — Python object serialization
   - 12.2. copyreg — Register pickle support functions
   - 12.3. shelve — Python object persistence
   - 12.4. marshal — Internal Python object serialization
   - 12.5. dbm — Interfaces to Unix “databases”
   - 12.6. sqlite3 — DB-API 2.0 interface for SQLite databases

13. Data Compression and Archiving
   - 13.1. zlib — Compression compatible with gzip
   - 13.2. gzip — Support for gzip files
   - 13.3. bz2 — Support for bzip2 compression
   - 13.4. lzma — Compression using the LZMA algorithm
   - 13.5. zipfile — Work with ZIP archives
   - 13.6. tarfile — Read and write tar archive files

14. File Formats
   - 14.1. csv — CSV File Reading and Writing
   - 14.2. configparser — Configuration file parser
   - 14.3. netrc — netrc file processing
- 14.4. xdrlib — Encode and decode XDR data
- 14.5. plistlib — Generate and parse Mac OS X .plist files

- **15. Cryptographic Services**
  - 15.1. hashlib — Secure hashes and message digests
  - 15.2. hmac — Keyed-Hashing for Message Authentication
  - 15.3. secrets — Generate secure random numbers for managing secrets

- **16. Generic Operating System Services**
  - 16.1. os — Miscellaneous operating system interfaces
  - 16.2. io — Core tools for working with streams
  - 16.3. time — Time access and conversions
  - 16.4. argparse — Parser for command-line options, arguments and sub-commands
  - 16.5. getopt — C-style parser for command line options
  - 16.6. logging — Logging facility for Python
  - 16.7. logging.config — Logging configuration
  - 16.8. logging.handlers — Logging handlers
  - 16.9. getpass — Portable password input
  - 16.10. curses — Terminal handling for character-cell displays
  - 16.11. curses.textpad — Text input widget for curses programs
  - 16.12. curses.ascii — Utilities for ASCII characters
  - 16.13. curses.panel — A panel stack extension for curses
  - 16.14. platform — Access to underlying platform's identifying data
  - 16.15. errno — Standard errno system symbols
  - 16.16. ctypes — A foreign function library for Python

- **17. Concurrent Execution**
  - 17.1. threading — Thread-based parallelism
  - 17.2. multiprocessing — Process-based parallelism
17.3. The concurrent package
17.4. concurrent.futures — Launching parallel tasks
17.5. subprocess — Subprocess management
17.6. sched — Event scheduler
17.7. queue — A synchronized queue class
17.8. dummy_threading — Drop-in replacement for the threading module
17.9. _thread — Low-level threading API
17.10. _dummy_thread — Drop-in replacement for the _thread module

18. Interprocess Communication and Networking
18.1. socket — Low-level networking interface
18.2. ssl — TLS/SSL wrapper for socket objects
18.3. select — Waiting for I/O completion
18.4. selectors — High-level I/O multiplexing
18.5. asyncio — Asynchronous I/O, event loop, coroutines and tasks
18.6. asyncore — Asynchronous socket handler
18.7. asynchat — Asynchronous socket command/response handler
18.8. signal — Set handlers for asynchronous events
18.9. mmap — Memory-mapped file support

19. Internet Data Handling
19.1. email — An email and MIME handling package
19.2. json — JSON encoder and decoder
19.3. mailcap — Mailcap file handling
19.4. mailbox — Manipulate mailboxes in various formats
19.5. mimetypes — Map filenames to MIME types
19.6. base64 — Base16, Base32, Base64, Base85 Data Encodings
19.7. binhex — Encode and decode binhex4 files
19.8. binascii — Convert between binary and ASCII
• 19.9. quopri — Encode and decode MIME quoted-printable data
• 19.10. uu — Encode and decode uuencode files

20. Structured Markup Processing Tools
  • 20.1. html — HyperText Markup Language support
  • 20.2. html.parser — Simple HTML and XHTML parser
  • 20.3. html.entities — Definitions of HTML general entities
  • 20.4. XML Processing Modules
    • 20.5. xml.etree.ElementTree — The ElementTree XML API
  • 20.6. xml.dom — The Document Object Model API
  • 20.7. xml.dom.minidom — Minimal DOM implementation
  • 20.8. xml.dom.pulldom — Support for building partial DOM trees
  • 20.9. xml.sax — Support for SAX2 parsers
  • 20.10. xml.sax.handler — Base classes for SAX handlers
  • 20.11. xml.sax.saxutils — SAX Utilities
  • 20.12. xml.sax.xmlreader — Interface for XML parsers
  • 20.13. xml.parsers.expat — Fast XML parsing using Expat

21. Internet Protocols and Support
  • 21.1. webbrowser — Convenient Web-browser controller
  • 21.2. cgi — Common Gateway Interface support
  • 21.3. cgitb — Traceback manager for CGI scripts
  • 21.4. wsgiref — WSGI Utilities and Reference Implementation
  • 21.5. urllib — URL handling modules
  • 21.6. urllib.request — Extensible library for opening URLs
  • 21.7. urllib.response — Response classes used by urllib
- 21.8. urllib.parse — Parse URLs into components
- 21.9. urllib.error — Exception classes raised by urllib.request
- 21.10. urllib.robotparser — Parser for robots.txt
- 21.11. http — HTTP modules
- 21.13. ftplib — FTP protocol client
- 21.14. poplib — POP3 protocol client
- 21.15. imaplib — IMAP4 protocol client
- 21.16. nntplib — NNTP protocol client
- 21.17. smtplib — SMTP protocol client
- 21.18. smtpd — SMTP Server
- 21.19. telnetlib — Telnet client
- 21.20. uuid — UUID objects according to RFC 4122
- 21.21. socketserver — A framework for network servers
- 21.22. http.server — HTTP servers
- 21.23. http.cookies — HTTP state management
- 21.24. http.cookiejar — Cookie handling for HTTP clients
- 21.25. xmlrpc — XMLRPC server and client modules
- 21.26. xmlrpc.client — XML-RPC client access
- 21.27. xmlrpc.server — Basic XML-RPC servers
- 21.28. ipaddress — IPv4/IPv6 manipulation library

- 22. Multimedia Services
- 22.1. audioop — Manipulate raw audio data
- 22.2. aifc — Read and write AIFF and AIFC files
- 22.3. sunau — Read and write Sun AU files
- 22.4. wave — Read and write WAV files
- 22.5. chunk — Read IFF chunked data
- 22.6. colorsys — Conversions between color systems
- 22.7. imghdr — Determine the type of an image
- 22.8. sndhdr — Determine type of sound file
22.9. ossaudiodev — Access to OSS-compatible audio devices

23. Internationalization
   23.1. gettext — Multilingual internationalization services
   23.2. locale — Internationalization services

24. Program Frameworks
   24.1. turtle — Turtle graphics
   24.2. cmd — Support for line-oriented command interpreters
   24.3. shlex — Simple lexical analysis

25. Graphical User Interfaces with Tk
   25.1. tkinter — Python interface to Tcl/Tk
   25.2. tkinter.ttk — Tk themed widgets
   25.3. tkinter.tix — Extension widgets for Tk
   25.4. tkinter.scrolledtext — Scrolled Text Widget
   25.5. IDLE
   25.6. Other Graphical User Interface Packages

26. Development Tools
   26.1. typing — Support for type hints
   26.2. pydoc — Documentation generator and online help system
   26.3. doctest — Test interactive Python examples
   26.4. unittest — Unit testing framework
   26.5. unittest.mock — mock object library
   26.6. unittest.mock — getting started
   26.7. 2to3 - Automated Python 2 to 3 code translation
   26.8. test — Regression tests package for Python
   26.9. test.support — Utilities for the Python test suite

27. Debugging and Profiling
   27.1. bdb — Debugger framework
   27.2. faulthandler — Dump the Python traceback
   27.3. pdb — The Python Debugger
   27.4. The Python Profilers
27.5. timeit — Measure execution time of small code snippets
27.6. trace — Trace or track Python statement execution
27.7. tracemalloc — Trace memory allocations

28. Software Packaging and Distribution
28.1. distutils — Building and installing Python modules
28.2. ensurepip — Bootstrapping the pip installer
28.3. venv — Creation of virtual environments
28.4. zipapp — Manage executable python zip archives

29. Python Runtime Services
29.1. sys — System-specific parameters and functions
29.2. sysconfig — Provide access to Python's configuration information
29.3. builtins — Built-in objects
29.4. __main__ — Top-level script environment
29.5. warnings — Warning control
29.6. contextlib — Utilities for with-statement contexts
29.7. abc — Abstract Base Classes
29.8. atexit — Exit handlers
29.9. traceback — Print or retrieve a stack traceback
29.10. __future__ — Future statement definitions
29.11. gc — Garbage Collector interface
29.12. inspect — Inspect live objects
29.13. site — Site-specific configuration hook
29.14. fpectl — Floating point exception control

30. Custom Python Interpreters
30.1. code — Interpreter base classes
30.2. codeop — Compile Python code

31. Importing Modules
31.1. zipimport — Import modules from Zip archives
31.2. pkgutil — Package extension utility
31.3. modulefinder — Find modules used by a script
31.4. runpy — Locating and executing Python modules
31.5. importlib — The implementation of import

• 32. Python Language Services
  • 32.1. parser — Access Python parse trees
  • 32.2. ast — Abstract Syntax Trees
  • 32.3. symtable — Access to the compiler's symbol tables
  • 32.4. symbol — Constants used with Python parse trees
  • 32.5. token — Constants used with Python parse trees
  • 32.6. keyword — Testing for Python keywords
  • 32.7. tokenize — Tokenizer for Python source
  • 32.8. tabnanny — Detection of ambiguous indentation
  • 32.9. pycclbr — Python class browser support
  • 32.10. py_compile — Compile Python source files
  • 32.11. compileall — Byte-compile Python libraries
  • 32.12. dis — Disassembler for Python bytecode
  • 32.13. pickletools — Tools for pickle developers

• 33. Miscellaneous Services
  • 33.1. formatter — Generic output formatting

• 34. MS Windows Specific Services
  • 34.1. msilib — Read and write Microsoft Installer files
  • 34.2. msvcrt — Useful routines from the MS VC++ runtime
  • 34.3. winreg — Windows registry access
  • 34.4. winsound — Sound-playing interface for Windows

• 35. Unix Specific Services
  • 35.1. posix — The most common POSIX system calls
  • 35.2. pwd — The password database
  • 35.3. spwd — The shadow password database
  • 35.4. grp — The group database
  • 35.5. crypt — Function to check Unix passwords
  • 35.6. termios — POSIX style tty control
  • 35.7. tty — Terminal control functions
  • 35.8. pty — Pseudo-terminal utilities
• 35.9. fcntl — The fcntl and ioctl system calls
• 35.10. pipes — Interface to shell pipelines
• 35.11. resource — Resource usage information
• 35.12. nis — Interface to Sun's NIS (Yellow Pages)
• 35.13. syslog — Unix syslog library routines

• 36. Superseded Modules
  • 36.1. optparse — Parser for command line options
  • 36.2. imp — Access the import internals

• 37. Undocumented Modules
  • 37.1. Platform specific modules
Extending and Embedding the Python Interpreter

This document describes how to write modules in C or C++ to extend the Python interpreter with new modules. Those modules can not only define new functions but also new object types and their methods. The document also describes how to embed the Python interpreter in another application, for use as an extension language. Finally, it shows how to compile and link extension modules so that they can be loaded dynamically (at run time) into the interpreter, if the underlying operating system supports this feature.

This document assumes basic knowledge about Python. For an informal introduction to the language, see The Python Tutorial. The Python Language Reference gives a more formal definition of the language. The Python Standard Library documents the existing object types, functions and modules (both built-in and written in Python) that give the language its wide application range.

For a detailed description of the whole Python/C API, see the separate Python/C API Reference Manual.
Recommended third party tools

This guide only covers the basic tools for creating extensions provided as part of this version of CPython. Third party tools like Cython, cffi, SWIG and Numba offer both simpler and more sophisticated approaches to creating C and C++ extensions for Python.

See also:

**Python Packaging User Guide: Binary Extensions**

The Python Packaging User Guide not only covers several available tools that simplify the creation of binary extensions, but also discusses the various reasons why creating an extension module may be desirable in the first place.
Creating extensions without third party tools

This section of the guide covers creating C and C++ extensions without assistance from third party tools. It is intended primarily for creators of those tools, rather than being a recommended way to create your own C extensions.

- **1. Extending Python with C or C++**
  - 1.1. A Simple Example
  - 1.2. Intermezzo: Errors and Exceptions
  - 1.3. Back to the Example
  - 1.4. The Module’s Method Table and Initialization Function
  - 1.5. Compilation and Linkage
  - 1.6. Calling Python Functions from C
  - 1.7. Extracting Parameters in Extension Functions
  - 1.8. Keyword Parameters for Extension Functions
  - 1.9. Building Arbitrary Values
  - 1.10. Reference Counts
  - 1.11. Writing Extensions in C++
  - 1.12. Providing a C API for an Extension Module

- **2. Defining New Types**
  - 2.1. The Basics
  - 2.2. Type Methods

- **3. Building C and C++ Extensions**
  - 3.1. Building C and C++ Extensions with distutils
  - 3.2. Distributing your extension modules

- **4. Building C and C++ Extensions on Windows**
  - 4.1. A Cookbook Approach
  - 4.2. Differences Between Unix and Windows
  - 4.3. Using DLLs in Practice
Embedding the CPython runtime in a larger application

Sometimes, rather than creating an extension that runs inside the Python interpreter as the main application, it is desirable to instead embed the CPython runtime inside a larger application. This section covers some of the details involved in doing that successfully.

- 1. Embedding Python in Another Application
  - 1.1. Very High Level Embedding
  - 1.2. Beyond Very High Level Embedding: An overview
  - 1.3. Pure Embedding
  - 1.4. Extending Embedded Python
  - 1.5. Embedding Python in C++
  - 1.6. Compiling and Linking under Unix-like systems
Python/C API Reference Manual

This manual documents the API used by C and C++ programmers who want to write extension modules or embed Python. It is a companion to Extending and Embedding the Python Interpreter, which describes the general principles of extension writing but does not document the API functions in detail.

Distributing Python Modules

Email: distutils-sig@python.org

As a popular open source development project, Python has an active supporting community of contributors and users that also make their software available for other Python developers to use under open source license terms.

This allows Python users to share and collaborate effectively, benefiting from the solutions others have already created to common (and sometimes even rare!) problems, as well as potentially contributing their own solutions to the common pool.

This guide covers the distribution part of the process. For a guide to installing other Python projects, refer to the installation guide.

Note: For corporate and other institutional users, be aware that many organisations have their own policies around using and contributing to open source software. Please take such policies into account when making use of the distribution and installation tools provided with Python.
Key terms

- the **Python Packaging Index** is a public repository of open source licensed packages made available for use by other Python users.
- the **Python Packaging Authority** are the group of developers and documentation authors responsible for the maintenance and evolution of the standard packaging tools and the associated metadata and file format standards. They maintain a variety of tools, documentation and issue trackers on both GitHub and BitBucket.
- **distutils** is the original build and distribution system first added to the Python standard library in 1998. While direct use of **distutils** is being phased out, it still laid the foundation for the current packaging and distribution infrastructure, and it not only remains part of the standard library, but its name lives on in other ways (such as the name of the mailing list used to coordinate Python packaging standards development).
- **setuptools** is a (largely) drop-in replacement for **distutils** first published in 2004. Its most notable addition over the unmodified **distutils** tools was the ability to declare dependencies on other packages. It is currently recommended as a more regularly updated alternative to **distutils** that offers consistent support for more recent packaging standards across a wide range of Python versions.
- **wheel** (in this context) is a project that adds the **bdist_wheel** command to **distutils/setuptools**. This produces a cross platform binary packaging format (called “wheels” or “wheel files” and defined in **PEP 427**) that allows Python libraries, even those including binary extensions, to be installed on a system without needing to be built locally.
Open source licensing and collaboration

In most parts of the world, software is automatically covered by copyright. This means that other developers require explicit permission to copy, use, modify and redistribute the software.

Open source licensing is a way of explicitly granting such permission in a relatively consistent way, allowing developers to share and collaborate efficiently by making common solutions to various problems freely available. This leaves many developers free to spend more time focusing on the problems that are relatively unique to their specific situation.

The distribution tools provided with Python are designed to make it reasonably straightforward for developers to make their own contributions back to that common pool of software if they choose to do so.

The same distribution tools can also be used to distribute software within an organisation, regardless of whether that software is published as open source software or not.
Installing the tools

The standard library does not include build tools that support modern Python packaging standards, as the core development team has found that it is important to have standard tools that work consistently, even on older versions of Python.

The currently recommended build and distribution tools can be installed by invoking the pip module at the command line:

```
python -m pip install setuptools wheel twine
```

**Note:** For POSIX users (including Mac OS X and Linux users), these instructions assume the use of a virtual environment.

For Windows users, these instructions assume that the option to adjust the system PATH environment variable was selected when installing Python.

The Python Packaging User Guide includes more details on the currently recommended tools.
Reading the guide

The Python Packaging User Guide covers the various key steps and elements involved in creating a project:

- Project structure
- Building and packaging the project
- Uploading the project to the Python Packaging Index
How do I…?

These are quick answers or links for some common tasks.

… choose a name for my project?

This isn't an easy topic, but here are a few tips:

- check the Python Packaging Index to see if the name is already in use
- check popular hosting sites like GitHub, BitBucket, etc to see if there is already a project with that name
- check what comes up in a web search for the name you're considering
- avoid particularly common words, especially ones with multiple meanings, as they can make it difficult for users to find your software when searching for it

… create and distribute binary extensions?

This is actually quite a complex topic, with a variety of alternatives available depending on exactly what you're aiming to achieve. See the Python Packaging User Guide for more information and recommendations.

Installing Python Modules

Email: distutils-sig@python.org

As a popular open source development project, Python has an active supporting community of contributors and users that also make their software available for other Python developers to use under open source license terms.

This allows Python users to share and collaborate effectively, benefiting from the solutions others have already created to common (and sometimes even rare!) problems, as well as potentially contributing their own solutions to the common pool.

This guide covers the installation part of the process. For a guide to creating and sharing your own Python projects, refer to the distribution guide.

Note: For corporate and other institutional users, be aware that many organisations have their own policies around using and contributing to open source software. Please take such policies into account when making use of the distribution and installation tools provided with Python.
Key terms

- **pip** is the preferred installer program. Starting with Python 3.4, it is included by default with the Python binary installers.
- A **virtual environment** is a semi-isolated Python environment that allows packages to be installed for use by a particular application, rather than being installed system wide.
- **venv** is the standard tool for creating virtual environments, and has been part of Python since Python 3.3. Starting with Python 3.4, it defaults to installing pip into all created virtual environments.
- **virtualenv** is a third party alternative (and predecessor) to venv. It allows virtual environments to be used on versions of Python prior to 3.4, which either don’t provide venv at all, or aren’t able to automatically install pip into created environments.
- The **Python Packaging Index** is a public repository of open source licensed packages made available for use by other Python users.
- The **Python Packaging Authority** are the group of developers and documentation authors responsible for the maintenance and evolution of the standard packaging tools and the associated metadata and file format standards. They maintain a variety of tools, documentation, and issue trackers on both GitHub and BitBucket.
- **distutils** is the original build and distribution system first added to the Python standard library in 1998. While direct use of distutils is being phased out, it still laid the foundation for the current packaging and distribution infrastructure, and it not only remains part of the standard library, but its name lives on in other ways (such as the name of the mailing list used to coordinate Python packaging standards development).

*Deprecated since version 3.6:* **pyvenv** was the recommended tool for
creating virtual environments for Python 3.3 and 3.4, and is deprecated in Python 3.6.

*Changed in version 3.5:* The use of `venv` is now recommended for creating virtual environments.

**See also:** Python Packaging User Guide: Creating and using virtual environments
Basic usage

The standard packaging tools are all designed to be used from the command line.

The following command will install the latest version of a module and its dependencies from the Python Packaging Index:

```bash
python -m pip install SomePackage
```

**Note:** For POSIX users (including Mac OS X and Linux users), the examples in this guide assume the use of a virtual environment.

For Windows users, the examples in this guide assume that the option to adjust the system PATH environment variable was selected when installing Python.

It's also possible to specify an exact or minimum version directly on the command line. When using comparator operators such as `>`, `<` or some other special character which get interpreted by shell, the package name and the version should be enclosed within double quotes:

```bash
python -m pip install SomePackage==1.0.4  # specific version
python -m pip install "SomePackage>=1.0.4"  # minimum version
```

Normally, if a suitable module is already installed, attempting to install it again will have no effect. Upgrading existing modules must be requested explicitly:

```bash
python -m pip install --upgrade SomePackage
```
More information and resources regarding `pip` and its capabilities can be found in the Python Packaging User Guide.

Creation of virtual environments is done through the `venv` module. Installing packages into an active virtual environment uses the commands shown above.

See also: Python Packaging User Guide: Installing Python Distribution Packages
How do I …?

These are quick answers or links for some common tasks.

... install pip in versions of Python prior to Python 3.4?

Python only started bundling pip with Python 3.4. For earlier versions, pip needs to be “bootstrapped” as described in the Python Packaging User Guide.

See also: Python Packaging User Guide: Requirements for Installing Packages

... install packages just for the current user?

Passing the --user option to python -m pip install will install a package just for the current user, rather than for all users of the system.

... install scientific Python packages?

A number of scientific Python packages have complex binary dependencies, and aren't currently easy to install using pip directly. At this point in time, it will often be easier for users to install these packages by other means rather than attempting to install them with pip.

See also: Python Packaging User Guide: Installing Scientific Packages
... work with multiple versions of Python installed in parallel?

On Linux, Mac OS X, and other POSIX systems, use the versioned Python commands in combination with the -m switch to run the appropriate copy of pip:

```bash
python2  -m pip install SomePackage  # default Python 2
python2.7 -m pip install SomePackage  # specifically Python 2.7
python3  -m pip install SomePackage  # default Python 3
python3.4 -m pip install SomePackage  # specifically Python 3.4
```

Appropriately versioned pip commands may also be available.

On Windows, use the py Python launcher in combination with the -m switch:

```bash
py -2   -m pip install SomePackage  # default Python 2
py -2.7 -m pip install SomePackage  # specifically Python 2.7
py -3   -m pip install SomePackage  # default Python 3
py -3.4 -m pip install SomePackage  # specifically Python 3.4
```
Common installation issues

Installing into the system Python on Linux

On Linux systems, a Python installation will typically be included as part of the distribution. Installing into this Python installation requires root access to the system, and may interfere with the operation of the system package manager and other components of the system if a component is unexpectedly upgraded using `pip`.

On such systems, it is often better to use a virtual environment or a per-user installation when installing packages with `pip`.

Pip not installed

It is possible that `pip` does not get installed by default. One potential fix is:

```
python -m ensurepip --default-pip
```

There are also additional resources for installing `pip`.

Installing binary extensions

Python has typically relied heavily on source based distribution, with end users being expected to compile extension modules from source as part of the installation process.

With the introduction of support for the binary `wheel` format, and the ability to publish wheels for at least Windows and Mac OS X through the Python Packaging Index, this problem is expected to diminish over
time, as users are more regularly able to install pre-built extensions rather than needing to build them themselves.

Some of the solutions for installing scientific software that are not yet available as pre-built wheel files may also help with obtaining other binary extensions without needing to build them locally.

Python HOWTOs

Python HOWTOs are documents that cover a single, specific topic, and attempt to cover it fairly completely. Modelled on the Linux Documentation Project’s HOWTO collection, this collection is an effort to foster documentation that’s more detailed than the Python Library Reference.

Currently, the HOWTOs are:

- Porting Python 2 Code to Python 3
- Porting Extension Modules to Python 3
- Curses Programming with Python
- Descriptor HowTo Guide
- Functional Programming HOWTO
- Logging HOWTO
- Logging Cookbook
- Regular Expression HOWTO
- Socket Programming HOWTO
- Sorting HOW TO
- Unicode HOWTO
- HOWTO Fetch Internet Resources Using The urllib Package
- Argpase Tutorial
- An introduction to the ipaddress module
- Argument Clinic How-To
- Instrumenting CPython with DTrace and SystemTap
Python Frequently Asked Questions

- General Python FAQ
- Programming FAQ
- Design and History FAQ
- Library and Extension FAQ

- Python on Windows FAQ
- Graphic User Interface FAQ
- “Why is Python Installed on my Computer?” FAQ
10. API Reference
10.1. distutils.core — Core Distutils functionality

The distutils.core module is the only module that needs to be installed to use the Distutils. It provides the setup() (which is called from the setup script). Indirectly provides the distutils.dist.Distribution and distutils.cmd.Command class.

distutils.core.setup(arguments)

The basic do-everything function that does most everything you could ever ask for from a Distutils method.

The setup function takes a large number of arguments. These are laid out in the following table.

<table>
<thead>
<tr>
<th>argument name</th>
<th>value</th>
<th>type</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>The name of the package</td>
<td>a string</td>
</tr>
<tr>
<td>version</td>
<td>The version number of the package; see distutils.version</td>
<td>a string</td>
</tr>
<tr>
<td>description</td>
<td>A single line describing the package</td>
<td>a string</td>
</tr>
<tr>
<td>long_description</td>
<td>Longer description of the package</td>
<td>a string</td>
</tr>
<tr>
<td>author</td>
<td>The name of the package author</td>
<td>a string</td>
</tr>
<tr>
<td>author_email</td>
<td>The email address of the package author</td>
<td>a string</td>
</tr>
<tr>
<td><strong>maintainer</strong></td>
<td>The name of the current maintainer, if different from the author. Note that if the maintainer is provided, distutils will use it as the author in <strong>PKG-INFO</strong></td>
<td>a string</td>
</tr>
<tr>
<td><strong>maintainer_email</strong></td>
<td>The email address of the current maintainer, if different from the author</td>
<td>a string</td>
</tr>
<tr>
<td><strong>url</strong></td>
<td>A URL for the package (homepage)</td>
<td>a string</td>
</tr>
<tr>
<td><strong>download_url</strong></td>
<td>A URL to download the package</td>
<td>a string</td>
</tr>
<tr>
<td><strong>packages</strong></td>
<td>A list of Python packages that distutils will manipulate</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>py_modules</strong></td>
<td>A list of Python modules that distutils will manipulate</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>scripts</strong></td>
<td>A list of standalone script files to be built and installed</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>ext_modules</strong></td>
<td>A list of Python extensions to be built</td>
<td>a list of instances of <code>distutils.core.Extension</code></td>
</tr>
<tr>
<td><strong>classifiers</strong></td>
<td>A list of categories for the package</td>
<td>a list of strings; valid listed on <strong>PyPI</strong>.</td>
</tr>
<tr>
<td><strong>distclass</strong></td>
<td>the <strong>Distribution</strong> class to use</td>
<td>a subclass of <code>distutils.core.Distribution</code></td>
</tr>
</tbody>
</table>

The name of the setup.py script -
<table>
<thead>
<tr>
<th><strong>script_name</strong></th>
<th>defaults to sys.argv[0]</th>
<th>a string</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>script_args</strong></td>
<td>Arguments to supply to the setup script</td>
<td>a list of strings</td>
</tr>
<tr>
<td><strong>options</strong></td>
<td>default options for the setup script</td>
<td>a dictionary</td>
</tr>
<tr>
<td><strong>license</strong></td>
<td>The license for the package</td>
<td>a string</td>
</tr>
<tr>
<td><strong>keywords</strong></td>
<td>Descriptive meta-data, see PEP 314</td>
<td>a list of strings or a comma-separated string</td>
</tr>
<tr>
<td><strong>platforms</strong></td>
<td></td>
<td>a list of strings or a comma-separated string</td>
</tr>
<tr>
<td><strong>cmdclass</strong></td>
<td>A mapping of command names to Command subclasses</td>
<td>a dictionary</td>
</tr>
<tr>
<td><strong>data_files</strong></td>
<td>A list of data files to install</td>
<td>a list</td>
</tr>
<tr>
<td><strong>package_dir</strong></td>
<td>A mapping of package to directory names</td>
<td>a dictionary</td>
</tr>
</tbody>
</table>

```
distutils.core.run_setup(script_name=[], script_args=None, stop_after='run')
```

Run a setup script in a somewhat controlled environment, and return the distutils.dist.Distribution instance that drives things. This is useful if you need to find out the distribution meta-data (passed as keyword args from script to setup()), or the contents of the config files or command-line.

*script_name* is a file that will be read and run with exec(). *sys.argv[0]* will be replaced with *script* for the duration of the
call. `script_args` is a list of strings; if supplied, `sys.argv[1:]` will be replaced by `script_args` for the duration of the call.

`stop_after` tells `setup()` when to stop processing; possible values:

<table>
<thead>
<tr>
<th>value</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>init</code></td>
<td>Stop after the <code>Distribution</code> instance has been created and populated with the keyword arguments to <code>setup()</code></td>
</tr>
<tr>
<td><code>config</code></td>
<td>Stop after config files have been parsed (and their data stored in the <code>Distribution</code> instance)</td>
</tr>
<tr>
<td><code>commandline</code></td>
<td>Stop after the command-line (<code>sys.argv[1:]</code> or <code>script_args</code>) have been parsed (and the data stored in the <code>Distribution</code> instance.)</td>
</tr>
<tr>
<td><code>run</code></td>
<td>Stop after all commands have been run (the same as if <code>setup()</code> had been called in the usual way). This is the default value.</td>
</tr>
</tbody>
</table>

In addition, the `distutils.core` module exposed a number of classes that live elsewhere.

- Extension from `distutils.extension`
- Command from `distutils.cmd`
- Distribution from `distutils.dist`

A short description of each of these follows, but see the relevant module for the full reference.

`class distutils.core.Extension`

The Extension class describes a single C or C++ extension module in a setup script. It accepts the following keyword arguments in its constructor:
<table>
<thead>
<tr>
<th>argument name</th>
<th>value</th>
<th>type</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>the full name of the extension, including any packages — <em>ie.</em> not a filename or pathname, but Python dotted name</td>
<td>a string</td>
</tr>
<tr>
<td>sources</td>
<td>list of source filenames, relative to the distribution root (where the setup script lives), in Unix form (slash-separated) for portability. Source files may be C, C++, SWIG (.i), platform-specific resource files, or whatever else is recognized by the <code>build_ext</code> command as source for a Python extension.</td>
<td>a list of strings</td>
</tr>
<tr>
<td>include_dirs</td>
<td>list of directories to search for C/C++ header files (in Unix form for portability)</td>
<td>a list of strings</td>
</tr>
<tr>
<td>define_macros</td>
<td>list of macros to define; each macro is defined using a 2-tuple <code>name, value</code>, where <code>value</code> is either the string to define it to or None to define it without a particular value (equivalent of <code>#define FOO in</code></td>
<td>a list of tuples</td>
</tr>
<tr>
<td>Variable</td>
<td>Description</td>
<td>Type</td>
</tr>
<tr>
<td>----------------------</td>
<td>-----------------------------------------------------------------------------</td>
<td>----------------</td>
</tr>
<tr>
<td>source or -DF00 on</td>
<td>list of macros to undefine explicitly</td>
<td>a list of strings</td>
</tr>
<tr>
<td>Unix C compiler</td>
<td>list of directories to search for C/C++ libraries at link time</td>
<td>a list of strings</td>
</tr>
<tr>
<td>command line)</td>
<td>list of directories to search for C/C++ libraries at run time (for</td>
<td>a list of strings</td>
</tr>
<tr>
<td></td>
<td>shared extensions, this is when the extension is loaded)</td>
<td></td>
</tr>
<tr>
<td>libraries</td>
<td>list of library names (not filenames or paths) to link against</td>
<td>a list of strings</td>
</tr>
<tr>
<td>libraries</td>
<td>list of library names (not filenames or paths) to link against</td>
<td>a list of strings</td>
</tr>

class distutils.core.Distribution

A Distribution describes how to build, install and package up a Python software package.

See the setup() function for a list of keyword arguments accepted by the Distribution constructor. setup() creates a Distribution instance.

class distutils.core.Command

A Command class (or rather, an instance of one of its subclasses) implement a single distutils command.
10.2. *distutils.ccompiler* —
CCompiler base class

This module provides the abstract base class for the *CCompiler* classes. A *CCompiler* instance can be used for all the compile and link steps needed to build a single project. Methods are provided to set options for the compiler — macro definitions, include directories, link path, libraries and the like.

This module provides the following functions.

**distutils.ccompiler.**`gen_lib_options`**(compiler, library_dirs, runtime_library_dirs, libraries)**

Generate linker options for searching library directories and linking with specific libraries. *libraries* and *library_dirs* are, respectively, lists of library names (not filenames!) and search directories. Returns a list of command-line options suitable for use with some compiler (depending on the two format strings passed in).

**distutils.ccompiler.**`gen_preprocess_options`**(macros, include_dirs)**

Generate C pre-processor options (-D, -U, -I) as used by at least two types of compilers: the typical Unix compiler and Visual C++. *macros* is the usual thing, a list of 1- or 2-tuples, where *(name,)* means undefine (-U) macro *name*, and *(name, value)* means define (-D) macro *name* to *value*. *include_dirs* is just a list of directory names to be added to the header file search path (-I). Returns a list of command-line options suitable for either Unix compilers or Visual C++.

**distutils.ccompiler.**`get_default_compiler`**(osname,
Determine the default compiler to use for the given platform.

`osname` should be one of the standard Python OS names (i.e. the ones returned by `os.name`) and `platform` the common value returned by `sys.platform` for the platform in question.

The default values are `os.name` and `sys.platform` in case the parameters are not given.

distutils.ccompiler.**new_compiler**(plat=None, compiler=None, verbose=0, dry_run=0, force=0)

Factory function to generate an instance of some CCompiler subclass for the supplied platform/compiler combination. `plat` defaults to `os.name` (eg. 'posix', 'nt'), and `compiler` defaults to the default compiler for that platform. Currently only 'posix' and 'nt' are supported, and the default compilers are “traditional Unix interface” (UnixCCompiler class) and Visual C++ (MSVCCompiler class). Note that it’s perfectly possible to ask for a Unix compiler object under Windows, and a Microsoft compiler object under Unix—if you supply a value for `compiler`, `plat` is ignored.

distutils.ccompiler.**show_compilers**()

Print list of available compilers (used by the --help-compiler options to `build, build_ext, build_clib`).

class distutils.ccompiler.**CCompiler**(verbose=0, dry_run=0, force=0)

The abstract base class `CCompiler` defines the interface that must be implemented by real compiler classes. The class also has some utility methods used by several compiler classes.
The basic idea behind a compiler abstraction class is that each instance can be used for all the compile/link steps in building a single project. Thus, attributes common to all of those compile and link steps — include directories, macros to define, libraries to link against, etc. — are attributes of the compiler instance. To allow for variability in how individual files are treated, most of those attributes may be varied on a per-compilation or per-link basis.

The constructor for each subclass creates an instance of the Compiler object. Flags are verbose (show verbose output), dry_run (don’t actually execute the steps) and force (rebuild everything, regardless of dependencies). All of these flags default to 0 (off). Note that you probably don’t want to instantiate CCompiler or one of its subclasses directly - use the distutils.CCompiler.new_compiler() factory function instead.

The following methods allow you to manually alter compiler options for the instance of the Compiler class.

**add_include_dir(dir)**
Add dir to the list of directories that will be searched for header files. The compiler is instructed to search directories in the order in which they are supplied by successive calls to add_include_dir().

**set_include_dirs(dirs)**
Set the list of directories that will be searched to dirs (a list of strings). Overrides any preceding calls to add_include_dir(); subsequent calls to add_include_dir() add to the list passed to set_include_dirs(). This does not affect any list of
standard include directories that the compiler may search by default.

**add_library**(*libname*)
Add *libname* to the list of libraries that will be included in all links driven by this compiler object. Note that *libname* should *not* be the name of a file containing a library, but the name of the library itself: the actual filename will be inferred by the linker, the compiler, or the compiler class (depending on the platform).

The linker will be instructed to link against libraries in the order they were supplied to **add_library()** and/or **set_libraries()**. It is perfectly valid to duplicate library names; the linker will be instructed to link against libraries as many times as they are mentioned.

**set_libraries**(*libnames*)
Set the list of libraries to be included in all links driven by this compiler object to *libnames* (a list of strings). This does not affect any standard system libraries that the linker may include by default.

**add_library_dir**(*dir*)
Add *dir* to the list of directories that will be searched for libraries specified to **add_library()** and **set_libraries()**. The linker will be instructed to search for libraries in the order they are supplied to **add_library_dir()** and/or **set_library_dirs()**.

**set_library_dirs**(*dirs*)
Set the list of library search directories to *dirs* (a list of strings). This does not affect any standard library search path that the
linker may search by default.

**add_runtime_library_dir(dir)**
Add *dir* to the list of directories that will be searched for shared libraries at runtime.

**set_runtime_library_dirs(dirs)**
Set the list of directories to search for shared libraries at runtime to *dirs* (a list of strings). This does not affect any standard search path that the runtime linker may search by default.

**define_macro(name[, value=None])**
Define a preprocessor macro for all compilations driven by this compiler object. The optional parameter *value* should be a string; if it is not supplied, then the macro will be defined without an explicit value and the exact outcome depends on the compiler used.

**undefine_macro(name)**
Undefine a preprocessor macro for all compilations driven by this compiler object. If the same macro is defined by **define_macro()** and undefined by **undefine_macro()** the last call takes precedence (including multiple redefinitions or undefinitions). If the macro is redefined/undefined on a per-compilation basis (ie. in the call to **compile()**), then that takes precedence.

**add_link_object(object)**
Add *object* to the list of object files (or analogues, such as explicitly named library files or the output of “resource compilers”) to be included in every link driven by this compiler
object.

**set_link_objects(objets)**

Set the list of object files (or analogues) to be included in every link to *objects*. This does not affect any standard object files that the linker may include by default (such as system libraries).

The following methods implement methods for autodetection of compiler options, providing some functionality similar to GNU autoconf.

**detect_language(sources)**

Detect the language of a given file, or list of files. Uses the instance attributes *language_map* (a dictionary), and *language_order* (a list) to do the job.

**find_library_file(dirs, lib[, debug=0])**

Search the specified list of directories for a static or shared library file *lib* and return the full path to that file. If *debug* is true, look for a debugging version (if that makes sense on the current platform). Return None if *lib* wasn’t found in any of the specified directories.

**has_function(funcname[, includes=None, include_dirs=None, libraries=None, library_dirs=None])**

Return a boolean indicating whether *funcname* is supported on the current platform. The optional arguments can be used to augment the compilation environment by providing additional include files and paths and libraries and paths.

**library_dir_option(dir)**

Return the compiler option to add *dir* to the list of directories
searched for libraries.

**library_option**(\textit{lib})

Return the compiler option to add \textit{lib} to the list of libraries linked into the shared library or executable.

**runtime_library_dir_option**(\textit{dir})

Return the compiler option to add \textit{dir} to the list of directories searched for runtime libraries.

**set_executables**(**\textit{args}**)

Define the executables (and options for them) that will be run to perform the various stages of compilation. The exact set of executables that may be specified here depends on the compiler class (via the ‘executables’ class attribute), but most will have:

<table>
<thead>
<tr>
<th>attribute</th>
<th>description</th>
</tr>
</thead>
<tbody>
<tr>
<td>\textit{compiler}</td>
<td>the C/C++ compiler</td>
</tr>
<tr>
<td>\textit{linker_so}</td>
<td>linker used to create shared objects and libraries</td>
</tr>
<tr>
<td>\textit{linker_exe}</td>
<td>linker used to create binary executables</td>
</tr>
<tr>
<td>\textit{archiver}</td>
<td>static library creator</td>
</tr>
</tbody>
</table>

On platforms with a command-line (Unix, DOS/Windows), each of these is a string that will be split into executable name and (optional) list of arguments. (Splitting the string is done similarly to how Unix shells operate: words are delimited by spaces, but quotes and backslashes can override this. See \texttt{distutils.util.split\_quoted()}.)

The following methods invoke stages in the build process.
`compile(sources[, output_dir=None, macros=None, include_dirs=None, debug=0, extra_preargs=None, extra_postargs=None, depends=None])`

Compile one or more source files. Generates object files (e.g. transforms a .c file to a .o file.)

`sources` must be a list of filenames, most likely C/C++ files, but in reality anything that can be handled by a particular compiler and compiler class (eg. MSVCCompiler can handle resource files in `sources`). Return a list of object filenames, one per source filename in `sources`. Depending on the implementation, not all source files will necessarily be compiled, but all corresponding object filenames will be returned.

If `output_dir` is given, object files will be put under it, while retaining their original path component. That is, `foo/bar.c` normally compiles to `foo/bar.o` (for a Unix implementation); if `output_dir` is `build`, then it would compile to `build/foo/bar.o`.

`macros`, if given, must be a list of macro definitions. A macro definition is either a `(name, value)` 2-tuple or a `(name,)` 1-tuple. The former defines a macro; if the value is `None`, the macro is defined without an explicit value. The 1-tuple case undefines a macro. Later definitions/redefinitions/undefinitions take precedence.

`include_dirs`, if given, must be a list of strings, the directories to add to the default include file search path for this compilation only.

`debug` is a boolean; if true, the compiler will be instructed to
output debug symbols in (or alongside) the object file(s).

extra_preargs and extra_postargs are implementation-dependent. On platforms that have the notion of a command-line (e.g. Unix, DOS/Windows), they are most likely lists of strings: extra command-line arguments to prepend/append to the compiler command line. On other platforms, consult the implementation class documentation. In any event, they are intended as an escape hatch for those occasions when the abstract compiler framework doesn’t cut the mustard.

depends, if given, is a list of filenames that all targets depend on. If a source file is older than any file in depends, then the source file will be recompiled. This supports dependency tracking, but only at a coarse granularity.

Raises CompileError on failure.

create_static_lib(objects, output_libname[, output_dir=None, debug=0, target_lang=None])

Link a bunch of stuff together to create a static library file. The “bunch of stuff” consists of the list of object files supplied as objects, the extra object files supplied to add_link_object() and/or set_link_objects(), the libraries supplied to add_library() and/or set_libraries(), and the libraries supplied as libraries (if any).

output_libname should be a library name, not a filename; the filename will be inferred from the library name. output_dir is the directory where the library file will be put.

debug is a boolean; if true, debugging information will be included in the library (note that on most platforms, it is the
compile step where this matters: the debug flag is included here just for consistency).

target_lang is the target language for which the given objects are being compiled. This allows specific linkage time treatment of certain languages.

Raises LibError on failure.

link(target_desc, objects, output_filename[, output_dir=None, libraries=None, library_dirs=None, runtime_library_dirs=None, export_symbols=None, debug=0, extra_preargs=None, extra_postargs=None, build_temp=None, target_lang=None])

Link a bunch of stuff together to create an executable or shared library file.

The “bunch of stuff” consists of the list of object files supplied as objects. output_filename should be a filename. If output_dir is supplied, output_filename is relative to it (i.e. output_filename can provide directory components if needed).

libraries is a list of libraries to link against. These are library names, not filenames, since they’re translated into filenames in a platform-specific way (eg. foo becomes libfoo.a on Unix and foo.lib on DOS/Windows). However, they can include a directory component, which means the linker will look in that specific directory rather than searching all the normal locations.

library_dirs, if supplied, should be a list of directories to search for libraries that were specified as bare library names (ie. no directory component). These are on top of the system default and those supplied to add_library_dir() and/or set_library_dirs(). runtime_library_dirs is a list of
directories that will be embedded into the shared library and used to search for other shared libraries that *it* depends on at run-time. (This may only be relevant on Unix.)

`export_symbols` is a list of symbols that the shared library will export. (This appears to be relevant only on Windows.)

`debug` is as for `compile()` and `create_static_lib()`, with the slight distinction that it actually matters on most platforms (as opposed to `create_static_lib()`, which includes a `debug` flag mostly for form's sake).

`extra_preargs` and `extra_postargs` are as for `compile()` (except of course that they supply command-line arguments for the particular linker being used).

`target_lang` is the target language for which the given objects are being compiled. This allows specific linkage time treatment of certain languages.

Raises `LinkError` on failure.

```python
link_executable(objects, output_progname=..., output_dir=None, libraries=None, library_dirs=None, runtime_library_dirs=None, debug=0, extra_preargs=None, extra_postargs=None, target_lang=None)
```

Link an executable. `output_progname` is the name of the file executable, while `objects` are a list of object filenames to link in. Other arguments are as for the `link()` method.

```python
link_shared_lib(objects, output_libname=..., output_dir=None, libraries=None, library_dirs=None, runtime_library_dirs=None, export_symbols=None, debug=0, extra ...
```
Link a shared library. output_libname is the name of the output library, while objects is a list of object filenames to link in. Other arguments are as for the link() method.

```python
link_shared_object(objects, output_filename=None, output_dir=None, libraries=None, library_dirs=None, runtime_library_dirs=None, export_symbols=None, debug=0, extra_preargs=None, extra_postargs=None, build_temp=None, target_lang=None)
```

Link a shared object. output_filename is the name of the shared object that will be created, while objects is a list of object filenames to link in. Other arguments are as for the link() method.

```python
preprocess(source, output_file=None, macros=None, include_dirs=None, extra_preargs=None, extra_postargs=None)
```

Preprocess a single C/C++ source file, named in source. Output will be written to file named output_file, or stdout if output_file not supplied. macros is a list of macro definitions as for compile(), which will augment the macros set with define_macro() and undefine_macro(). include_dirs is a list of directory names that will be added to the default list, in the same way as add_include_dir().

Raises PreprocessError on failure.

The following utility methods are defined by the CCompiler class, for use by the various concrete subclasses.
**executable_filename**(basename[, strip_dir=0, output_dir=‘’])

Returns the filename of the executable for the given basename. Typically for non-Windows platforms this is the same as the basename, while Windows will get a .exe added.

**library_filename**(libname[, lib_type='static', strip_dir=0, output_dir=‘’])

Returns the filename for the given library name on the current platform. On Unix a library with lib_type of 'static' will typically be of the form liblibname.a, while a lib_type of 'dynamic' will be of the form liblibname.so.

**object_filenames**(source_filenames[, strip_dir=0, output_dir=‘’])

Returns the name of the object files for the given source files. source_filenames should be a list of filenames.

**shared_object_filename**(basename[, strip_dir=0, output_dir=‘’])

Returns the name of a shared object file for the given file name basename.

**execute**(func, args[, msg=None, level=1])

Invokes distutils.util.execute(). This method invokes a Python function func with the given arguments args, after logging and taking into account the dry_run flag.

**spawn**(cmd)

Invokes distutils.util.spawn(). This invokes an
external process to run the given command.

**mkpath**(*name[, mode=511]*)

Invokes `distutils.dir_util.mkpath()`. This creates a directory and any missing ancestor directories.

**move_file**(*src, dst*)

Invokes `distutils.file_util.move_file()`. Renames *src* to *dst*.

**announce**(*msg[, level=1]*)

Write a message using `distutils.log.debug()`.

**warn**(*msg*)

Write a warning message *msg* to standard error.

**debug_print**(*msg*)

If the *debug* flag is set on this `CCompiler` instance, print *msg* to standard output, otherwise do nothing.
10.3. distutils.unixccompiler — Unix C Compiler

This module provides the UnixCCompiler class, a subclass of CCompiler that handles the typical Unix-style command-line C compiler:

- macros defined with -Dname[=value]
- macros undefined with -Uname
- include search directories specified with -Idir
- libraries specified with -llib
- library search directories specified with -Ldir
- compile handled by cc (or similar) executable with -c option: compiles .c to .o
- link static library handled by ar command (possibly with ranlib)
- link shared library handled by cc -shared
10.4. `distutils.msvccompiler` — Microsoft Compiler

This module provides MSVCCCompiler, an implementation of the abstract CCompiler class for Microsoft Visual Studio. Typically, extension modules need to be compiled with the same compiler that was used to compile Python. For Python 2.3 and earlier, the compiler was Visual Studio 6. For Python 2.4 and 2.5, the compiler is Visual Studio .NET 2003. The AMD64 and Itanium binaries are created using the Platform SDK.

MSVCCCompiler will normally choose the right compiler, linker etc. on its own. To override this choice, the environment variables `DISTUTILS_USE_SDK` and `MSSdk` must be both set. `MSSdk` indicates that the current environment has been setup by the SDK’s `SetEnv.Cmd` script, or that the environment variables had been registered when the SDK was installed; `DISTUTILS_USE_SDK` indicates that the distutils user has made an explicit choice to override the compiler selection by MSVCCCompiler.
10.5. *distutils.bcppcompiler* — Borland Compiler

This module provides BorlandCCompiler, a subclass of the abstract CCompiler class for the Borland C++ compiler.
10.6. distutils.cygwincompiler — Cygwin Compiler

This module provides the CygwinCCompiler class, a subclass of UnixCCompiler that handles the Cygwin port of the GNU C compiler to Windows. It also contains the Mingw32CCompiler class which handles the mingw32 port of GCC (same as cygwin in no-cygwin mode).
10.7. `distutils.archive_util` — Archiving utilities

This module provides a few functions for creating archive files, such as tarballs or zipfiles.

```
distutils.archive_util.make_archive(base_name, format[, root_dir=None, base_dir=None, verbose=0, dry_run=0])
```

Create an archive file (eg. zip or tar). `base_name` is the name of the file to create, minus any format-specific extension; `format` is the archive format: one of zip, tar, gztar, bztar, xztar, or ztar. `root_dir` is a directory that will be the root directory of the archive; ie. we typically `chdir` into `root_dir` before creating the archive. `base_dir` is the directory where we start archiving from; ie. `base_dir` will be the common prefix of all files and directories in the archive. `root_dir` and `base_dir` both default to the current directory. Returns the name of the archive file.

*Changed in version 3.5:* Added support for the xztar format.

```
distutils.archive_util.make_tarball(base_name, base_dir[, compress='gzip', verbose=0, dry_run=0])
```

‘Create an (optional compressed) archive as a tar file from all files in and under `base_dir`. `compress` must be 'gzip' (the default), 'bzip2', 'xz', 'compress', or None. For the 'compress' method the compression utility named by `compress` must be on the default program search path, so this is probably Unix-specific. The output tar file will be named `base_dir.tar`, possibly plus the appropriate compression extension (.gz, .bz2, .xz or .Z). Return the output filename.
Changed in version 3.5: Added support for the \texttt{xz} compression.

\texttt{distutils.archive_util.make_zipfile}(\textit{base\_name}, \textit{base\_dir}[\textit{, verbose=0, dry\_run=0}])

Create a zip file from all files in and under \textit{base\_dir}. The output zip file will be named \textit{base\_name} + \texttt{.zip}. Uses either the \texttt{zipfile} Python module (if available) or the InfoZIP \texttt{zip} utility (if installed and found on the default search path). If neither tool is available, raises \texttt{DistutilsExecError}. Returns the name of the output zip file.
10.8. `distutils.dep_util` — Dependency checking

This module provides functions for performing simple, timestamp-based dependency of files and groups of files; also, functions based entirely on such timestamp dependency analysis.

`distutils.dep_util.newer(source, target)`

Return true if `source` exists and is more recently modified than `target`, or if `source` exists and `target` doesn't. Return false if both exist and `target` is the same age or newer than `source`. Raise `DistutilsFileError` if `source` does not exist.

`distutils.dep_util.newer_pairwise(sources, targets)`

Walk two filename lists in parallel, testing if each source is newer than its corresponding target. Return a pair of lists (`sources`, `targets`) where source is newer than target, according to the semantics of `newer()`.

`distutils.dep_util.newer_group(sources, target[, missing='error'])`  

Return true if `target` is out-of-date with respect to any file listed in `sources` In other words, if `target` exists and is newer than every file in `sources`, return false; otherwise return true. `missing` controls what we do when a source file is missing; the default (`'error'`) is to blow up with an `OSError` from inside `os.stat()`; if it is `ignore`, we silently drop any missing source files; if it is `newer`, any missing source files make us assume that `target` is out-of-date (this is handy in “dry-run” mode: it’ll make you pretend to carry out commands that wouldn’t work because inputs are
missing, but that doesn't matter because you're not actually going to run the commands).
10.9. **distutils.dir_util** — Directory tree operations

This module provides functions for operating on directories and trees of directories.

```python
distutils.dir_util.mkpath(name[, mode=0o777, verbose=0, dry_run=0])
```
Create a directory and any missing ancestor directories. If the directory already exists (or if name is the empty string, which means the current directory, which of course exists), then do nothing. Raise DistutilsFileError if unable to create some directory along the way (eg. some sub-path exists, but is a file rather than a directory). If verbose is true, print a one-line summary of each mkdir to stdout. Return the list of directories actually created.

```python
distutils.dir_util.create_tree(base_dir, files[, mode=0o777, verbose=0, dry_run=0])
```
Create all the empty directories under base_dir needed to put files there. base_dir is just the name of a directory which doesn’t necessarily exist yet; files is a list of filenames to be interpreted relative to base_dir. base_dir + the directory portion of every file in files will be created if it doesn’t already exist. mode, verbose and dry_run flags are as for mkpath().

```python
distutils.dir_util.copy_tree(src, dst[, preserve_mode=1, preserve_times=1, preserve_symlinks=0, update=0, verbose=0, dry_run=0])
```
Copy an entire directory tree src to a new location dst. Both src and
**dst** must be directory names. If **src** is not a directory, raise DistutilsFileError. If **dst** does not exist, it is created with **mkpath()**. The end result of the copy is that every file in **src** is copied to **dst**, and directories under **src** are recursively copied to **dst**. Return the list of files that were copied or might have been copied, using their output name. The return value is unaffected by **update** or **dry_run**: it is simply the list of all files under **src**, with the names changed to be under **dst**.

**preserve_mode** and **preserve_times** are the same as for **distutils.file_util.copy_file()**; note that they only apply to regular files, not to directories. If **preserve_symlinks** is true, symlinks will be copied as symlinks (on platforms that support them!); otherwise (the default), the destination of the symlink will be copied. **update** and **verbose** are the same as for **copy_file()**.

Files in **src** that begin with **.nfs** are skipped (more information on these files is available in answer D2 of the NFS FAQ page).

*Changed in version 3.3.1*: NFS files are ignored.

**distutils.dir_util.remove_tree**( **directory**, **verbose=0, dry_run=0**)

Recursively remove **directory** and all files and directories underneath it. Any errors are ignored (apart from being reported to **sys.stdout** if **verbose** is true).
10.10. `distutils.file_util` — Single file operations

This module contains some utility functions for operating on individual files.

```python
import distutils.file_util

distutils.file_util.copy_file(src, dst[, preserve_mode=1, preserve_times=1, update=0, link=None, verbose=0, dry_run=0])
```

Copy file `src` to `dst`. If `dst` is a directory, then `src` is copied there with the same name; otherwise, it must be a filename. (If the file exists, it will be ruthlessly clobbered.) If `preserve_mode` is true (the default), the file’s mode (type and permission bits, or whatever is analogous on the current platform) is copied. If `preserve_times` is true (the default), the last-modified and last-access times are copied as well. If `update` is true, `src` will only be copied if `dst` does not exist, or if `dst` does exist but is older than `src`.

`link` allows you to make hard links (using `os.link()`) or symbolic links (using `os.symlink()`) instead of copying: set it to 'hard' or 'sym'; if it is `None` (the default), files are copied. Don’t set `link` on systems that don’t support it: `copy_file()` doesn’t check if hard or symbolic linking is available. It uses `_copy_file_contents()` to copy file contents.

Return a tuple `(dest_name, copied)`: `dest_name` is the actual name of the output file, and `copied` is true if the file was copied (or would have been copied, if `dry_run` true).

```python
import distutils.file_util

distutils.file_util.move_file(src, dst[, verbose, dry_run])
```
Move file src to dst. If dst is a directory, the file will be moved into it with the same name; otherwise, src is just renamed to dst. Returns the new full name of the file.

**Warning:** Handles cross-device moves on Unix using copy_file(). What about other systems?

```python
distutils.file_util.write_file(filename, contents)
```
Create a file called filename and write contents (a sequence of strings without line terminators) to it.
This module contains other assorted bits and pieces that don’t fit into any other utility module.

**distutils.util.get_platform()**

Return a string that identifies the current platform. This is used mainly to distinguish platform-specific build directories and platform-specific built distributions. Typically includes the OS name and version and the architecture (as supplied by `os.uname()`), although the exact information included depends on the OS; eg. for IRIX the architecture isn’t particularly important (IRIX only runs on SGI hardware), but for Linux the kernel version isn’t particularly important.

Examples of returned values:

- `linux-i586`
- `linux-alpha`
- `solaris-2.6-sun4u`
- `irix-5.3`
- `irix64-6.2`

For non-POSIX platforms, currently just returns `sys.platform`.

For Mac OS X systems the OS version reflects the minimal version on which binaries will run (that is, the value of `MACOSX_DEPLOYMENT_TARGET` during the build of Python), not the OS version of the current system.

For universal binary builds on Mac OS X the architecture value
reflects the universal binary status instead of the architecture of the current processor. For 32-bit universal binaries the architecture is fat, for 64-bit universal binaries the architecture is fat64, and for 4-way universal binaries the architecture is universal. Starting from Python 2.7 and Python 3.2 the architecture fat3 is used for a 3-way universal build (ppc, i386, x86_64) and intel is used for a universal build with the i386 and x86_64 architectures

Examples of returned values on Mac OS X:

- macosx-10.3-ppc
- macosx-10.3-fat
- macosx-10.5-universal
- macosx-10.6-intel

**distutils.util.convert_path(pathname)**
Return ‘pathname’ as a name that will work on the native filesystem, i.e. split it on ‘/’ and put it back together again using the current directory separator. Needed because filenames in the setup script are always supplied in Unix style, and have to be converted to the local convention before we can actually use them in the filesystem. Raises ValueError on non-Unix-ish systems if pathname either starts or ends with a slash.

**distutils.util.change_root(new_root, pathname)**
Return pathname with new_root prepended. If pathname is relative, this is equivalent to os.path.join(new_root, pathname) Otherwise, it requires making pathname relative and then joining the two, which is tricky on DOS/Windows.

**distutils.util.check_environ()**
Ensure that ‘os.environ’ has all the environment variables we guarantee that users can use in config files, command-line options, etc. Currently this includes:

- HOME - user's home directory (Unix only)
- PLAT - description of the current platform, including hardware and OS (see get_platform())

\texttt{distutils.util.subst\_vars(s, local\_vars)}

Perform shell/Perl-style variable substitution on \( s \). Every occurrence of \$ followed by a name is considered a variable, and variable is substituted by the value found in the \texttt{local\_vars} dictionary, or in \texttt{os.environ} if it's not in \texttt{local\_vars}. \texttt{os.environ} is first checked/augmented to guarantee that it contains certain values: see \texttt{check\_environ()}. Raise \texttt{ValueError} for any variables not found in either \texttt{local\_vars} or \texttt{os.environ}.

Note that this is not a fully-fledged string interpolation function. A valid \$variable can consist only of upper and lower case letters, numbers and an underscore. No \{ \} or ( ) style quoting is available.

\texttt{distutils.util.split\_quoted(s)}

Split a string up according to Unix shell-like rules for quotes and backslashes. In short: words are delimited by spaces, as long as those spaces are not escaped by a backslash, or inside a quoted string. Single and double quotes are equivalent, and the quote characters can be backslash-escaped. The backslash is stripped from any two-character escape sequence, leaving only the escaped character. The quote characters are stripped from any quoted string. Returns a list of words.

\texttt{distutils.util.execute(func, args[, msg=None, verbose=0,}
Perform some action that affects the outside world (for instance, writing to the filesystem). Such actions are special because they are disabled by the `dry_run` flag. This method takes care of all that bureaucracy for you; all you have to do is supply the function to call and an argument tuple for it (to embody the “external action” being performed), and an optional message to print.

```python
distutils.util.strtobool(val)
```

Convert a string representation of truth to true (1) or false (0).

True values are `y`, `yes`, `t`, `true`, `on` and `1`; false values are `n`, `no`, `f`, `false`, `off` and `0`. Raises `ValueError` if `val` is anything else.

```python
distutils.util.byte_compile(py_files[, optimize=0, force=0, prefix=None, base_dir=None, verbose=1, dry_run=0, direct=None])
```

Byte-compile a collection of Python source files to `.pyc` files in a `__pycache__` subdirectory (see PEP 3147 and PEP 488). `py_files` is a list of files to compile; any files that don’t end in `.py` are silently skipped. `optimize` must be one of the following:

- 0 - don’t optimize
- 1 - normal optimization (like `python -O`)
- 2 - extra optimization (like `python -OO`)

If `force` is true, all files are recompiled regardless of timestamps.

The source filename encoded in each `bytecode` file defaults to the filenames listed in `py_files`; you can modify these with `prefix` and `basedir`. `prefix` is a string that will be stripped off of each source filename, and `base_dir` is a directory name that will be prepended
(after $prefix$ is stripped). You can supply either or both (or neither) of $prefix$ and $base_dir$, as you wish.

If $dry_run$ is true, doesn’t actually do anything that would affect the filesystem.

Byte-compilation is either done directly in this interpreter process with the standard $py_compile$ module, or indirectly by writing a temporary script and executing it. Normally, you should let $byte_compile()$ figure out to use direct compilation or not (see the source for details). The $direct$ flag is used by the script generated in indirect mode; unless you know what you’re doing, leave it set to $None$.

*Changed in version 3.2.3:* Create $\text{.pyc}$ files with an $\text{import magic tag}$ in their name, in a $\text{__pycache__}$ subdirectory instead of files without tag in the current directory.

*Changed in version 3.5:* Create $\text{.pyc}$ files according to $\text{PEP 488}$.

$\text{distutils.util.rfc822_escape(header)}$

Return a version of $header$ escaped for inclusion in an $\text{RFC 822}$ header, by ensuring there are 8 spaces space after each newline. Note that it does no other modification of the string.
10.12. distutils.dist — The Distribution class

This module provides the Distribution class, which represents the module distribution being built/installed/distributed.
10.13. `distutils.extension` — The Extension class

This module provides the Extension class, used to describe C/C++ extension modules in setup scripts.
10.14. distutils.debug — Distutils debug mode

This module provides the DEBUG flag.
10.15. distutils.errors — Distutils exceptions

Provides exceptions used by the Distutils modules. Note that Distutils modules may raise standard exceptions; in particular, SystemExit is usually raised for errors that are obviously the end-user’s fault (eg. bad command-line arguments).

This module is safe to use in from ... import * mode; it only exports symbols whose names start with Distutils and end with Error.
10.16. **distutils.fancy_getopt** —
Wrapper around the standard getopt module

This module provides a wrapper around the standard `getopt` module that provides the following additional features:

- short and long options are tied together
- options have help strings, so `fancy_getopt()` could potentially create a complete usage summary
- options set attributes of a passed-in object
- boolean options can have “negative aliases” — eg. if `--quiet` is the “negative alias” of `--verbose`, then `--quiet` on the command line sets `verbose` to false.

```
distutils.fancy_getopt.fancy_getopt(options, negative_opt, object, args)
```

Wrapper function. `options` is a list of `(long_option, short_option, help_string)` 3-tuples as described in the constructor for `FancyGetopt`. `negative_opt` should be a dictionary mapping option names to option names, both the key and value should be in the `options` list. `object` is an object which will be used to store values (see the `getopt()` method of the `FancyGetopt` class). `args` is the argument list. Will use `sys.argv[1:]` if you pass `None` as `args`.

```
distutils.fancy_getopt.wrap_text(text, width)
```

Wraps text to less than `width` wide.

```
class
distutils.fancy_getopt.FancyGetopt([option_table=None])
```
The option_table is a list of 3-tuples: (long_option, short_option, help_string)

If an option takes an argument, its long_option should have '=' appended; short_option should just be a single character, no ':' in any case. short_option should be None if a long_option doesn't have a corresponding short_option. All option tuples must have long options.

The FancyGetopt class provides the following methods:

FancyGetopt.getopt([args=None, object=None])
Parse command-line options in args. Store as attributes on object.

If args is None or not supplied, uses sys.argv[1:]. If object is None or not supplied, creates a new OptionDummy instance, stores option values there, and returns a tuple (args, object). If object is supplied, it is modified in place and getopt() just returns args; in both cases, the returned args is a modified copy of the passed-in args list, which is left untouched.

FancyGetopt.get_option_order()
Returns the list of (option, value) tuples processed by the previous run of getopt() Raises RuntimeError if getopt() hasn't been called yet.

FancyGetopt.generate_help([header=None])
Generate help text (a list of strings, one per suggested line of output) from the option table for this FancyGetopt object.

If supplied, prints the supplied header at the top of the help.
10.17. `distutils.filelist` — The FileList class

This module provides the FileList class, used for poking about the filesystem and building lists of files.
10.18. distutils.log — Simple PEP 282-style logging
10.19. `distutils.spawn` — Spawn a sub-process

This module provides the `spawn()` function, a front-end to various platform-specific functions for launching another program in a sub-process. Also provides `find_executable()` to search the path for a given executable name.
10.20. `distutils.sysconfig` — System configuration information

The `distutils.sysconfig` module provides access to Python's low-level configuration information. The specific configuration variables available depend heavily on the platform and configuration. The specific variables depend on the build process for the specific version of Python being run; the variables are those found in the Makefile and configuration header that are installed with Python on Unix systems. The configuration header is called `pyconfig.h` for Python versions starting with 2.2, and `config.h` for earlier versions of Python.

Some additional functions are provided which perform some useful manipulations for other parts of the `distutils` package.

`distutils.sysconfig.PREFIX`

The result of `os.path.normpath(sys.prefix)`.

`distutils.sysconfig.EXEC_PREFIX`

The result of `os.path.normpath(sys.exec_prefix)`.

`distutils.sysconfig.get_config_var(name)`

Return the value of a single variable. This is equivalent to `get_config_vars().get(name)`.

`distutils.sysconfig.get_config_vars(...)`

Return a set of variable definitions. If there are no arguments, this returns a dictionary mapping names of configuration variables to values. If arguments are provided, they should be strings, and the return value will be a sequence giving the associated values. If a
given name does not have a corresponding value, None will be included for that variable.

distutils.sysconfig.get_config_h_filename()
Returns the full path name of the configuration header. For Unix, this will be the header generated by the configure script; for other platforms the header will have been supplied directly by the Python source distribution. The file is a platform-specific text file.

distutils.sysconfig.get_makefile_filename()
Returns the full path name of the Makefile used to build Python. For Unix, this will be a file generated by the configure script; the meaning for other platforms will vary. The file is a platform-specific text file, if it exists. This function is only useful on POSIX platforms.

distutils.sysconfig.get_python_inc([plat_specific, prefix])
Returns the directory for either the general or platform-dependent C include files. If plat_specific is true, the platform-dependent include directory is returned; if false or omitted, the platform-independent directory is returned. If prefix is given, it is used as either the prefix instead of PREFIX, or as the exec-prefix instead of EXEC_PREFIX if plat_specific is true.

distutils.sysconfig.get_python_lib([plat_specific, standard_lib, prefix])
Returns the directory for either the general or platform-dependent library installation. If plat_specific is true, the platform-dependent include directory is returned; if false or omitted, the platform-independent directory is returned. If prefix is given, it is used as either the prefix instead of PREFIX, or as the exec-prefix instead of
**EXEC_PREFIX** if `plat_specific` is true. If `standard_lib` is true, the directory for the standard library is returned rather than the directory for the installation of third-party extensions.

The following function is only intended for use within the `distutils` package.

```python
def customize_compiler(compiler):
    # Do any platform-specific customization of a distutils.ccompiler.CCompiler instance.
```

This function is only needed on Unix at this time, but should be called consistently to support forward-compatibility. It inserts the information that varies across Unix flavors and is stored in Python's Makefile. This information includes the selected compiler, compiler and linker options, and the extension used by the linker for shared objects.

This function is even more special-purpose, and should only be used from Python's own build procedures.

```python
def set_python_build():
    # Inform the distutils.sysconfig module that it is being used as part of the build process for Python. This changes a lot of relative locations for files, allowing them to be located in the build area rather than in an installed Python.
```
10.21. `distutils.text_file` — The TextFile class

This module provides the `TextFile` class, which gives an interface to text files that (optionally) takes care of stripping comments, ignoring blank lines, and joining lines with backslashes.

```python
class distutils.text_file.TextFile([filename=None, file=None, **options])
```

This class provides a file-like object that takes care of all the things you commonly want to do when processing a text file that has some line-by-line syntax: strip comments (as long as `#` is your comment character), skip blank lines, join adjacent lines by escaping the newline (ie. backslash at end of line), strip leading and/or trailing whitespace. All of these are optional and independently controllable.

The class provides a `warn()` method so you can generate warning messages that report physical line number, even if the logical line in question spans multiple physical lines. Also provides `unreadline()` for implementing line-at-a-time lookahead.

`TextFile` instances are create with either `filename`, `file`, or both. `RuntimeError` is raised if both are `None`. `filename` should be a string, and `file` a file object (or something that provides `readline()` and `close()` methods). It is recommended that you supply at least `filename`, so that `TextFile` can include it in warning messages. If `file` is not supplied, `TextFile` creates its own using the `open()` built-in function.
The options are all boolean, and affect the values returned by `readline()`

<table>
<thead>
<tr>
<th>option name</th>
<th>description</th>
<th>default</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>strip_comments</code></td>
<td>strip from ' # ' to end-of-line, as well as any whitespace leading up to the ' # '—unless it is escaped by a backslash</td>
<td>true</td>
</tr>
<tr>
<td><code>lstrip_ws</code></td>
<td>strip leading whitespace from each line before returning it</td>
<td>false</td>
</tr>
<tr>
<td><code>rstrip_ws</code></td>
<td>strip trailing whitespace (including line terminator!) from each line before returning it.</td>
<td>true</td>
</tr>
<tr>
<td><code>skip_blanks</code></td>
<td>skip lines that are empty <em>after</em> stripping comments and whitespace. (If both lstrip_ws and rstrip_ws are false, then some lines may consist of solely whitespace: these will <em>not</em> be skipped, even if skip_blanks is true.)</td>
<td>true</td>
</tr>
<tr>
<td><code>join_lines</code></td>
<td>if a backslash is the last non-newline character on a line after stripping comments and whitespace, join the following line to it to form one logical line; if N consecutive lines end with a backslash, then N+1 physical lines will be joined to form one logical line.</td>
<td>false</td>
</tr>
<tr>
<td><code>collapse_join</code></td>
<td>strip leading whitespace from lines that are joined to their predecessor; only matters if (join_lines and not lstrip_ws)</td>
<td>false</td>
</tr>
</tbody>
</table>
Note that since *rstrip_ws* can strip the trailing newline, the semantics of *readline()* must differ from those of the built-in file object’s *readline()* method! In particular, *readline()* returns *None* for end-of-file: an empty string might just be a blank line (or an all-whitespace line), if *rstrip_ws* is true but *skip_blanks* is not.

**open(filename)**

Open a new file *filename*. This overrides any *file* or *filename* constructor arguments.

**close()**

Close the current file and forget everything we know about it (including the filename and the current line number).

**warn(msg[, line=None])**

Print (to stderr) a warning message tied to the current logical line in the current file. If the current logical line in the file spans multiple physical lines, the warning refers to the whole range, such as "lines 3-5". If *line* is supplied, it overrides the current line number; it may be a list or tuple to indicate a range of physical lines, or an integer for a single physical line.

**readline()**

Read and return a single logical line from the current file (or from an internal buffer if lines have previously been “unread” with *unreadline()*). If the *join_lines* option is true, this may involve reading multiple physical lines concatenated into a single string. Updates the current line number, so calling *warn()* after *readline()* emits a warning about the physical line(s) just read. Returns *None* on end-of-file, since the empty string can occur if *rstrip_ws* is true but *strip_blanks* is not.
**readlines()**

Read and return the list of all logical lines remaining in the current file. This updates the current line number to the last line of the file.

**unreadline(line)**

Push line (a string) onto an internal buffer that will be checked by future **readline()** calls. Handy for implementing a parser with line-at-a-time lookahead. Note that lines that are “unread” with **unreadline()** are not subsequently re-cleansed (whitespace stripped, or whatever) when read with **readline()**. If multiple calls are made to **unreadline()** before a call to **readline()**, the lines will be returned most in most recent first order.
10.22. `distutils.version` — Version number classes
10.23. **distutils.cmd** — Abstract base class for Distutils commands

This module supplies the abstract base class `Command`.

```python
class distutils.cmd.**Command**(dist)
```

Abstract base class for defining command classes, the “worker bees” of the Distutils. A useful analogy for command classes is to think of them as subroutines with local variables called `options`. The options are declared in `initialize_options()` and defined (given their final values) in `finalize_options()`, both of which must be defined by every command class. The distinction between the two is necessary because option values might come from the outside world (command line, config file, ...), and any options dependent on other options must be computed after these outside influences have been processed — hence `finalize_options()`. The body of the subroutine, where it does all its work based on the values of its options, is the `run()` method, which must also be implemented by every command class.

The class constructor takes a single argument `dist`, a `Distribution` instance.
10.24. Creating a new Distutils command

This section outlines the steps to create a new Distutils command.

A new command lives in a module in the `distutils.command` package. There is a sample template in that directory called `command_template`. Copy this file to a new module with the same name as the new command you're implementing. This module should implement a class with the same name as the module (and the command). So, for instance, to create the command `peel_banana` (so that users can run `setup.py peel_banana`), you’d copy `command_template` to `distutils/command/peel_banana.py`, then edit it so that it's implementing the class `peel_banana`, a subclass of `distutils.cmd.Command`.

Subclasses of `Command` must define the following methods.

**Command.** `initialize_options()`

Set default values for all the options that this command supports. Note that these defaults may be overridden by other commands, by the setup script, by config files, or by the command-line. Thus, this is not the place to code dependencies between options; generally, `initialize_options()` implementations are just a bunch of `self.foo = None` assignments.

**Command.** `finalize_options()`

Set final values for all the options that this command supports. This is always called as late as possible, ie. after any option assignments from the command-line or from other commands have been done. Thus, this is the place to code option dependencies: if `foo` depends on `bar`, then it is safe to set `foo` from `bar` as long as 

foo still has the same value it was assigned in initialize_options().

Command.run()
A command's raison d'être: carry out the action it exists to perform, controlled by the options initialized in initialize_options(), customized by other commands, the setup script, the command-line, and config files, and finalized in finalize_options(). All terminal output and filesystem interaction should be done by run().

Command.sub_commands
sub_commands formalizes the notion of a “family” of commands, e.g. install as the parent with sub-commands install_lib, install_headers, etc. The parent of a family of commands defines sub_commands as a class attribute; it’s a list of 2-tuples (command_name, predicate), with command_name a string and predicate a function, a string or None. predicate is a method of the parent command that determines whether the corresponding command is applicable in the current situation. (E.g. install_headers is only applicable if we have any C header files to install.) If predicate is None, that command is always applicable.

sub_commands is usually defined at the end of a class, because predicates can be methods of the class, so they must already have been defined. The canonical example is the install command.
10.25. distutils.command — Individual Distutils commands
10.26. distutils.command.bdist —
Build a binary installer
10.27. 
distutils.command.bdist_packager
— Abstract base class for packagers
10.28. 
distutils.command.bdist_dumb — 
Build a “dumb” installer
10.29. **distutils.command.bdist_msi** — Build a Microsoft Installer binary package

```python
class distutils.command.bdist_msi.bdist_msi

Builds a Windows Installer (.msi) binary package.
```

In most cases, the `bdist_msi` installer is a better choice than the `bdist_wininst` installer, because it provides better support for Win64 platforms, allows administrators to perform non-interactive installations, and allows installation through group policies.
10.30.
*distutils.command.bdist_rpm* —
Build a binary distribution as a Redhat RPM and SRPM
10.31.
distutils.command.bdist_wininst
— Build a Windows installer
10.32. distutils.command.sdist — Build a source distribution
10.33. `distutils.command.build` — Build all files of a package
10.34. distutils.command.build_clib — Build any C libraries in a package
10.35.
```
distutils.command.build_ext —
Build any extensions in a package
```
10.36. `distutils.command.build_py` — Build the .py/.pyc files of a package

class distutils.command.build_py. `build_py`

class distutils.command.build_py. `build_py_2to3`

Alternative implementation of build_py which also runs the 2to3 conversion library on each .py file that is going to be installed. To use this in a setup.py file for a distribution that is designed to run with both Python 2.x and 3.x, add:

```python
try:
    from distutils.command.build_py import build_py
except ImportError:
    from distutils.command.build_py import build_py
```

to your setup.py, and later:

```python
cmdclass = {'build_py': build_py}
```

to the invocation of setup().
10.37. 
\texttt{distutils.command.build_scripts}
— Build the scripts of a package
10.38. distutils.command.clean —
Clean a package build area

This command removes the temporary files created by `build` and its subcommands, like intermediary compiled object files. With the `--all` option, the complete build directory will be removed.

Extension modules built in place will not be cleaned, as they are not in the build directory.
10.39. `distutils.command.config` — Perform package configuration
10.40. `distutils.command.install` — Install a package
10.41. `distutils.command.install_data` — Install data files from a package
10.42. \texttt{distutils.command.install\_header} — Install C/C++ header files from a package
10.43.
distutils.command.install_lib —
Install library files from a package
10.44.

distutils.command.install_script
— Install script files from a package
10.45. **distutils.command.register**  
— Register a module with the Python Package Index

The `register` command registers the package with the Python Package Index. This is described in more detail in [PEP 301](#).
10.46. `distutils.command.check` — Check the meta-data of a package

The `check` command performs some tests on the meta-data of a package. For example, it verifies that all required meta-data are provided as the arguments passed to the `setup()` function.
Installing Python Modules (Legacy version)

Author: Greg Ward

Installing Python Modules
   The up to date module installation documentations

This document describes the Python Distribution Utilities (“Distutils”) from the end-user’s point-of-view, describing how to extend the capabilities of a standard Python installation by building and installing third-party Python modules and extensions.

Note: This guide only covers the basic tools for building and distributing extensions that are provided as part of this version of Python. Third party tools offer easier to use and more secure alternatives. Refer to the quick recommendations section in the Python Packaging User Guide for more information.
Introduction

Although Python’s extensive standard library covers many programming needs, there often comes a time when you need to add some new functionality to your Python installation in the form of third-party modules. This might be necessary to support your own programming, or to support an application that you want to use and that happens to be written in Python.

In the past, there has been little support for adding third-party modules to an existing Python installation. With the introduction of the Python Distribution Utilities (Distutils for short) in Python 2.0, this changed.

This document is aimed primarily at the people who need to install third-party Python modules: end-users and system administrators who just need to get some Python application running, and existing Python programmers who want to add some new goodies to their toolbox. You don’t need to know Python to read this document; there will be some brief forays into using Python’s interactive mode to explore your installation, but that’s it. If you’re looking for information on how to distribute your own Python modules so that others may use them, see the Distributing Python Modules (Legacy version) manual. Debugging the setup script may also be of interest.

Best case: trivial installation

In the best case, someone will have prepared a special version of the module distribution you want to install that is targeted specifically at your platform and is installed just like any other software on your platform. For example, the module developer might make an executable installer available for Windows users, an RPM package for
users of RPM-based Linux systems (Red Hat, SuSE, Mandrake, and many others), a Debian package for users of Debian-based Linux systems, and so forth.

In that case, you would download the installer appropriate to your platform and do the obvious thing with it: run it if it's an executable installer, `rpm --install` if it's an RPM, etc. You don't need to run Python or a setup script, you don't need to compile anything—you might not even need to read any instructions (although it's always a good idea to do so anyway).

Of course, things will not always be that easy. You might be interested in a module distribution that doesn't have an easy-to-use installer for your platform. In that case, you'll have to start with the source distribution released by the module's author/maintainer. Installing from a source distribution is not too hard, as long as the modules are packaged in the standard way. The bulk of this document is about building and installing modules from standard source distributions.

**The new standard: Distutils**

If you download a module source distribution, you can tell pretty quickly if it was packaged and distributed in the standard way, i.e. using the Distutils. First, the distribution's name and version number will be featured prominently in the name of the downloaded archive, e.g. `foo-1.0.tar.gz` or `widget-0.9.7.zip`. Next, the archive will unpack into a similarly-named directory: `foo-1.0` or `widget-0.9.7`. Additionally, the distribution will contain a setup script `setup.py`, and a file named `README.txt` or possibly just `README`, which should explain that building and installing the module distribution is a simple matter of running one command from a terminal:
For Windows, this command should be run from a command prompt window (Start • Accessories):

```python
setup.py install
```

If all these things are true, then you already know how to build and install the modules you’ve just downloaded: Run the command above. Unless you need to install things in a non-standard way or customize the build process, you don’t really need this manual. Or rather, the above command is everything you need to get out of this manual.
Standard Build and Install

As described in section The new standard: Distutils, building and installing a module distribution using the Distutils is usually one simple command to run from a terminal:

```
python setup.py install
```

Platform variations

You should always run the setup command from the distribution root directory, i.e. the top-level subdirectory that the module source distribution unpacks into. For example, if you've just downloaded a module source distribution foo-1.0.tar.gz onto a Unix system, the normal thing to do is:

```
gunzip -c foo-1.0.tar.gz | tar xf -   # unpacks into directory foo-1.0
cd foo-1.0
python setup.py install
```

On Windows, you'd probably download foo-1.0.zip. If you downloaded the archive file to C:\Temp, then it would unpack into C:\Temp\foo-1.0; you can use either an archive manipulator with a graphical user interface (such as WinZip) or a command-line tool (such as unzip or pkunzip) to unpack the archive. Then, open a command prompt window and run:

```
cd c:\Temp\foo-1.0
python setup.py install
```
Splitting the job up

Running `setup.py install` builds and installs all modules in one run. If you prefer to work incrementally—especially useful if you want to customize the build process, or if things are going wrong—you can use the setup script to do one thing at a time. This is particularly helpful when the build and install will be done by different users—for example, you might want to build a module distribution and hand it off to a system administrator for installation (or do it yourself, with super-user privileges).

For example, you can build everything in one step, and then install everything in a second step, by invoking the setup script twice:

```bash
python setup.py build
python setup.py install
```

If you do this, you will notice that running the `install` command first runs the `build` command, which—in this case—quickly notices that it has nothing to do, since everything in the `build` directory is up-to-date.

You may not need this ability to break things down often if all you do is install modules downloaded off the ‘net, but it’s very handy for more advanced tasks. If you get into distributing your own Python modules and extensions, you’ll run lots of individual Distutils commands on their own.

How building works

As implied above, the `build` command is responsible for putting the files to install into a `build directory`. By default, this is `build` under the
distribution root; if you’re excessively concerned with speed, or want to keep the source tree pristine, you can change the build directory with the --build-base option. For example:

```
python setup.py build --build-base=/path/to/pybuild/
```

(Or you could do this permanently with a directive in your system or personal Distutils configuration file; see section Distutils Configuration Files.) Normally, this isn’t necessary.

The default layout for the build tree is as follows:

```
--- build/ --- lib/
or
--- build/ --- lib.<plat>/
    temp.<plat>/
```

where `<plat>` expands to a brief description of the current OS/hardware platform and Python version. The first form, with just a `lib` directory, is used for “pure module distributions”—that is, module distributions that include only pure Python modules. If a module distribution contains any extensions (modules written in C/C++), then the second form, with two `<plat>` directories, is used. In that case, the `temp.plat` directory holds temporary files generated by the compile/link process that don’t actually get installed. In either case, the `lib` (or `lib.plat`) directory contains all Python modules (pure Python and extensions) that will be installed.

In the future, more directories will be added to handle Python scripts, documentation, binary executables, and whatever else is needed to handle the job of installing Python modules and applications.
How installation works

After the **build** command runs (whether you run it explicitly, or the **install** command does it for you), the work of the **install** command is relatively simple: all it has to do is copy everything under `build/lib` (or `build/lib.plat`) to your chosen installation directory.

If you don't choose an installation directory—i.e., if you just run `setup.py install`—then the **install** command installs to the standard location for third-party Python modules. This location varies by platform and by how you built/installed Python itself. On Unix (and Mac OS X, which is also Unix-based), it also depends on whether the module distribution being installed is pure Python or contains extensions (“non-pure”):

<table>
<thead>
<tr>
<th>Platform</th>
<th>Standard installation location</th>
<th>Default value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Unix (pure)</td>
<td><code>prefix/lib/pythonX.Y/site-packages</code></td>
<td><code>/usr/local/lib/packages</code></td>
</tr>
<tr>
<td>Unix (non-pure)</td>
<td><code>exec-prefix/lib/pythonX.Y/site-packages</code></td>
<td><code>/usr/local/lib/packages</code></td>
</tr>
<tr>
<td>Windows</td>
<td><code>prefix\Lib\site-packages</code></td>
<td><code>C:\PythonXY\Lib</code></td>
</tr>
</tbody>
</table>

Notes:

1. Most Linux distributions include Python as a standard part of the system, so `prefix` and `exec-prefix` are usually both `/usr` on Linux. If you build Python yourself on Linux (or any Unix-like system), the default `prefix` and `exec-prefix` are `/usr/local`.

2. The default installation directory on Windows was `C:\Program Files\Python` under Python 1.6a1, 1.5.2, and earlier.
prefix and exec-prefix stand for the directories that Python is installed to, and where it finds its libraries at run-time. They are always the same under Windows, and very often the same under Unix and Mac OS X. You can find out what your Python installation uses for prefix and exec-prefix by running Python in interactive mode and typing a few simple commands. Under Unix, just type python at the shell prompt. Under Windows, choose Start ‣ Programs ‣ Python X.Y ‣ Python (command line). Once the interpreter is started, you type Python code at the prompt. For example, on my Linux system, I type the three Python statements shown below, and get the output as shown, to find out my prefix and exec-prefix:

```python
>>> import sys
>>> sys.prefix
'/usr'
>>> sys.exec_prefix
'/usr'
```

A few other placeholders are used in this document: X.Y stands for the version of Python, for example 3.2; abiflags will be replaced by the value of sys.abiflags or the empty string for platforms which don’t define ABI flags; distname will be replaced by the name of the module distribution being installed. Dots and capitalization are important in the paths; for example, a value that uses python3.2 on UNIX will typically use Python32 on Windows.

If you don’t want to install modules to the standard location, or if you don’t have permission to write there, then you need to read about alternate installations in section Alternate Installation. If you want to customize your installation directories more heavily, see section
Custom Installation on custom installations.
Alternate Installation

Often, it is necessary or desirable to install modules to a location other than the standard location for third-party Python modules. For example, on a Unix system you might not have permission to write to the standard third-party module directory. Or you might wish to try out a module before making it a standard part of your local Python installation. This is especially true when upgrading a distribution already present: you want to make sure your existing base of scripts still works with the new version before actually upgrading.

The Distutils install command is designed to make installing module distributions to an alternate location simple and painless. The basic idea is that you supply a base directory for the installation, and the install command picks a set of directories (called an installation scheme) under this base directory in which to install files. The details differ across platforms, so read whichever of the following sections applies to you.

Note that the various alternate installation schemes are mutually exclusive: you can pass --user, or --home, or --prefix and --exec-prefix, or --install-base and --install-platbase, but you can’t mix from these groups.

Alternate installation: the user scheme

This scheme is designed to be the most convenient solution for users that don’t have write permission to the global site-packages directory or don’t want to install into it. It is enabled with a simple option:

```
python setup.py install --user
```
Files will be installed into subdirectories of `site.USER_BASE` (written as `userbase` hereafter). This scheme installs pure Python modules and extension modules in the same location (also known as `site.USER_SITE`). Here are the values for UNIX, including Mac OS X:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation directory</th>
</tr>
</thead>
<tbody>
<tr>
<td>modules</td>
<td><code>userbase/lib/pythonX.Y/site-packages</code></td>
</tr>
<tr>
<td>scripts</td>
<td><code>userbase/bin</code></td>
</tr>
<tr>
<td>data</td>
<td><code>userbase</code></td>
</tr>
<tr>
<td>C headers</td>
<td><code>userbase/include/pythonX.Yabiflags/distname</code></td>
</tr>
</tbody>
</table>

And here are the values used on Windows:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation directory</th>
</tr>
</thead>
<tbody>
<tr>
<td>modules</td>
<td><code>userbase\PythonXY\site-packages</code></td>
</tr>
<tr>
<td>scripts</td>
<td><code>userbase\PythonXY\Scripts</code></td>
</tr>
<tr>
<td>data</td>
<td><code>userbase</code></td>
</tr>
<tr>
<td>C headers</td>
<td><code>userbase\PythonXY\Include\distname</code></td>
</tr>
</tbody>
</table>

The advantage of using this scheme compared to the other ones described below is that the user site-packages directory is under normal conditions always included in `sys.path` (see `site` for more information), which means that there is no additional step to perform after running the `setup.py` script to finalize the installation.

The `build_ext` command also has a `--user` option to add `userbase/include` to the compiler search path for header files and
userbase/lib to the compiler search path for libraries as well as to the runtime search path for shared C libraries (rpath).

Alternate installation: the home scheme

The idea behind the “home scheme” is that you build and maintain a personal stash of Python modules. This scheme's name is derived from the idea of a “home” directory on Unix, since it's not unusual for a Unix user to make their home directory have a layout similar to /usr/ or /usr/local/. This scheme can be used by anyone, regardless of the operating system they are installing for.

Installing a new module distribution is as simple as

```
python setup.py install --home=<dir>
```

where you can supply any directory you like for the --home option. On Unix, lazy typists can just type a tilde (~); the install command will expand this to your home directory:

```
python setup.py install --home=~
```

To make Python find the distributions installed with this scheme, you may have to modify Python's search path or edit sitecustomize (see site) to call site.addsitedir() or edit sys.path.

The --home option defines the installation base directory. Files are installed to the following directories under the installation base as follows:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation directory</th>
</tr>
</thead>
<tbody>
<tr>
<td>modules</td>
<td>home/lib/python</td>
</tr>
</tbody>
</table>
scripts  |  home/bin  
----|-----------
data   |  home     
C headers  |  home/include/python/distname

(Mentally replace slashes with backslashes if you’re on Windows.)

Alternate installation: Unix (the prefix scheme)

The “prefix scheme” is useful when you wish to use one Python installation to perform the build/install (i.e., to run the setup script), but install modules into the third-party module directory of a different Python installation (or something that looks like a different Python installation). If this sounds a trifle unusual, it is—that’s why the user and home schemes come before. However, there are at least two known cases where the prefix scheme will be useful.

First, consider that many Linux distributions put Python in `/usr`, rather than the more traditional `/usr/local`. This is entirely appropriate, since in those cases Python is part of “the system” rather than a local add-on. However, if you are installing Python modules from source, you probably want them to go in `/usr/local/lib/python2.X` rather than `/usr/lib/python2.X`. This can be done with

```
/usr/bin/python setup.py install --prefix=/usr/local
```

Another possibility is a network filesystem where the name used to write to a remote directory is different from the name used to read it: for example, the Python interpreter accessed as `/usr/local/bin/python` might search for modules in `/usr/local/lib/python2.X`, but those modules would have to be
installed to, say, `/mnt/@server/export/lib/python2.X`. This could be done with

```
/usr/local/bin/python setup.py install --prefix=/mnt
```

In either case, the `--prefix` option defines the installation base, and the `--exec-prefix` option defines the platform-specific installation base, which is used for platform-specific files. (Currently, this just means non-pure module distributions, but could be expanded to C libraries, binary executables, etc.) If `--exec-prefix` is not supplied, it defaults to `--prefix`. Files are installed as follows:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation directory</th>
</tr>
</thead>
<tbody>
<tr>
<td>Python modules</td>
<td><code>prefix/lib/pythonX.Y/site-packages</code></td>
</tr>
<tr>
<td>extension modules</td>
<td><code>exec-prefix/lib/pythonX.Y/site-packages</code></td>
</tr>
<tr>
<td>scripts</td>
<td><code>prefix/bin</code></td>
</tr>
<tr>
<td>data</td>
<td><code>prefix</code></td>
</tr>
<tr>
<td>C headers</td>
<td><code>prefix/include/pythonX.Yabiflags/distname</code></td>
</tr>
</tbody>
</table>

There is no requirement that `--prefix` or `--exec-prefix` actually point to an alternate Python installation; if the directories listed above do not already exist, they are created at installation time.

Incidentally, the real reason the prefix scheme is important is simply that a standard Unix installation uses the prefix scheme, but with `--prefix` and `--exec-prefix` supplied by Python itself as `sys.prefix` and `sys.exec_prefix`. Thus, you might think you'll
never use the prefix scheme, but every time you run `python setup.py install` without any other options, you’re using it.

Note that installing extensions to an alternate Python installation has no effect on how those extensions are built: in particular, the Python header files (`Python.h` and friends) installed with the Python interpreter used to run the setup script will be used in compiling extensions. It is your responsibility to ensure that the interpreter used to run extensions installed in this way is compatible with the interpreter used to build them. The best way to do this is to ensure that the two interpreters are the same version of Python (possibly different builds, or possibly copies of the same build). (Of course, if your `--prefix` and `--exec-prefix` don’t even point to an alternate Python installation, this is immaterial.)

Alternate installation: Windows (the prefix scheme)

Windows has no concept of a user’s home directory, and since the standard Python installation under Windows is simpler than under Unix, the `--prefix` option has traditionally been used to install additional packages in separate locations on Windows.

```bash
python setup.py install --prefix="\Temp\Python"
```

to install modules to the `\Temp\Python` directory on the current drive.

The installation base is defined by the `--prefix` option; the `--exec-prefix` option is not supported under Windows, which means that pure Python modules and extension modules are installed into the
same location. Files are installed as follows:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Installation directory</th>
</tr>
</thead>
<tbody>
<tr>
<td>modules</td>
<td><code>prefix\Lib\site-packages</code></td>
</tr>
<tr>
<td>scripts</td>
<td><code>prefix\Scripts</code></td>
</tr>
<tr>
<td>data</td>
<td><code>prefix</code></td>
</tr>
<tr>
<td>C headers</td>
<td><code>prefix\Include\distname</code></td>
</tr>
</tbody>
</table>
Custom Installation

Sometimes, the alternate installation schemes described in section Alternate Installation just don’t do what you want. You might want to tweak just one or two directories while keeping everything under the same base directory, or you might want to completely redefine the installation scheme. In either case, you’re creating a custom installation scheme.

To create a custom installation scheme, you start with one of the alternate schemes and override some of the installation directories used for the various types of files, using these options:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Override option</th>
</tr>
</thead>
<tbody>
<tr>
<td>Python modules</td>
<td>--install-purelib</td>
</tr>
<tr>
<td>extension modules</td>
<td>--install-platlib</td>
</tr>
<tr>
<td>all modules</td>
<td>--install-lib</td>
</tr>
<tr>
<td>scripts</td>
<td>--install-scripts</td>
</tr>
<tr>
<td>data</td>
<td>--install-data</td>
</tr>
<tr>
<td>C headers</td>
<td>--install-headers</td>
</tr>
</tbody>
</table>

These override options can be relative, absolute, or explicitly defined in terms of one of the installation base directories. (There are two installation base directories, and they are normally the same— they only differ when you use the Unix “prefix scheme” and supply different --prefix and --exec-prefix options; using --install-lib
will override values computed or given for `--install-purelib` and `--install-platlib`, and is recommended for schemes that don’t make a difference between Python and extension modules.)

For example, say you’re installing a module distribution to your home directory under Unix—but you want scripts to go in `~/scripts` rather than `~/bin`. As you might expect, you can override this directory with the `--install-scripts` option; in this case, it makes most sense to supply a relative path, which will be interpreted relative to the installation base directory (your home directory, in this case):

```
python setup.py install --home=~ --install-scripts=scripts
```

Another Unix example: suppose your Python installation was built and installed with a prefix of `/usr/local/python`, so under a standard installation scripts will wind up in `/usr/local/python/bin`. If you want them in `/usr/local/bin` instead, you would supply this absolute directory for the `--install-scripts` option:

```
python setup.py install --install-scripts=/usr/local/bin
```

(This performs an installation using the “prefix scheme,” where the prefix is whatever your Python interpreter was installed with—`/usr/local/python` in this case.)

If you maintain Python on Windows, you might want third-party modules to live in a subdirectory of `prefix`, rather than right in `prefix` itself. This is almost as easy as customizing the script installation directory —you just have to remember that there are two types of modules to worry about, Python and extension modules, which can conveniently be both controlled by one option:
The specified installation directory is relative to `prefix`. Of course, you also have to ensure that this directory is in Python’s module search path, such as by putting a `.pth` file in a site directory (see `site`). See section Modifying Python’s Search Path to find out how to modify Python’s search path.

If you want to define an entire installation scheme, you just have to supply all of the installation directory options. The recommended way to do this is to supply relative paths; for example, if you want to maintain all Python module-related files under `python` in your home directory, and you want a separate directory for each platform that you use your home directory from, you might define the following installation scheme:

```
python setup.py install --home=~ \n  --install-purelib=python/lib \n  --install-platlib=python/lib \n  --install-scripts=python/scripts \n  --install-data=python/data
```

or, equivalently,

```
python setup.py install --home=/python \n  --install-purelib=lib \n  --install-platlib='lib.$PLAT' \n  --install-scripts=scripts \n  --install-data=data
```

`$PLAT` is not (necessarily) an environment variable—it will be expanded by the Distutils as it parses your command line options, just
as it does when parsing your configuration file(s).

Obviously, specifying the entire installation scheme every time you install a new module distribution would be very tedious. Thus, you can put these options into your Distutils config file (see section Distutils Configuration Files):

```
[install]
install-base=$HOME
install-purelib=python/lib
install-platlib=python/lib.$PLAT
install-scripts=python/scripts
install-data=python/data
```

or, equivalently,

```
[install]
install-base=$HOME/python
install-purelib=lib
install-platlib=lib.$PLAT
install-scripts=scripts
install-data=data
```

Note that these two are not equivalent if you supply a different installation base directory when you run the setup script. For example,

```
python setup.py install --install-base=/tmp
```

would install pure modules to `/tmp/python/lib` in the first case, and to `/tmp/lib` in the second case. (For the second case, you probably want to supply an installation base of `/tmp/python`.)

You probably noticed the use of $HOME and $PLAT in the sample configuration file input. These are Distutils configuration variables,
which bear a strong resemblance to environment variables. In fact, you can use environment variables in config files on platforms that have such a notion but the Distutils additionally define a few extra variables that may not be in your environment, such as $PLAT$. (And of course, on systems that don’t have environment variables, such as Mac OS 9, the configuration variables supplied by the Distutils are the only ones you can use.) See section Distutils Configuration Files for details.

Note: When a virtual environment is activated, any options that change the installation path will be ignored from all distutils configuration files to prevent inadvertently installing projects outside of the virtual environment.

Modifying Python’s Search Path

When the Python interpreter executes an import statement, it searches for both Python code and extension modules along a search path. A default value for the path is configured into the Python binary when the interpreter is built. You can determine the path by importing the sys module and printing the value of sys.path.

```bash
$ python
[GCC 2.96 20000731 (Red Hat Linux 7.3 2.96-112)] on linux2
Type "help", "copyright", "credits" or "license" for more information.
>>> import sys
>>> sys.path
```
The null string in `sys.path` represents the current working directory.

The expected convention for locally installed packages is to put them in the `../site-packages/` directory, but you may want to install Python modules into some arbitrary directory. For example, your site may have a convention of keeping all software related to the web server under `/www`. Add-on Python modules might then belong in `/www/python`, and in order to import them, this directory must be added to `sys.path`. There are several different ways to add the directory.

The most convenient way is to add a path configuration file to a directory that's already on Python's path, usually to the `../site-packages/` directory. Path configuration files have an extension of `.pth`, and each line must contain a single path that will be appended to `sys.path`. (Because the new paths are appended to `sys.path`, modules in the added directories will not override standard modules. This means you can't use this mechanism for installing fixed versions of standard modules.)

Paths can be absolute or relative, in which case they're relative to the directory containing the `.pth` file. See the documentation of the `site` module for more information.

A slightly less convenient way is to edit the `site.py` file in Python's standard library, and modify `sys.path`. `site.py` is automatically imported when the Python interpreter is executed, unless the `-S` switch is supplied to suppress this behaviour. So you could simply edit `site.py` and add two lines to it:

```python
import sys
sys.path.append('/www/python/')
```
However, if you reinstall the same major version of Python (perhaps when upgrading from 2.2 to 2.2.2, for example) site.py will be overwritten by the stock version. You’d have to remember that it was modified and save a copy before doing the installation.

There are two environment variables that can modify sys.path. PYTHONHOME sets an alternate value for the prefix of the Python installation. For example, if PYTHONHOME is set to /www/python, the search path will be set to ['', '/www/python/lib/pythonX.Y/','/www/python/lib/pythonX.Y/plat-linux2', ...].

The PYTHONPATH variable can be set to a list of paths that will be added to the beginning of sys.path. For example, if PYTHONPATH is set to /www/python:/opt/py, the search path will begin with ['/www/python','/opt/py']. (Note that directories must exist in order to be added to sys.path; the site module removes paths that don’t exist.)

Finally, sys.path is just a regular Python list, so any Python application can modify it by adding or removing entries.
Distutils Configuration Files

As mentioned above, you can use Distutils configuration files to record personal or site preferences for any Distutils options. That is, any option to any command can be stored in one of two or three (depending on your platform) configuration files, which will be consulted before the command-line is parsed. This means that configuration files will override default values, and the command-line will in turn override configuration files. Furthermore, if multiple configuration files apply, values from “earlier” files are overridden by “later” files.

Location and names of config files

The names and locations of the configuration files vary slightly across platforms. On Unix and Mac OS X, the three configuration files (in the order they are processed) are:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Location and filename</th>
</tr>
</thead>
<tbody>
<tr>
<td>system</td>
<td><code>prefix/lib/pythonver/distutils/distutils.cfg</code></td>
</tr>
<tr>
<td>personal</td>
<td><code>$HOME/.pydistutils.cfg</code></td>
</tr>
<tr>
<td>local</td>
<td><code>setup.cfg</code></td>
</tr>
</tbody>
</table>

And on Windows, the configuration files are:

<table>
<thead>
<tr>
<th>Type of file</th>
<th>Location and filename</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>system</td>
<td><code>prefix\Lib\distutils\distutils.cfg</code></td>
<td>(4)</td>
</tr>
<tr>
<td>personal</td>
<td><code>%HOME%\pydistutils.cfg</code></td>
<td>(5)</td>
</tr>
</tbody>
</table>
On all platforms, the “personal” file can be temporarily disabled by passing the \textit{–no-user-cfg} option.

Notes:

1. Strictly speaking, the system-wide configuration file lives in the directory where the Distutils are installed; under Python 1.6 and later on Unix, this is as shown. For Python 1.5.2, the Distutils will normally be installed to \texttt{prefix/lib/python1.5/site-packages/distutils}, so the system configuration file should be put there under Python 1.5.2.

2. On Unix, if the \texttt{HOME} environment variable is not defined, the user’s home directory will be determined with the \texttt{getpwuid()} function from the standard \texttt{pwd} module. This is done by the \texttt{os.path.expanduser()} function used by Distutils.

3. I.e., in the current directory (usually the location of the setup script).

4. (See also note (1).) Under Python 1.6 and later, Python's default “installation prefix” is \texttt{C:\Python}, so the system configuration file is normally \texttt{C:\Python\Lib\distutils\distutils.cfg}. Under Python 1.5.2, the default prefix was \texttt{C:\Program Files\Python}, and the Distutils were not part of the standard library—so the system configuration file would be \texttt{C:\Program Files\Python\distutils\distutils.cfg} in a standard Python 1.5.2 installation under Windows.

5. On Windows, if the \texttt{HOME} environment variable is not defined, \texttt{USERPROFILE} then \texttt{HOMEDRIVE} and \texttt{HOMEPATH} will be tried. This is done by the \texttt{os.path.expanduser()} function used by Distutils.

\textbf{Syntax of config files}
The Distutils configuration files all have the same syntax. The config files are grouped into sections. There is one section for each Distutils command, plus a `global` section for global options that affect every command. Each section consists of one option per line, specified as `option=value`.

For example, the following is a complete config file that just forces all commands to run quietly by default:

```
[global]
verbose=0
```

If this is installed as the system config file, it will affect all processing of any Python module distribution by any user on the current system. If it is installed as your personal config file (on systems that support them), it will affect only module distributions processed by you. And if it is used as the `setup.cfg` for a particular module distribution, it affects only that distribution.

You could override the default “build base” directory and make the `build*` commands always forcibly rebuild all files with the following:

```
[build]
build-base=blib
force=1
```

which corresponds to the command-line arguments

```
python setup.py build --build-base=blib --force
```

except that including the `build` command on the command-line means that command will be run. Including a particular command in config files has no such implication; it only means that if the command is run,
the options in the config file will apply. (Or if other commands that derive values from it are run, they will use the values in the config file.)

You can find out the complete list of options for any command using the --help option, e.g.:

```
python setup.py build --help
```

and you can find out the complete list of global options by using --help without a command:

```
python setup.py --help
```

See also the “Reference” section of the “Distributing Python Modules” manual.
Building Extensions: Tips and Tricks

Whenever possible, the Distutils try to use the configuration information made available by the Python interpreter used to run the `setup.py` script. For example, the same compiler and linker flags used to compile Python will also be used for compiling extensions. Usually this will work well, but in complicated situations this might be inappropriate. This section discusses how to override the usual Distutils behaviour.

**Tweaking compiler/linker flags**

Compiling a Python extension written in C or C++ will sometimes require specifying custom flags for the compiler and linker in order to use a particular library or produce a special kind of object code. This is especially true if the extension hasn’t been tested on your platform, or if you’re trying to cross-compile Python.

In the most general case, the extension author might have foreseen that compiling the extensions would be complicated, and provided a `Setup` file for you to edit. This will likely only be done if the module distribution contains many separate extension modules, or if they often require elaborate sets of compiler flags in order to work.

A `Setup` file, if present, is parsed in order to get a list of extensions to build. Each line in a `Setup` describes a single module. Lines have the following structure:

```
module ... [sourcefile ...] [cpparg ...] [library ...
```

Let's examine each of the fields in turn.
- **module** is the name of the extension module to be built, and should be a valid Python identifier. You can't just change this in order to rename a module (edits to the source code would also be needed), so this should be left alone.
- **sourcefile** is anything that's likely to be a source code file, at least judging by the filename. Filenames ending in `.c` are assumed to be written in C, filenames ending in `.C`, `.cc`, and `.c++` are assumed to be C++, and filenames ending in `.m` or `.mm` are assumed to be in Objective C.
- **cpparg** is an argument for the C preprocessor, and is anything starting with `-I`, `-D`, `-U` or `-C`.
- **library** is anything ending in `.a` or beginning with `-l` or `-L`.

If a particular platform requires a special library on your platform, you can add it by editing the `Setup` file and running `python setup.py build`. For example, if the module defined by the line

```plaintext
foo foomodule.c
```

must be linked with the math library `libm.a` on your platform, simply add `-lm` to the line:

```plaintext
foo foomodule.c -lm
```

Arbitrary switches intended for the compiler or the linker can be supplied with the `-Xcompiler arg` and `-Xlinker arg` options:

```plaintext
foo foomodule.c -Xcompiler -o32 -Xlinker -shared -lm
```

The next option after `-Xcompiler` and `-Xlinker` will be appended to the proper command line, so in the above example the compiler will be passed the `-o32` option, and the linker will be passed `-shared`. If
a compiler option requires an argument, you’ll have to supply multiple
-Xcompiler options; for example, to pass `-x c++` the Setup file
would have to contain `-Xcompiler -x -Xcompiler c++`.

Compiler flags can also be supplied through setting the CFLAGS
environment variable. If set, the contents of CFLAGS will be added to
the compiler flags specified in the Setup file.

Using non-Microsoft compilers on Windows

Borland/CodeGear C++

This subsection describes the necessary steps to use Distutils with the
Borland C++ compiler version 5.5. First you have to know that
Borland’s object file format (OMF) is different from the format used by
the Python version you can download from the Python or ActiveState
Web site. (Python is built with Microsoft Visual C++, which uses COFF
as the object file format.) For this reason you have to convert Python's
library `python25.lib` into the Borland format. You can do this as
follows:

```
coff2omf python25.lib python25_bcpp.lib
```

The `coff2omf` program comes with the Borland compiler. The file
`python25.lib` is in the `Libs` directory of your Python installation. If
your extension uses other libraries (`zlib, …`) you have to convert them
too.

The converted files have to reside in the same directories as the
normal libraries.

How does Distutils manage to use these libraries with their changed
names? If the extension needs a library (eg. `foo`) Distutils checks first if it finds a library with suffix `_bcpp` (eg. `foo_bcpp.lib`) and then uses this library. In the case it doesn’t find such a special library it uses the default name (`foo.lib`). [1]

To let Distutils compile your extension with Borland C++ you now have to type:

```
python setup.py build --compiler=bcpp
```

If you want to use the Borland C++ compiler as the default, you could specify this in your personal or system-wide configuration file for Distutils (see section Distutils Configuration Files.)

See also:

**C++Builder Compiler**
Information about the free C++ compiler from Borland, including links to the download pages.

**Creating Python Extensions Using Borland’s Free Compiler**
Document describing how to use Borland’s free command-line C++ compiler to build Python.

**GNU C / Cygwin / MinGW**

This section describes the necessary steps to use Distutils with the GNU C/C++ compilers in their Cygwin and MinGW distributions. [2]
For a Python interpreter that was built with Cygwin, everything should work without any of these following steps.

Not all extensions can be built with MinGW or Cygwin, but many can. Extensions most likely to not work are those that use C++ or depend
on Microsoft Visual C extensions.

To let Distutils compile your extension with Cygwin you have to type:

```bash
python setup.py build --compiler=cygwin
```

and for Cygwin in no-cygwin mode [3] or for MinGW type:

```bash
python setup.py build --compiler=mingw32
```

If you want to use any of these options/compilers as default, you should consider writing it in your personal or system-wide configuration file for Distutils (see section Distutils Configuration Files.)

Older Versions of Python and MinGW

The following instructions only apply if you’re using a version of Python inferior to 2.4.1 with a MinGW inferior to 3.0.0 (with binutils-2.13.90-20030111-1).

These compilers require some special libraries. This task is more complex than for Borland’s C++, because there is no program to convert the library. First you have to create a list of symbols which the Python DLL exports. (You can find a good program for this task at https://sourceforge.net/projects/mingw/files/MinGW/Extension/pexports/)

```bash
pexports python25.dll >python25.def
```

The location of an installed `python25.dll` will depend on the installation options and the version and language of Windows. In a “just for me” installation, it will appear in the root of the installation directory. In a shared installation, it will be located in the system directory.
Then you can create from these information an import library for gcc.

```
/cygwin/bin/dlltool --dllname python25.dll --def python25.def --output-lib libpython25.a
```

The resulting library has to be placed in the same directory as `python25.lib`. (Should be the `libs` directory under your Python installation directory.)

If your extension uses other libraries (zlib,...) you might have to convert them too. The converted files have to reside in the same directories as the normal libraries do.

See also:

**Building Python modules on MS Windows platform with MinGW**

Information about building the required libraries for the MinGW environment.

Footnotes

[1] This also means you could replace all existing COFF-libraries with OMF-libraries of the same name.

[3] Then you have no POSIX emulation available, but you also don't need `cygwin1.dll`. 
Distributing Python Modules (Legacy version)

Distributing Python Modules
The up to date module distribution documentations

This document describes the Python Distribution Utilities (“Distutils”) from the module developer’s point of view, describing how to use the Distutils to make Python modules and extensions easily available to a wider audience with very little overhead for build/release/install mechanics.

Note: This guide only covers the basic tools for building and distributing extensions that are provided as part of this version of Python. Third party tools offer easier to use and more secure alternatives. Refer to the quick recommendations section in the Python Packaging User Guide for more information.

10.26. distutils.command.bdist — Build a binary installer
• 10.27. distutils.command.bdist_packager — Abstract base class for packagers
• 10.28. distutils.command.bdist_dumb — Build a “dumb” installer
• 10.29. distutils.command.bdist_msi — Build a Microsoft Installer binary package
• 10.30. distutils.command.bdist_rpm — Build a binary distribution as a Redhat RPM and SRPM
• 10.31. distutils.command.bdist_wininst — Build a Windows installer
• 10.32. distutils.command.sdist — Build a source distribution
• 10.33. distutils.command.build — Build all files of a package
• 10.34. distutils.command.build_clib — Build any C libraries in a package
• 10.35. distutils.command.build_ext — Build any extensions in a package
• 10.36. distutils.command.build_py — Build the .py/.pyc files of a package
• 10.37. distutils.command.build_scripts — Build the scripts of a package
• 10.38. distutils.command.clean — Clean a package build area
• 10.39. distutils.command.config — Perform package configuration
• 10.40. distutils.command.install — Install a package
• 10.41. distutils.command.install_data — Install data files from a package
• 10.42. distutils.command.install_headers — Install C/C++ header files from a package
• 10.43. distutils.command.install_lib — Install library files from a package
- 10.44. distutils.command.install_scripts — Install script files from a package
- 10.45. distutils.command.register — Register a module with the Python Package Index
- 10.46. distutils.command.check — Check the metadata of a package
8. Extending Distutils

Distutils can be extended in various ways. Most extensions take the form of new commands or replacements for existing commands. New commands may be written to support new types of platform-specific packaging, for example, while replacements for existing commands may be made to modify details of how the command operates on a package.

Most extensions of the distutils are made within setup.py scripts that want to modify existing commands; many simply add a few file extensions that should be copied into packages in addition to .py files as a convenience.

Most distutils command implementations are subclasses of the distutils.cmd.Command class. New commands may directly inherit from Command, while replacements often derive from Command indirectly, directly subclassing the command they are replacing. Commands are required to derive from Command.
8.1. Integrating new commands

There are different ways to integrate new command implementations into distutils. The most difficult is to lobby for the inclusion of the new features in distutils itself, and wait for (and require) a version of Python that provides that support. This is really hard for many reasons.

The most common, and possibly the most reasonable for most needs, is to include the new implementations with your setup.py script, and cause the distutils.core.setup() function use them:

```python
from distutils.command.build_py import build_py as _build_py
from distutils.core import setup

class build_py(_build_py):
    """Specialized Python source builder."""

    # implement whatever needs to be different...

setup(cmdclass={'build_py': build_py},
     ...
)
```

This approach is most valuable if the new implementations must be used to use a particular package, as everyone interested in the package will need to have the new command implementation.

Beginning with Python 2.4, a third option is available, intended to allow new commands to be added which can support existing setup.py scripts without requiring modifications to the Python installation. This is expected to allow third-party extensions to provide support for additional packaging systems, but the commands can be used for anything distutils commands can be used for. A new configuration
option, command_packages (command-line option --command-packages), can be used to specify additional packages to be searched for modules implementing commands. Like all distutils options, this can be specified on the command line or in a configuration file. This option can only be set in the [global] section of a configuration file, or before any commands on the command line. If set in a configuration file, it can be overridden from the command line; setting it to an empty string on the command line causes the default to be used. This should never be set in a configuration file provided with a package.

This new option can be used to add any number of packages to the list of packages searched for command implementations; multiple package names should be separated by commas. When not specified, the search is only performed in the distutils.command package. When setup.py is run with the option --command-packages distcmds,buildcmds, however, the packages distutils.command, distcmds, and buildcmds will be searched in that order. New commands are expected to be implemented in modules of the same name as the command by classes sharing the same name. Given the example command line option above, the command bdist_openpkg could be implemented by the class distcmds.bdist_openpkg.bdist_openpkg or buildcmds.bdist_openpkg.bdist_openpkg.
8.2. Adding new distribution types

Commands that create distributions (files in the dist/ directory) need to add (command, filename) pairs to self.distribution.dist_files so that upload can upload it to PyPI. The filename in the pair contains no path information, only the name of the file itself. In dry-run mode, pairs should still be added to represent what would have been created.
4. Creating a Source Distribution

As shown in section A Simple Example, you use the sdist command to create a source distribution. In the simplest case,

```
python setup.py sdist
```

(assuming you haven’t specified any sdist options in the setup script or config file), sdist creates the archive of the default format for the current platform. The default format is a gzip’ed tar file (.tar.gz) on Unix, and ZIP file on Windows.

You can specify as many formats as you like using the --formats option, for example:

```
python setup.py sdist --formats=gztar,zip
```

to create a gzipped tarball and a zip file. The available formats are:

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>zip</td>
<td>zip file (.zip)</td>
<td>(1),(3)</td>
</tr>
<tr>
<td>gztar</td>
<td>gzip’ed tar file (.tar.gz)</td>
<td>(2)</td>
</tr>
<tr>
<td>bztar</td>
<td>bzip2’ed tar file (.tar.bz2)</td>
<td></td>
</tr>
<tr>
<td>xztar</td>
<td>xz’ed tar file (.tar.xz)</td>
<td></td>
</tr>
<tr>
<td>ztar</td>
<td>compressed tar file (.tar.Z)</td>
<td>(4)</td>
</tr>
<tr>
<td>tar</td>
<td>tar file (.tar)</td>
<td></td>
</tr>
</tbody>
</table>

*Changed in version 3.5:* Added support for the xztar format.
Notes:

1. default on Windows
2. default on Unix
3. requires either external **zip** utility or **zipfile** module (part of the standard Python library since Python 1.6)
4. requires the **compress** program. Notice that this format is now pending for deprecation and will be removed in the future versions of Python.

When using any **tar** format (gztar, bztar, xztar, ztar or tar), under Unix you can specify the owner and group names that will be set for each member of the archive.

For example, if you want all files of the archive to be owned by root:

```
python setup.py sdist --owner=root --group=root
```
4.1. Specifying the files to distribute

If you don’t supply an explicit list of files (or instructions on how to generate one), the \texttt{sdist} command puts a minimal default set into the source distribution:

- all Python source files implied by the \texttt{py_modules} and \texttt{packages} options
- all C source files mentioned in the \texttt{ext_modules} or \texttt{libraries} options
- scripts identified by the \texttt{scripts} option See \texttt{Installing Scripts}.
- anything that looks like a test script: \texttt{test/test*.py} (currently, the Distutils don’t do anything with test scripts except include them in source distributions, but in the future there will be a standard for testing Python module distributions)
- \texttt{README.txt} (or \texttt{README}), \texttt{setup.py} (or whatever you called your setup script), and \texttt{setup.cfg}
- all files that matches the \texttt{package_data} metadata. See \texttt{Installing Package Data}.
- all files that matches the \texttt{data_files} metadata. See \texttt{Installing Additional Files}.

Sometimes this is enough, but usually you will want to specify additional files to distribute. The typical way to do this is to write a \texttt{manifest template}, called \texttt{MANIFEST.in} by default. The manifest template is just a list of instructions for how to generate your manifest file, \texttt{MANIFEST}, which is the exact list of files to include in your source distribution. The \texttt{sdist} command processes this template and generates a manifest based on its instructions and what it finds in the filesystem.

If you prefer to roll your own manifest file, the format is simple: one
filename per line, regular files (or symlinks to them) only. If you do supply your own MANIFEST, you must specify everything: the default set of files described above does not apply in this case.

*Changed in version 3.1:* An existing generated MANIFEST will be regenerated without *sdist* comparing its modification time to the one of MANIFEST.in or setup.py.

*Changed in version 3.1.3:* MANIFEST files start with a comment indicating they are generated. Files without this comment are not overwritten or removed.

*Changed in version 3.2.2:* *sdist* will read a MANIFEST file if no MANIFEST.in exists, like it used to do.

The manifest template has one command per line, where each command specifies a set of files to include or exclude from the source distribution. For an example, again we turn to the Distutils' own manifest template:

```
include *.txt
recursive-include examples *.txt *.py
prune examples/sample/?/build
```

The meanings should be fairly clear: include all files in the distribution root matching *.txt, all files anywhere under the examples directory matching *.txt or *.py, and exclude all directories matching examples/sample/?/build. All of this is done after the standard include set, so you can exclude files from the standard set with explicit instructions in the manifest template. (Or, you can use the --no-defaults option to disable the standard set entirely.) There are several other commands available in the manifest template mini-language; see section *Creating a source distribution: the sdist*
command.

The order of commands in the manifest template matters: initially, we have the list of default files as described above, and each command in the template adds to or removes from that list of files. Once we have fully processed the manifest template, we remove files that should not be included in the source distribution:

- all files in the Distutils “build” tree (default build/)
- all files in directories named RCS, CVS, .svn, .hg, .git, .bzr or _darcs

Now we have our complete list of files, which is written to the manifest for future reference, and then used to build the source distribution archive(s).

You can disable the default set of included files with the --no-defaults option, and you can disable the standard exclude set with --no-prune.

Following the Distutils’ own manifest template, let’s trace how the sdist command builds the list of files to include in the Distutils source distribution:

1. include all Python source files in the distutils and distutils/command subdirectories (because packages corresponding to those two directories were mentioned in the packages option in the setup script—see section Writing the Setup Script)
2. include README.txt, setup.py, and setup.cfg (standard files)
3. include test/test*.py (standard files)
4. include *.txt in the distribution root (this will find README.txt a
second time, but such redundancies are weeded out later)
5. include anything matching *.txt or *.py in the sub-tree under examples,
6. exclude all files in the sub-trees starting at directories matching examples/sample*/build—this may exclude files included by the previous two steps, so it's important that the prune command in the manifest template comes after the recursive-include command
7. exclude the entire build tree, and any RCS, CVS, .svn, .hg, .git, .bzr and _darcs directories

Just like in the setup script, file and directory names in the manifest template should always be slash-separated; the Distutils will take care of converting them to the standard representation on your platform. That way, the manifest template is portable across operating systems.
4.2. Manifest-related options

The normal course of operations for the `sdist` command is as follows:

- if the manifest file (`MANIFEST` by default) exists and the first line does not have a comment indicating it is generated from `MANIFEST.in`, then it is used as is, unaltered
- if the manifest file doesn't exist or has been previously automatically generated, read `MANIFEST.in` and create the manifest
- if neither `MANIFEST` nor `MANIFEST.in` exist, create a manifest with just the default file set
- use the list of files now in `MANIFEST` (either just generated or read in) to create the source distribution archive(s)

There are a couple of options that modify this behaviour. First, use the `--no-defaults` and `--no-prune` to disable the standard “include” and “exclude” sets.

Second, you might just want to (re)generate the manifest, but not create a source distribution:

```
python setup.py sdist --manifest-only
```

- `-o` is a shortcut for `--manifest-only`.

9. Command Reference
9.1. Installing modules: the install command family

The install command ensures that the build commands have been run and then runs the subcommands `install_lib`, `install_data` and `install_scripts`.

9.1.1. install_data

This command installs all data files provided with the distribution.

9.1.2. install_scripts

This command installs all (Python) scripts in the distribution.
9.2. Creating a source distribution: the sdist command

The manifest template commands are:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>include pat1 pat2 ...</td>
<td>include all files matching any of the listed patterns</td>
</tr>
<tr>
<td>exclude pat1 pat2 ...</td>
<td>exclude all files matching any of the listed patterns</td>
</tr>
<tr>
<td>recursive-including dir pat1</td>
<td>include all files under dir matching any of the listed patterns</td>
</tr>
<tr>
<td>pat2 ...</td>
<td></td>
</tr>
<tr>
<td>recursive-excluding dir pat1</td>
<td>exclude all files under dir matching any of the listed patterns</td>
</tr>
<tr>
<td>pat2 ...</td>
<td></td>
</tr>
<tr>
<td>global-including pat1 pat2</td>
<td>include all files anywhere in the source tree matching — &amp; any of the</td>
</tr>
<tr>
<td>...</td>
<td>listed patterns</td>
</tr>
<tr>
<td>global-excluding pat1 pat2</td>
<td>exclude all files anywhere in the source tree matching — &amp; any of the</td>
</tr>
<tr>
<td>...</td>
<td>listed patterns</td>
</tr>
<tr>
<td>prune dir</td>
<td>exclude all files under dir</td>
</tr>
<tr>
<td>graft dir</td>
<td>include all files under dir</td>
</tr>
</tbody>
</table>

The patterns here are Unix-style “glob” patterns: * matches any sequence of regular filename characters, ? matches any single regular filename character, and [range] matches any of the characters in range (e.g., a-z, a-zA-Z, a-f0-9_.). The definition of “regular filename character” is platform-specific: on Unix it is anything except slash; on Windows anything except backslash or colon.
3. Writing the Setup Configuration File

Often, it’s not possible to write down everything needed to build a distribution *a priori*: you may need to get some information from the user, or from the user’s system, in order to proceed. As long as that information is fairly simple—a list of directories to search for C header files or libraries, for example—then providing a configuration file, setup.cfg, for users to edit is a cheap and easy way to solicit it. Configuration files also let you provide default values for any command option, which the installer can then override either on the command-line or by editing the config file.

The setup configuration file is a useful middle-ground between the setup script—which, ideally, would be opaque to installers [1]—and the command-line to the setup script, which is outside of your control and entirely up to the installer. In fact, setup.cfg (and any other Distutils configuration files present on the target system) are processed after the contents of the setup script, but before the command-line. This has several useful consequences:

- installers can override some of what you put in setup.py by editing setup.cfg
- you can provide non-standard defaults for options that are not easily set in setup.py
- installers can override anything in setup.cfg using the command-line options to setup.py

The basic syntax of the configuration file is simple:

```
[command]
```
option=value

...  

where *command* is one of the Distutils commands (e.g. build\_py, install), and *option* is one of the options that command supports. Any number of options can be supplied for each command, and any number of command sections can be included in the file. Blank lines are ignored, as are comments, which run from a '#\text{#}' character until the end of the line. Long option values can be split across multiple lines simply by indenting the continuation lines.

You can find out the list of options supported by a particular command with the universal --help option, e.g.

```
> python setup.py --help build_ext
[...]  
Options for 'build\_ext' command:
  --build-lib (-b) directory for compiled extension
  --build-temp (-t) directory for temporary files
  --inplace (-i) ignore build-lib and put compiled source directory alongside your
  --include-dirs (-I) list of directories to search
  --define (-D) C preprocessor macros to define
  --undef (-U) C preprocessor macros to undefine
  --swig-opts list of SWIG command line options
[...]  
```

Note that an option spelled --foo-bar on the command-line is spelled foo\_bar in configuration files.

For example, say you want your extensions to be built “in-place”—that is, you have an extension pkg\_ext, and you want the compiled extension file (ext.so on Unix, say) to be put in the same source
directory as your pure Python modules pkg.mod1 and pkg.mod2. You can always use the --inplace option on the command-line to ensure this:

```
python setup.py build_ext --inplace
```

But this requires that you always specify the build_ext command explicitly, and remember to provide --inplace. An easier way is to “set and forget” this option, by encoding it in `setup.cfg`, the configuration file for this distribution:

```
[build_ext]
inplace=1
```

This will affect all builds of this module distribution, whether or not you explicitly specify build_ext. If you include `setup.cfg` in your source distribution, it will also affect end-user builds—which is probably a bad idea for this option, since always building extensions in-place would break installation of the module distribution. In certain peculiar cases, though, modules are built right in their installation directory, so this is conceivably a useful ability. (Distributing extensions that expect to be built in their installation directory is almost always a bad idea, though.)

Another example: certain commands take a lot of options that don’t change from run to run; for example, `bdist_rpm` needs to know everything required to generate a “spec” file for creating an RPM distribution. Some of this information comes from the setup script, and some is automatically generated by the Distutils (such as the list of files installed). But some of it has to be supplied as options to `bdist_rpm`, which would be very tedious to do on the command-line for every run. Hence, here is a snippet from the Distutils’ own `setup.cfg`:
[bdist_rpm]
release = 1
packager = Greg Ward <gward@python.net>
doc_files = CHANGES.txt
            README.txt
            USAGE.txt
doc/
examples/

Note that the doc_files option is simply a whitespace-separated string split across multiple lines for readability.

See also:

**Syntax of config files** in “Installing Python Modules”

More information on the configuration files is available in the manual for system administrators.

Footnotes

[1] This ideal probably won’t be achieved until auto-configuration is fully supported by the Distutils.
2. Writing the Setup Script

The setup script is the centre of all activity in building, distributing, and installing modules using the Distutils. The main purpose of the setup script is to describe your module distribution to the Distutils, so that the various commands that operate on your modules do the right thing. As we saw in section A Simple Example above, the setup script consists mainly of a call to setup(), and most information supplied to the Distutils by the module developer is supplied as keyword arguments to setup().

Here’s a slightly more involved example, which we'll follow for the next couple of sections: the Distutils' own setup script. (Keep in mind that although the Distutils are included with Python 1.6 and later, they also have an independent existence so that Python 1.5.2 users can use them to install other module distributions. The Distutils’ own setup script, shown here, is used to install the package into Python 1.5.2.)

```python
#!/usr/bin/env python

from distutils.core import setup

setup(name='Distutils',
      version='1.0',
      description='Python Distribution Utilities',
      author='Greg Ward',
      author_email='gward@python.net',
      url='https://www.python.org/sigs/distutils-sig/',
      packages=[
        'distutils',
        'distutils.command'
      ],
)
```

There are only two differences between this and the trivial one-file
distribution presented in section **A Simple Example**: more metadata, and the specification of pure Python modules by package, rather than by module. This is important since the Distutils consist of a couple of dozen modules split into (so far) two packages; an explicit list of every module would be tedious to generate and difficult to maintain. For more information on the additional meta-data, see section **Additional meta-data**.

Note that any pathnames (files or directories) supplied in the setup script should be written using the Unix convention, i.e. slash-separated. The Distutils will take care of converting this platform-neutral representation into whatever is appropriate on your current platform before actually using the pathname. This makes your setup script portable across operating systems, which of course is one of the major goals of the Distutils. In this spirit, all pathnames in this document are slash-separated.

This, of course, only applies to pathnames given to Distutils functions. If you, for example, use standard Python functions such as `glob.glob()` or `os.listdir()` to specify files, you should be careful to write portable code instead of hardcoding path separators:

```python
glob.glob(os.path.join('mydir', 'subdir', '*.html'))
os.listdir(os.path.join('mydir', 'subdir'))
```
2.1. Listing whole packages

The packages option tells the Distutils to process (build, distribute, install, etc.) all pure Python modules found in each package mentioned in the packages list. In order to do this, of course, there has to be a correspondence between package names and directories in the filesystem. The default correspondence is the most obvious one, i.e. package distutils is found in the directory distutils relative to the distribution root. Thus, when you say packages = ['foo'] in your setup script, you are promising that the Distutils will find a file foo/__init__.py (which might be spelled differently on your system, but you get the idea) relative to the directory where your setup script lives. If you break this promise, the Distutils will issue a warning but still process the broken package anyway.

If you use a different convention to lay out your source directory, that’s no problem: you just have to supply the package_dir option to tell the Distutils about your convention. For example, say you keep all Python source under lib, so that modules in the “root package” (i.e., not in any package at all) are in lib, modules in the foo package are in lib/foo, and so forth. Then you would put

```
package_dir = {'': 'lib'}
```

in your setup script. The keys to this dictionary are package names, and an empty package name stands for the root package. The values are directory names relative to your distribution root. In this case, when you say packages = ['foo'], you are promising that the file lib/foo/__init__.py exists.

Another possible convention is to put the foo package right in lib,
the foo.bar package in lib/bar, etc. This would be written in the setup script as

```python
package_dir = {'foo': 'lib'}
```

A package: dir entry in the package_dir dictionary implicitly applies to all packages below package, so the foo.bar case is automatically handled here. In this example, having `packages = ['foo', 'foo.bar']` tells the Distutils to look for `lib/__init__.py` and `lib/bar/__init__.py`. (Keep in mind that although package_dir applies recursively, you must explicitly list all packages in packages: the Distutils will not recursively scan your source tree looking for any directory with a __init__.py file.)
2.2. Listing individual modules

For a small module distribution, you might prefer to list all modules rather than listing packages—especially the case of a single module that goes in the “root package” (i.e., no package at all). This simplest case was shown in section A Simple Example; here is a slightly more involved example:

```
py_modules = ['mod1', 'pkg.mod2']
```

This describes two modules, one of them in the “root” package, the other in the pkg package. Again, the default package/directory layout implies that these two modules can be found in `mod1.py` and `pkg/mod2.py`, and that `pkg/__init__.py` exists as well. And again, you can override the package/directory correspondence using the `package_dir` option.
2.3. Describing extension modules

Just as writing Python extension modules is a bit more complicated than writing pure Python modules, describing them to the Distutils is a bit more complicated. Unlike pure modules, it's not enough just to list modules or packages and expect the Distutils to go out and find the right files; you have to specify the extension name, source file(s), and any compile/link requirements (include directories, libraries to link with, etc.).

All of this is done through another keyword argument to setup(), the `ext_modules` option. `ext_modules` is just a list of `Extension` instances, each of which describes a single extension module. Suppose your distribution includes a single extension, called `foo` and implemented by `foo.c`. If no additional instructions to the compiler/linker are needed, describing this extension is quite simple:

```python
Extension('foo', ['foo.c'])
```

The `Extension` class can be imported from `distutils.core` along with `setup()`. Thus, the setup script for a module distribution that contains only this one extension and nothing else might be:

```python
from distutils.core import setup, Extension
setup(name='foo',
      version='1.0',
      ext_modules=[Extension('foo', ['foo.c'])],
)
```

The `Extension` class (actually, the underlying extension-building machinery implemented by the `build_ext` command) supports a great deal of flexibility in describing Python extensions, which is explained in
the following sections.

2.3.1. Extension names and packages

The first argument to the Extension constructor is always the name of the extension, including any package names. For example,

```python
Extension('foo', ['src/foo1.c', 'src/foo2.c'])
```

describes an extension that lives in the root package, while

```python
Extension('pkg.foo', ['src/foo1.c', 'src/foo2.c'])
```

describes the same extension in the pkg package. The source files and resulting object code are identical in both cases; the only difference is where in the filesystem (and therefore where in Python’s namespace hierarchy) the resulting extension lives.

If you have a number of extensions all in the same package (or all under the same base package), use the `ext_package` keyword argument to `setup()`. For example,

```python
setup(...,
    ext_package='pkg',
    ext_modules=[Extension('foo', ['foo.c']),
                 Extension('subpkg.bar', ['bar.c'])
               ]
)
```

will compile `foo.c` to the extension pkg.foo, and `bar.c` to `pkg.subpkg.bar`.

2.3.2. Extension source files
The second argument to the `Extension` constructor is a list of source files. Since the Distutils currently only support C, C++, and Objective-C extensions, these are normally C/C++/Objective-C source files. (Be sure to use appropriate extensions to distinguish C++ source files: `.cc` and `.cpp` seem to be recognized by both Unix and Windows compilers.)

However, you can also include SWIG interface (.i) files in the list; the `build_ext` command knows how to deal with SWIG extensions: it will run SWIG on the interface file and compile the resulting C/C++ file into your extension.

This warning notwithstanding, options to SWIG can be currently passed like this:

```python
setup(...,
    ext_modules=[Extension('_foo', ['foo.i'],
                           swig_opts=['-modern', ',
                           py_modules=['foo'],
    )
```

Or on the commandline like this:

```
> python setup.py build_ext --swig-opts=-modern -I.
```

On some platforms, you can include non-source files that are processed by the compiler and included in your extension. Currently, this just means Windows message text (.mc) files and resource definition (.rc) files for Visual C++. These will be compiled to binary resource (.res) files and linked into the executable.

### 2.3.3. Preprocessor options
Three optional arguments to `Extension` will help if you need to specify include directories to search or preprocessor macros to define/undefine: `include_dirs`, `define_macros`, and `undef_macros`.

For example, if your extension requires header files in the `include` directory under your distribution root, use the `include_dirs` option:

```python
Extension('foo', ['foo.c'], include_dirs=['include'])
```

You can specify absolute directories there; if you know that your extension will only be built on Unix systems with X11R6 installed to `/usr`, you can get away with

```python
Extension('foo', ['foo.c'], include_dirs=['/usr/include'])
```

You should avoid this sort of non-portable usage if you plan to distribute your code: it’s probably better to write C code like

```c
#include <X11/Xlib.h>
```

If you need to include header files from some other Python extension, you can take advantage of the fact that header files are installed in a consistent way by the Distutils `install_headers` command. For example, the Numerical Python header files are installed (on a standard Unix installation) to `/usr/local/include/python1.5/Numerical`. (The exact location will differ according to your platform and Python installation.) Since the Python include directory — `/usr/local/include/python1.5` in this case—is always
included in the search path when building Python extensions, the best approach is to write C code like

```c
#include <Numerical/arrayobject.h>
```

If you must put the `Numerical` include directory right into your header search path, though, you can find that directory using the Distutils `distutils.sysconfig` module:

```python
from distutils.sysconfig import get_python_inc
incdir = os.path.join(get_python_inc(plat_specific=1),
setup(...,
    Extension(..., include_dirs=[incdir]),
)
```

Even though this is quite portable—it will work on any Python installation, regardless of platform—it’s probably easier to just write your C code in the sensible way.

You can define and undefine pre-processor macros with the `define_macros` and `undef_macros` options. `define_macros` takes a list of (name, value) tuples, where name is the name of the macro to define (a string) and value is its value: either a string or None. (Defining a macro FOO to None is the equivalent of a bare `#define FOO` in your C source: with most compilers, this sets FOO to the string 1.) `undef_macros` is just a list of macros to undefine.

For example:

```python
Extension(...,
    define_macros=[('NDEBUG', '1'),
                  ('HAVE_STRFTIME', None)],
    undef_macros=[ 'HAVE_FOO', 'HAVE_BAR' ])
```
is the equivalent of having this at the top of every C source file:

```c
#define NDEBUG 1
#define HAVE_STRFTIME
#undef HAVE_FOO
#undef HAVE_BAR
```

### 2.3.4. Library options

You can also specify the libraries to link against when building your extension, and the directories to search for those libraries. The `libraries` option is a list of libraries to link against, `library_dirs` is a list of directories to search for libraries at link-time, and `runtime_library_dirs` is a list of directories to search for shared (dynamically loaded) libraries at run-time.

For example, if you need to link against libraries known to be in the standard library search path on target systems

```python
Extension(...,
    libraries=['gdbm', 'readline'])
```

If you need to link with libraries in a non-standard location, you'll have to include the location in `library_dirs`:

```python
Extension(...,
    library_dirs=['/usr/X11R6/lib'],
    libraries=['X11', 'Xt'])
```

(Again, this sort of non-portable construct should be avoided if you intend to distribute your code.)

### 2.3.5. Other options
There are still some other options which can be used to handle special cases.

The `optional` option is a boolean; if it is true, a build failure in the extension will not abort the build process, but instead simply not install the failing extension.

The `extra_objects` option is a list of object files to be passed to the linker. These files must not have extensions, as the default extension for the compiler is used.

`extra_compile_args` and `extra_link_args` can be used to specify additional command line options for the respective compiler and linker command lines.

`export_symbols` is only useful on Windows. It can contain a list of symbols (functions or variables) to be exported. This option is not needed when building compiled extensions: Distutils will automatically add `initmodule` to the list of exported symbols.

The `depends` option is a list of files that the extension depends on (for example header files). The build command will call the compiler on the sources to rebuild extension if any on this files has been modified since the previous build.
2.4. Relationships between Distributions and Packages

A distribution may relate to packages in three specific ways:

1. It can require packages or modules.
2. It can provide packages or modules.
3. It can obsolete packages or modules.

These relationships can be specified using keyword arguments to the `distutils.core.setup()` function.

Dependencies on other Python modules and packages can be specified by supplying the `requires` keyword argument to `setup()`. The value must be a list of strings. Each string specifies a package that is required, and optionally what versions are sufficient.

To specify that any version of a module or package is required, the string should consist entirely of the module or package name. Examples include 'mymodule' and 'xml.parsers.expat'.

If specific versions are required, a sequence of qualifiers can be supplied in parentheses. Each qualifier may consist of a comparison operator and a version number. The accepted comparison operators are:

```
<  >  ==
<=  >=  !=
```

These can be combined by using multiple qualifiers separated by commas (and optional whitespace). In this case, all of the qualifiers must be matched; a logical AND is used to combine the evaluations.
Let's look at a bunch of examples:

<table>
<thead>
<tr>
<th>Requires Expression</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>==1.0</td>
<td>Only version 1.0 is compatible</td>
</tr>
<tr>
<td>&gt;1.0, !=1.5.1, &lt;2.0</td>
<td>Any version after 1.0 and before 2.0 is compatible, except 1.5.1</td>
</tr>
</tbody>
</table>

Now that we can specify dependencies, we also need to be able to specify what we provide that other distributions can require. This is done using the `provides` keyword argument to `setup()`. The value for this keyword is a list of strings, each of which names a Python module or package, and optionally identifies the version. If the version is not specified, it is assumed to match that of the distribution.

Some examples:

<table>
<thead>
<tr>
<th>Provides Expression</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>mypkg</td>
<td>Provide mypkg, using the distribution version</td>
</tr>
<tr>
<td>mypkg (1.1)</td>
<td>Provide mypkg version 1.1, regardless of the distribution version</td>
</tr>
</tbody>
</table>

A package can declare that it obsoletes other packages using the `obsoletes` keyword argument. The value for this is similar to that of the `requires` keyword: a list of strings giving module or package specifiers. Each specifier consists of a module or package name optionally followed by one or more version qualifiers. Version qualifiers are given in parentheses after the module or package name.

The versions identified by the qualifiers are those that are obsoleted by the distribution being described. If no qualifiers are given, all
versions of the named module or package are understood to be obsoleted.
2.5. Installing Scripts

So far we have been dealing with pure and non-pure Python modules, which are usually not run by themselves but imported by scripts.

Scripts are files containing Python source code, intended to be started from the command line. Scripts don’t require Distutils to do anything very complicated. The only clever feature is that if the first line of the script starts with `#!` and contains the word “python”, the Distutils will adjust the first line to refer to the current interpreter location. By default, it is replaced with the current interpreter location. The `-- executable (or -e)` option will allow the interpreter path to be explicitly overridden.

The `scripts` option simply is a list of files to be handled in this way. From the PyXML setup script:

```python
setup(...,
   scripts=['scripts/xmlproc_parse', 'scripts/xml']
)
```

*Changed in version 3.1:* All the scripts will also be added to the MANIFEST file if no template is provided. See [Specifying the files to distribute.](#)
2.6. Installing Package Data

Often, additional files need to be installed into a package. These files are often data that’s closely related to the package’s implementation, or text files containing documentation that might be of interest to programmers using the package. These files are called *package data*.

Package data can be added to packages using the `package_data` keyword argument to the `setup()` function. The value must be a mapping from package name to a list of relative path names that should be copied into the package. The paths are interpreted as relative to the directory containing the package (information from the `package_dir` mapping is used if appropriate); that is, the files are expected to be part of the package in the source directories. They may contain glob patterns as well.

The path names may contain directory portions; any necessary directories will be created in the installation.

For example, if a package should contain a subdirectory with several data files, the files can be arranged like this in the source tree:

```
setup.py
src/
  mypkg/
    __init__.py
    module.py
    data/
      tables.dat
      spoons.dat
      forks.dat
```

The corresponding call to `setup()` might be:
Changed in version 3.1: All the files that match `package_data` will be added to the `MANIFEST` file if no template is provided. See `Specifying the files to distribute`.
2.7. Installing Additional Files

The `data_files` option can be used to specify additional files needed by the module distribution: configuration files, message catalogs, data files, anything which doesn’t fit in the previous categories.

`data_files` specifies a sequence of (directory, files) pairs in the following way:

```python
def setup(...,
    data_files=[('bitmaps', ['bm/b1.gif', 'bm/b2.gif']),
                ('config', ['cfg/data.cfg']),
                ('/etc/init.d', ['init-script'])])
```

Note that you can specify the directory names where the data files will be installed, but you cannot rename the data files themselves.

Each (directory, files) pair in the sequence specifies the installation directory and the files to install there. If directory is a relative path, it is interpreted relative to the installation prefix (Python’s `sys.prefix` for pure-Python packages, `sys.exec_prefix` for packages that contain extension modules). Each file name in files is interpreted relative to the `setup.py` script at the top of the package source distribution. No directory information from files is used to determine the final location of the installed file; only the name of the file is used.

You can specify the `data_files` options as a simple sequence of files without specifying a target directory, but this is not recommended, and the `install` command will print a warning in this case. To install data files directly in the target directory, an empty string should be
given as the directory.

*Changed in version 3.1:* All the files that match `data_files` will be added to the `MANIFEST` file if no template is provided. See *[Specifying the files to distribute]*.
2.8. Additional meta-data

The setup script may include additional meta-data beyond the name and version. This information includes:

<table>
<thead>
<tr>
<th>Meta-Data</th>
<th>Description</th>
<th>Value</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>name</td>
<td>name of the package</td>
<td>short string</td>
<td>(1)</td>
</tr>
<tr>
<td>version</td>
<td>version of this release</td>
<td>short string</td>
<td>(1)(2)</td>
</tr>
<tr>
<td>author</td>
<td>package author's name</td>
<td>short string</td>
<td>(3)</td>
</tr>
<tr>
<td>author_email</td>
<td>email address of the package author</td>
<td>email address</td>
<td>(3)</td>
</tr>
<tr>
<td>maintainer</td>
<td>package maintainer’s name</td>
<td>short string</td>
<td>(3)</td>
</tr>
<tr>
<td>maintainer_email</td>
<td>email address of the package maintainer</td>
<td>email address</td>
<td>(3)</td>
</tr>
<tr>
<td>url</td>
<td>home page for the package</td>
<td>URL</td>
<td>(1)</td>
</tr>
<tr>
<td>description</td>
<td>short, summary description of the package</td>
<td>short string</td>
<td></td>
</tr>
<tr>
<td>long_description</td>
<td>longer description of the package</td>
<td>long string</td>
<td>(5)</td>
</tr>
<tr>
<td>download_url</td>
<td>location where the package may be downloaded</td>
<td>URL</td>
<td>(4)</td>
</tr>
<tr>
<td>classifiers</td>
<td>a list of classifiers</td>
<td>list of strings</td>
<td>(4)</td>
</tr>
<tr>
<td>platforms</td>
<td>a list of platforms</td>
<td>list of strings</td>
<td></td>
</tr>
<tr>
<td>---</td>
<td>---</td>
<td>---</td>
<td></td>
</tr>
<tr>
<td>license</td>
<td>license for the package</td>
<td>short string</td>
<td></td>
</tr>
</tbody>
</table>

Notes:

1. These fields are required.
2. It is recommended that versions take the form `major.minor[.patch[.sub]]`.
3. Either the author or the maintainer must be identified. If maintainer is provided, distutils lists it as the author in `PKG-INFO`.
4. These fields should not be used if your package is to be compatible with Python versions prior to 2.2.3 or 2.3. The list is available from the [PyPI website](https://pypi.org/).
5. The `long_description` field is used by PyPI when you are registering a package, to build its home page.
6. The `license` field is a text indicating the license covering the package where the license is not a selection from the “License” Trove classifiers. See the `Classifier` field. Notice that there’s a `licence` distribution option which is deprecated but still acts as an alias for `license`.

‘short string’
A single line of text, not more than 200 characters.

‘long string’
Multiple lines of plain text in reStructuredText format (see [http://docutils.sourceforge.net/](http://docutils.sourceforge.net/)).

‘list of strings’
See below.

Encoding the version information is an art in itself. Python packages generally adhere to the version format `major.minor[.patch][sub]`. The
major number is 0 for initial, experimental releases of software. It is incremented for releases that represent major milestones in a package. The minor number is incremented when important new features are added to the package. The patch number increments when bug-fix releases are made. Additional trailing version information is sometimes used to indicate sub-releases. These are “a1,a2,…,aN” (for alpha releases, where functionality and API may change), “b1,b2,…,bN” (for beta releases, which only fix bugs) and “pr1,pr2,…,prN” (for final pre-release release testing). Some examples:

0.1.0
the first, experimental release of a package
1.0.1a2
the second alpha release of the first patch version of 1.0

classifiers are specified in a Python list:

```python
setup(...,
    classifiers=[
        'Development Status :: 4 - Beta',
        'Environment :: Console',
        'Environment :: Web Environment',
        'Intended Audience :: End Users/Desktop',
        'Intended Audience :: Developers',
        'Intended Audience :: System Administrators',
        'License :: OSI Approved :: Python Software Foundation License',
        'Operating System :: MacOS :: MacOS X',
        'Operating System :: Microsoft :: Windows',
        'Operating System :: POSIX',
        'Programming Language :: Python',
        'Topic :: Communications :: Email',
        'Topic :: Office/Business',
        'Topic :: Software Development :: Bug Tracking',
    ],
)
```
2.9. Debugging the setup script

Sometimes things go wrong, and the setup script doesn’t do what the developer wants.

Distutils catches any exceptions when running the setup script, and print a simple error message before the script is terminated. The motivation for this behaviour is to not confuse administrators who don’t know much about Python and are trying to install a package. If they get a big long traceback from deep inside the guts of Distutils, they may think the package or the Python installation is broken because they don’t read all the way down to the bottom and see that it’s a permission problem.

On the other hand, this doesn’t help the developer to find the cause of the failure. For this purpose, the DISTUTILS_DEBUG environment variable can be set to anything except an empty string, and distutils will now print detailed information about what it is doing, dump the full traceback when an exception occurs, and print the whole command line when an external program (like a C compiler) fails.
1. An Introduction to Distutils

This document covers using the Distutils to distribute your Python modules, concentrating on the role of developer/distributor: if you're looking for information on installing Python modules, you should refer to the Installing Python Modules (Legacy version) chapter.
1.1. Concepts & Terminology

Using the Distutils is quite simple, both for module developers and for users/administrators installing third-party modules. As a developer, your responsibilities (apart from writing solid, well-documented and well-tested code, of course!) are:

- write a setup script (setup.py by convention)
- (optional) write a setup configuration file
- create a source distribution
- (optional) create one or more built (binary) distributions

Each of these tasks is covered in this document.

Not all module developers have access to a multitude of platforms, so it’s not always feasible to expect them to create a multitude of built distributions. It is hoped that a class of intermediaries, called packagers, will arise to address this need. Packagers will take source distributions released by module developers, build them on one or more platforms, and release the resulting built distributions. Thus, users on the most popular platforms will be able to install most popular Python module distributions in the most natural way for their platform, without having to run a single setup script or compile a line of code.
1.2. A Simple Example

The setup script is usually quite simple, although since it's written in Python, there are no arbitrary limits to what you can do with it, though you should be careful about putting arbitrarily expensive operations in your setup script. Unlike, say, Autoconf-style configure scripts, the setup script may be run multiple times in the course of building and installing your module distribution.

If all you want to do is distribute a module called foo, contained in a file `foo.py`, then your setup script can be as simple as this:

```python
from distutils.core import setup
setup(name='foo',
      version='1.0',
      py_modules=['foo'],
)
```

Some observations:

- most information that you supply to the Distutils is supplied as keyword arguments to the `setup()` function
- those keyword arguments fall into two categories: package metadata (name, version number) and information about what's in the package (a list of pure Python modules, in this case)
- modules are specified by module name, not filename (the same will hold true for packages and extensions)
- it's recommended that you supply a little more metadata, in particular your name, email address and a URL for the project (see section Writing the Setup Script for an example)

To create a source distribution for this module, you would create a setup script, `setup.py`, containing the above code, and run this
command from a terminal:

```bash
python setup.py sdist
```

For Windows, open a command prompt window (Start » Accessories) and change the command to:

```bash
setup.py sdist
```

`sdist` will create an archive file (e.g., tarball on Unix, ZIP file on Windows) containing your setup script `setup.py`, and your module `foo.py`. The archive file will be named `foo-1.0.tar.gz` (or `.zip`), and will unpack into a directory `foo-1.0`.

If an end-user wishes to install your `foo` module, all she has to do is download `foo-1.0.tar.gz` (or `.zip`), unpack it, and—from the `foo-1.0` directory—run

```bash
python setup.py install
```

which will ultimately copy `foo.py` to the appropriate directory for third-party modules in their Python installation.

This simple example demonstrates some fundamental concepts of the Distutils. First, both developers and installers have the same basic user interface, i.e. the setup script. The difference is which Distutils commands they use: the `sdist` command is almost exclusively for module developers, while `install` is more often for installers (although most developers will want to install their own code occasionally).

If you want to make things really easy for your users, you can create one or more built distributions for them. For instance, if you are running on a Windows machine, and want to make things easy for
other Windows users, you can create an executable installer (the most appropriate type of built distribution for this platform) with the `bdist_wininst` command. For example:

```
python setup.py bdist_wininst
```

will create an executable installer, `foo-1.0.win32.exe`, in the current directory.

Other useful built distribution formats are RPM, implemented by the `bdist_rpm` command, Solaris `pkgtool` (`bdist_pkgtool`), and HP-UX `swinstall` (`bdist_sdux`). For example, the following command will create an RPM file called `foo-1.0.noarch.rpm`:

```
python setup.py bdist_rpm
```

(The `bdist_rpm` command uses the `rpm` executable, therefore this has to be run on an RPM-based system such as Red Hat Linux, SuSE Linux, or Mandrake Linux.)

You can find out what distribution formats are available at any time by running

```
python setup.py bdist --help-formats
```
1.3. General Python terminology

If you’re reading this document, you probably have a good idea of what modules, extensions, and so forth are. Nevertheless, just to be sure that everyone is operating from a common starting point, we offer the following glossary of common Python terms:

module
the basic unit of code reusability in Python: a block of code imported by some other code. Three types of modules concern us here: pure Python modules, extension modules, and packages.

pure Python module
a module written in Python and contained in a single .py file (and possibly associated .pyc files). Sometimes referred to as a “pure module.”

extension module
a module written in the low-level language of the Python implementation: C/C++ for Python, Java for Jython. Typically contained in a single dynamically loadable pre-compiled file, e.g. a shared object (.so) file for Python extensions on Unix, a DLL (given the .pyd extension) for Python extensions on Windows, or a Java class file for Jython extensions. (Note that currently, the Distutils only handles C/C++ extensions for Python.)

package
a module that contains other modules; typically contained in a directory in the filesystem and distinguished from other directories by the presence of a file __init__.py.

root package
the root of the hierarchy of packages. (This isn’t really a package, since it doesn’t have an __init__.py file. But we have to call it something.) The vast majority of the standard library is in the root
package, as are many small, standalone third-party modules that don't belong to a larger module collection. Unlike regular packages, modules in the root package can be found in many directories: in fact, every directory listed in sys.path contributes modules to the root package.
1.4. Distutils-specific terminology

The following terms apply more specifically to the domain of distributing Python modules using the Distutils:

module distribution
a collection of Python modules distributed together as a single downloadable resource and meant to be installed *en masse*. Examples of some well-known module distributions are NumPy, SciPy, PIL (the Python Imaging Library), or mxBase. (This would be called a package, except that term is already taken in the Python context: a single module distribution may contain zero, one, or many Python packages.)

pure module distribution
a module distribution that contains only pure Python modules and packages. Sometimes referred to as a “pure distribution.”

non-pure module distribution
a module distribution that contains at least one extension module. Sometimes referred to as a “non-pure distribution.”

distribution root
the top-level directory of your source tree (or source distribution); the directory where setup.py exists. Generally setup.py will be run from this directory.
5. Creating Built Distributions

A “built distribution” is what you’re probably used to thinking of either as a “binary package” or an “installer” (depending on your background). It’s not necessarily binary, though, because it might contain only Python source code and/or byte-code; and we don’t call it a package, because that word is already spoken for in Python. (And “installer” is a term specific to the world of mainstream desktop systems.)

A built distribution is how you make life as easy as possible for installers of your module distribution: for users of RPM-based Linux systems, it’s a binary RPM; for Windows users, it’s an executable installer; for Debian-based Linux users, it’s a Debian package; and so forth. Obviously, no one person will be able to create built distributions for every platform under the sun, so the Distutils are designed to enable module developers to concentrate on their specialty—writing code and creating source distributions—while an intermediary species called packagers springs up to turn source distributions into built distributions for as many platforms as there are packagers.

Of course, the module developer could be his own packager; or the packager could be a volunteer “out there” somewhere who has access to a platform which the original developer does not; or it could be software periodically grabbing new source distributions and turning them into built distributions for as many platforms as the software has access to. Regardless of who they are, a packager uses the setup script and the `bdist` command family to generate built distributions.

As a simple example, if I run the following command in the Distutils source tree:
then the Distutils builds my module distribution (the Distutils itself in this case), does a “fake” installation (also in the build directory), and creates the default type of built distribution for my platform. The default format for built distributions is a “dumb” tar file on Unix, and a simple executable installer on Windows. (That tar file is considered “dumb” because it has to be unpacked in a specific location to work.)

Thus, the above command on a Unix system creates Distutils-1.0.plat.tar.gz; unpacking this tarball from the right place installs the Distutils just as though you had downloaded the source distribution and run python setup.py install. (The “right place” is either the root of the filesystem or Python's prefix directory, depending on the options given to the bdist_dumb command; the default is to make dumb distributions relative to prefix.)

Obviously, for pure Python distributions, this isn’t any simpler than just running python setup.py install—but for non-pure distributions, which include extensions that would need to be compiled, it can mean the difference between someone being able to use your extensions or not. And creating “smart” built distributions, such as an RPM package or an executable installer for Windows, is far more convenient for users even if your distribution doesn’t include any extensions.

The bdist command has a --formats option, similar to the sdist command, which you can use to select the types of built distribution to generate: for example,

python setup.py bdist --format=zip
would, when run on a Unix system, create Distutils-1.0.plat.zip—again, this archive would be unpacked from the root directory to install the Distutils.

The available formats for built distributions are:

<table>
<thead>
<tr>
<th>Format</th>
<th>Description</th>
<th>Notes</th>
</tr>
</thead>
<tbody>
<tr>
<td>gztar</td>
<td>gzipped tar file (.tar.gz)</td>
<td>(1)</td>
</tr>
<tr>
<td>bztar</td>
<td>bzipped tar file (.tar.bz2)</td>
<td></td>
</tr>
<tr>
<td>xztar</td>
<td>xzipped tar file (.tar.xz)</td>
<td></td>
</tr>
<tr>
<td>ztar</td>
<td>compressed tar file (.tar.Z)</td>
<td>(3)</td>
</tr>
<tr>
<td>tar</td>
<td>tar file (.tar)</td>
<td></td>
</tr>
<tr>
<td>zip</td>
<td>zip file (.zip)</td>
<td>(2),(4)</td>
</tr>
<tr>
<td>rpm</td>
<td>RPM</td>
<td>(5)</td>
</tr>
<tr>
<td>pkgtool</td>
<td>Solaris pkgtool</td>
<td></td>
</tr>
<tr>
<td>sdux</td>
<td>HP-UX swinstall</td>
<td></td>
</tr>
<tr>
<td>wininst</td>
<td>self-extracting ZIP file for Windows</td>
<td>(4)</td>
</tr>
<tr>
<td>msi</td>
<td>Microsoft Installer.</td>
<td></td>
</tr>
</tbody>
</table>

*Changed in version 3.5:* Added support for the xztar format.

Notes:

1. default on Unix
2. default on Windows
3. requires external **compress** utility.
4. requires either external **zip** utility or ** zipfile** module (part of the standard Python library since Python 1.6)
5. requires external **rpm** utility, version 3.0.4 or better (use rpm --
version to find out which version you have)

You don't have to use the `bdist` command with the `--formats` option; you can also use the command that directly implements the format you're interested in. Some of these `bdist` “sub-commands” actually generate several similar formats; for instance, the `bdist_dumb` command generates all the “dumb” archive formats (tar, gztar, bztar, xztar, ztar, and zip), and `bdist_rpm` generates both binary and source RPMs. The `bdist` sub-commands, and the formats generated by each, are:

<table>
<thead>
<tr>
<th>Command</th>
<th>Formats</th>
</tr>
</thead>
<tbody>
<tr>
<td>bdist_dumb</td>
<td>tar, gztar, bztar, xztar, ztar, zip</td>
</tr>
<tr>
<td>bdist_rpm</td>
<td>rpm, srpm</td>
</tr>
<tr>
<td>bdist_wininst</td>
<td>wininst</td>
</tr>
<tr>
<td>bdist_msi</td>
<td>msi</td>
</tr>
</tbody>
</table>

The following sections give details on the individual `bdist_*` commands.
5.1. Creating RPM packages

The RPM format is used by many popular Linux distributions, including Red Hat, SuSE, and Mandrake. If one of these (or any of the other RPM-based Linux distributions) is your usual environment, creating RPM packages for other users of that same distribution is trivial. Depending on the complexity of your module distribution and differences between Linux distributions, you may also be able to create RPMs that work on different RPM-based distributions.

The usual way to create an RPM of your module distribution is to run the `bdist_rpm` command:

```
python setup.py bdist_rpm
```

or the `bdist` command with the `--format` option:

```
python setup.py bdist --formats=rpm
```

The former allows you to specify RPM-specific options; the latter allows you to easily specify multiple formats in one run. If you need to do both, you can explicitly specify multiple `bdist_*` commands and their options:

```
python setup.py bdist_rpm --packager="John Doe <jdoe@example.org>
bdist_wininst --target-version="2.0"
```

Creating RPM packages is driven by a `.spec` file, much as using the Distutils is driven by the setup script. To make your life easier, the `bdist_rpm` command normally creates a `.spec` file based on the information you supply in the setup script, on the command line, and in
any Distutils configuration files. Various options and sections in the .spec file are derived from options in the setup script as follows:

<table>
<thead>
<tr>
<th>RPM .spec file option or section</th>
<th>Distutils setup script option</th>
</tr>
</thead>
<tbody>
<tr>
<td>Name</td>
<td>name</td>
</tr>
<tr>
<td>Summary (in preamble)</td>
<td>description</td>
</tr>
<tr>
<td>Version</td>
<td>version</td>
</tr>
<tr>
<td>Vendor</td>
<td>author and author_email, or — &amp; maintainer and maintainer_email</td>
</tr>
<tr>
<td>Copyright</td>
<td>license</td>
</tr>
<tr>
<td>Url</td>
<td>url</td>
</tr>
<tr>
<td>%description (section)</td>
<td>long_description</td>
</tr>
</tbody>
</table>

Additionally, there are many options in .spec files that don’t have corresponding options in the setup script. Most of these are handled through options to the `bdist_rpm` command as follows:

<table>
<thead>
<tr>
<th>RPM .spec file option or section</th>
<th>bdist_rpm option</th>
<th>default value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Release</td>
<td>release</td>
<td>“1”</td>
</tr>
<tr>
<td>Group</td>
<td>group</td>
<td>“Development/Libraries”</td>
</tr>
<tr>
<td>Vendor</td>
<td>vendor</td>
<td>(see above)</td>
</tr>
<tr>
<td>Packager</td>
<td>packager</td>
<td>(none)</td>
</tr>
<tr>
<td>Provides</td>
<td>provides</td>
<td>(none)</td>
</tr>
<tr>
<td>Requires</td>
<td>requires</td>
<td>(none)</td>
</tr>
<tr>
<td>Conflicts</td>
<td>conflicts</td>
<td>(none)</td>
</tr>
</tbody>
</table>
Obviously, supplying even a few of these options on the command-line would be tedious and error-prone, so it’s usually best to put them in the setup configuration file, `setup.cfg`—see section Writing the Setup Configuration File. If you distribute or package many Python module distributions, you might want to put options that apply to all of them in your personal Distutils configuration file (`~/.pydistutils.cfg`). If you want to temporarily disable this file, you can pass the `--no-user-cfg` option to `setup.py`.

There are three steps to building a binary RPM package, all of which are handled automatically by the Distutils:

1. create a `.spec` file, which describes the package (analogous to the Distutils setup script; in fact, much of the information in the setup script winds up in the `.spec` file)
2. create the source RPM
3. create the “binary” RPM (which may or may not contain binary code, depending on whether your module distribution contains Python extensions)

Normally, RPM bundles the last two steps together; when you use the Distutils, all three steps are typically bundled together.

If you wish, you can separate these three steps. You can use the `--spec-only` option to make `bdist_rpm` just create the `.spec` file and exit; in this case, the `.spec` file will be written to the “distribution directory”—normally `dist/`, but customizable with the `--dist-dir`
option. (Normally, the .spec file winds up deep in the “build tree,” in a temporary directory created by bdist_rpm.)
5.2. Creating Windows Installers

Executable installers are the natural format for binary distributions on Windows. They display a nice graphical user interface, display some information about the module distribution to be installed taken from the metadata in the setup script, let the user select a few options, and start or cancel the installation.

Since the metadata is taken from the setup script, creating Windows installers is usually as easy as running:

```python
python setup.py bdist_wininst
```

or the `bdist` command with the `--formats` option:

```python
python setup.py bdist --formats=wininst
```

If you have a pure module distribution (only containing pure Python modules and packages), the resulting installer will be version independent and have a name like `foo-1.0.win32.exe`. These installers can even be created on Unix platforms or Mac OS X.

If you have a non-pure distribution, the extensions can only be created on a Windows platform, and will be Python version dependent. The installer filename will reflect this and now has the form `foo-1.0.win32-py2.0.exe`. You have to create a separate installer for every Python version you want to support.

The installer will try to compile pure modules into bytecode after installation on the target system in normal and optimizing mode. If you don’t want this to happen for some reason, you can run the `bdist_wininst` command with the `--no-target-compile` and/or
the --no-target-optimize option.

By default the installer will display the cool “Python Powered” logo when it is run, but you can also supply your own 152x261 bitmap which must be a Windows .bmp file with the --bitmap option.

The installer will also display a large title on the desktop background window when it is run, which is constructed from the name of your distribution and the version number. This can be changed to another text by using the --title option.

The installer file will be written to the “distribution directory” — normally dist/, but customizable with the --dist-dir option.
5.3. Cross-compiling on Windows

Starting with Python 2.6, distutils is capable of cross-compiling between Windows platforms. In practice, this means that with the correct tools installed, you can use a 32bit version of Windows to create 64bit extensions and vice-versa.

To build for an alternate platform, specify the --plat-name option to the build command. Valid values are currently ‘win32’, ‘win-amd64’ and ‘win-ia64’. For example, on a 32bit version of Windows, you could execute:

```bash
python setup.py build --plat-name=win-amd64
```

to build a 64bit version of your extension. The Windows Installers also support this option, so the command:

```bash
python setup.py build --plat-name=win-amd64 bdist_wininst
```

would create a 64bit installation executable on your 32bit version of Windows.

To cross-compile, you must download the Python source code and cross-compile Python itself for the platform you are targeting - it is not possible from a binary installation of Python (as the .lib etc file for other platforms are not included.) In practice, this means the user of a 32 bit operating system will need to use Visual Studio 2008 to open the \PCBuild\PCbuild.sln solution in the Python source tree and build the “x64” configuration of the ‘pythoncore’ project before cross-compiling extensions is possible.

Note that by default, Visual Studio 2008 does not install 64bit
compilers or tools. You may need to reexecute the Visual Studio setup process and select these tools (using Control Panel->[Add/Remove] Programs is a convenient way to check or modify your existing install.)

5.3.1. The Postinstallation script

Starting with Python 2.3, a postinstallation script can be specified with the --install-script option. The basename of the script must be specified, and the script filename must also be listed in the scripts argument to the setup function.

This script will be run at installation time on the target system after all the files have been copied, with \texttt{argv[1]} set to \texttt{-install}, and again at uninstallation time before the files are removed with \texttt{argv[1]} set to \texttt{-remove}.

The installation script runs embedded in the windows installer, every output (\texttt{sys.stdout}, \texttt{sys.stderr}) is redirected into a buffer and will be displayed in the GUI after the script has finished.

Some functions especially useful in this context are available as additional built-in functions in the installation script.

\texttt{directory\_created(path)}
\texttt{file\_created(path)}

These functions should be called when a directory or file is created by the postinstall script at installation time. It will register \texttt{path} with the uninstaller, so that it will be removed when the distribution is uninstalled. To be safe, directories are only removed if they are empty.

\texttt{get\_special\_folder\_path(csidl\_string)}
This function can be used to retrieve special folder locations on Windows like the Start Menu or the Desktop. It returns the full path to the folder. `csidl_string` must be one of the following strings:

"CSIDL_APPDATA"
"CSIDL_COMMON_STARTMENU"
"CSIDL_STARTMENU"
"CSIDL_COMMON_DESKTOPDIRECTORY"
"CSIDL_DESKTOPDIRECTORY"
"CSIDL_COMMON_STARTUP"
"CSIDL_STARTUP"
"CSIDL_COMMON_PROGRAMS"
"CSIDL_PROGRAMS"
"CSIDL_FONTS"

If the folder cannot be retrieved, `OSError` is raised.

Which folders are available depends on the exact Windows version, and probably also the configuration. For details refer to Microsoft's documentation of the `SHGetSpecialFolderPath()` function.

`create_shortcut(target, description, filename[, arguments[, workdir[, iconpath[, iconindex]]]]])`

This function creates a shortcut. `target` is the path to the program to be started by the shortcut. `description` is the description of the shortcut. `filename` is the title of the shortcut that the user will see. `arguments` specifies the command line arguments, if any. `workdir` is the working directory for the program. `iconpath` is the file containing
the icon for the shortcut, and *iconindex* is the index of the icon in the file *iconpath*. Again, for details consult the Microsoft documentation for the IShellLink interface.
5.4. Vista User Access Control (UAC)

Starting with Python 2.6, bdist_wininst supports a --user-access-control option. The default is ‘none’ (meaning no UAC handling is done), and other valid values are ‘auto’ (meaning prompt for UAC elevation if Python was installed for all users) and ‘force’ (meaning always prompt for elevation).
6. The Python Package Index (PyPI)

The Python Package Index (PyPI) stores meta-data describing distributions packaged with distutils, as well as package data like distribution files if a package author wishes.

Distutils provides the register and upload commands for pushing meta-data and distribution files to PyPI, respectively. See Distutils commands for information on these commands.
6.1. PyPI overview

PyPI lets you submit any number of versions of your distribution to the index. If you alter the meta-data for a particular version, you can submit it again and the index will be updated.

PyPI holds a record for each (name, version) combination submitted. The first user to submit information for a given name is designated the Owner of that name. Changes can be submitted through the register command or through the web interface. Owners can designate other users as Owners or Maintainers. Maintainers can edit the package information, but not designate new Owners or Maintainers.

By default PyPI displays only the newest version of a given package. The web interface lets one change this default behavior and manually select which versions to display and hide.

For each version, PyPI displays a home page. The home page is created from the long_description which can be submitted via the register command. See PyPI package display for more information.
6.2. Distutils commands

Distutils exposes two commands for submitting package data to PyPI: the `register` command for submitting meta-data to PyPI and the `upload` command for submitting distribution files. Both commands read configuration data from a special file called a `.pypirc` file.

6.2.1. The register command

The distutils command `register` is used to submit your distribution's meta-data to an index server. It is invoked as follows:

```
python setup.py register
```

Distutils will respond with the following prompt:

```
running register
We need to know who you are, so please choose either
  1. use your existing login,
  2. register as a new user,
  3. have the server generate a new password for you
  4. quit
Your selection [default 1]:
```

Note: if your username and password are saved locally, you will not see this menu. Also, refer to The `.pypirc file` for how to store your credentials in a `.pypirc` file.

If you have not registered with PyPI, then you will need to do so now. You should choose option 2, and enter your details as required. Soon after submitting your details, you will receive an email which will be used to confirm your registration.
Once you are registered, you may choose option 1 from the menu. You will be prompted for your PyPI username and password, and `register` will then submit your meta-data to the index.

See **Additional command options** for options to the `register` command.

### 6.2.2. The upload command

The distutils command **upload** pushes the distribution files to PyPI.

The command is invoked immediately after building one or more distribution files. For example, the command

```
python setup.py sdist bdist_wininst upload
```

will cause the source distribution and the Windows installer to be uploaded to PyPI. Note that these will be uploaded even if they are built using an earlier invocation of `setup.py`, but that only distributions named on the command line for the invocation including the `upload` command are uploaded.

If a `register` command was previously called in the same command, and if the password was entered in the prompt, `upload` will reuse the entered password. This is useful if you do not want to store a password in clear text in a `.pypirc` file.

You can use the `--sign` option to tell `upload` to sign each uploaded file using GPG (GNU Privacy Guard). The `gpg` program must be available for execution on the system PATH. You can also specify which key to use for signing using the `--identity=name` option.

See **Additional command options** for additional options to the `upload` command.
6.2.3. Additional command options

This section describes options common to both the **register** and **upload** commands.

The **--repository** or **-r** option lets you specify a PyPI server different from the default. For example:

```
python setup.py sdist bdist_wininst upload -r https:
```

For convenience, a name can be used in place of the URL when the .pypirc file is configured to do so. For example:

```
python setup.py register -r other
```

See The .pypirc file for more information on defining alternate servers.

The **--show-response** option displays the full response text from the PyPI server, which is useful when debugging problems with registering and uploading.

6.2.4. The .pypirc file

The **register** and **upload** commands both check for the existence of a .pypirc file at the location $HOME/.pypirc. If this file exists, the command uses the username, password, and repository URL configured in the file. The format of a .pypirc file is as follows:

```
[distutils]
index-servers =
  pypi
```
The `distutils` section defines an `index-servers` variable that lists the name of all sections describing a repository.

Each section describing a repository defines three variables:

- `repository`, that defines the url of the PyPI server. Defaults to `https://upload.pypi.org/legacy/`.
- `username`, which is the registered username on the PyPI server.
- `password`, that will be used to authenticate. If omitted the user will be prompt to type it when needed.

If you want to define another server a new section can be created and listed in the `index-servers` variable:

```
[distutils]
index-servers =
   pypi
   other

[pypi]
repository: <repository-url>
username: <username>
password: <password>

[other]
repository: https://example.com/pypi
username: <username>
password: <password>
```

This allows the `register` and `upload` commands to be called with the -
The `-repository` option as described in Additional command options.

Specifically, you might want to add the PyPI Test Repository to your `.pypirc` to facilitate testing before doing your first upload to PyPI itself.
6.3. PyPI package display

The `long_description` field plays a special role at PyPI. It is used by the server to display a home page for the registered package.

If you use the reStructuredText syntax for this field, PyPI will parse it and display an HTML output for the package home page.

The `long_description` field can be attached to a text file located in the package:

```python
from distutils.core import setup

with open('README.txt') as file:
    long_description = file.read()

setup(name='Distutils',
      long_description=long_description)
```

In that case, `README.txt` is a regular reStructuredText text file located in the root of the package besides `setup.py`.

To prevent registering broken reStructuredText content, you can use the `rst2html` program that is provided by the docutils package and check the `long_description` from the command line:

```
$ python setup.py --long-description | rst2html.py > output.html
```

docutils will display a warning if there's something wrong with your syntax. Because PyPI applies additional checks (e.g. by passing `--no-raw` to `rst2html.py` in the command above), being able to run the command above without warnings does not guarantee that PyPI
will convert the content successfully.
7. Examples

This chapter provides a number of basic examples to help get started with distutils. Additional information about using distutils can be found in the Distutils Cookbook.

See also:

Distutils Cookbook
Collection of recipes showing how to achieve more control over distutils.
7.1. Pure Python distribution (by module)

If you're just distributing a couple of modules, especially if they don't live in a particular package, you can specify them individually using the py_modules option in the setup script.

In the simplest case, you'll have two files to worry about: a setup script and the single module you're distributing, foo.py in this example:

```
<root>/
   setup.py
   foo.py
```

(In all diagrams in this section, <root> will refer to the distribution root directory.) A minimal setup script to describe this situation would be:

```
from distutils.core import setup
setup(name='foo',
      version='1.0',
      py_modules=['foo'],
)
```

Note that the name of the distribution is specified independently with the `name` option, and there's no rule that says it has to be the same as the name of the sole module in the distribution (although that's probably a good convention to follow). However, the distribution name is used to generate filenames, so you should stick to letters, digits, underscores, and hyphens.

Since `py_modules` is a list, you can of course specify multiple modules, eg. if you're distributing modules foo and bar, your setup might look like this:
and the setup script might be

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      py_modules=['foo', 'bar'],
)
```

You can put module source files into another directory, but if you have enough modules to do that, it's probably easier to specify modules by package rather than listing them individually.
7.2. Pure Python distribution (by package)

If you have more than a couple of modules to distribute, especially if they are in multiple packages, it's probably easier to specify whole packages rather than individual modules. This works even if your modules are not in a package; you can just tell the Distutils to process modules from the root package, and that works the same as any other package (except that you don't have to have an __init__.py file).

The setup script from the last example could also be written as

```python
from distutils.core import setup
setup(name='foobar',
    version='1.0',
    packages=[''],
)
```

(The empty string stands for the root package.)

If those two files are moved into a subdirectory, but remain in the root package, e.g.:

```
<root>/
    setup.py
    src/
        foo.py
        bar.py
```

then you would still specify the root package, but you have to tell the Distutils where source files in the root package live:

```python
from distutils.core import setup
setup(name='foobar',
    version='1.0',
    package_dir={':': 'src'},
)
More typically, though, you will want to distribute multiple modules in the same package (or in sub-packages). For example, if the foo and bar modules belong in package foobar, one way to layout your source tree is

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      packages=['foobar',],
)
```

If you want to put modules in directories not named for their package, then you need to use the `package_dir` option again. For example, if the `src` directory holds modules in the foobar package:
an appropriate setup script would be

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'foobar': 'src'},
      packages=['foobar'],
)
```

Or, you might put modules from your main package right in the distribution root:

```bash
<root>/
    setup.py
    __init__.py
    foo.py
    bar.py
```

in which case your setup script would be

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      package_dir={'foobar': ''},
      packages=['foobar'],
)
```

(The empty string also stands for the current directory.)

If you have sub-packages, they must be explicitly listed in `packages`, but any entries in `package_dir` automatically extend to sub-packages. (In other words, the Distutils does not scan your source tree, trying to figure out which directories correspond to Python packages by looking for `__init__.py` files.) Thus, if the default layout grows a sub-package:
then the corresponding setup script would be

```python
from distutils.core import setup
setup(name='foobar',
      version='1.0',
      packages=['foobar', 'foobar.subfoo'],
)```
7.3. Single extension module

Extension modules are specified using the `ext_modules` option. `package_dir` has no effect on where extension source files are found; it only affects the source for pure Python modules. The simplest case, a single extension module in a single C source file, is:

```
<root>/
    setup.py
    foo.c
```

If the `foo` extension belongs in the root package, the setup script for this could be

```python
from distutils.core import setup
from distutils.extension import Extension
setup(name='foobar',
    version='1.0',
    ext_modules=[Extension('foo', ['foo.c'])],
)
```

If the extension actually belongs in a package, say `foopkg`, then

With exactly the same source tree layout, this extension can be put in the `foopkg` package simply by changing the name of the extension:

```python
from distutils.core import setup
from distutils.extension import Extension
setup(name='foobar',
    version='1.0',
    ext_modules=[Extension('foopkg.foo', ['foo.c'])],
)
```
7.4. Checking a package

The check command allows you to verify if your package meta-data meet the minimum requirements to build a distribution.

To run it, just call it using your `setup.py` script. If something is missing, `check` will display a warning.

Let's take an example with a simple script:

```python
from distutils.core import setup
setup(name='foobar')
```

Running the `check` command will display some warnings:

```
$ python setup.py check
running check
warning: check: missing required meta-data: version,
warning: check: missing meta-data: either (author and author_email) or (maintainer and maintainer_email) must be supplied
```

If you use the reStructuredText syntax in the `long_description` field and `docutils` is installed you can check if the syntax is fine with the `check` command, using the `restructuredtext` option.

For example, if the `setup.py` script is changed like this:

```python
from distutils.core import setup
desc = """
My description
"""
```
This is the description of the ``foobar`` package.

```
setup(
    name='foobar',
    version='1',
    author='tarek',
    author_email='tarek@ziade.org',
    url='http://example.com',
    long_description=desc)
```

Where the long description is broken, check will be able to detect it by using the docutils parser:

```
$ python setup.py check --restructuredtext
running check
warning: check: Title underline too short. (line 2)
warning: check: Could not finish the parsing.
```
7.5. Reading the metadata

The `distutils.core.setup()` function provides a command-line interface that allows you to query the metadata fields of a project through the `setup.py` script of a given project:

```
$ python setup.py --name distribute
```

This call reads the `name` metadata by running the `distutils.core.setup()` function. Although, when a source or binary distribution is created with Distutils, the metadata fields are written in a static file called `PKG-INFO`. When a Distutils-based project is installed in Python, the `PKG-INFO` file is copied alongside the modules and packages of the distribution under `NAME-VERSION-pyX.X.egg-info`, where `NAME` is the name of the project, `VERSION` its version as defined in the Metadata, and `pyX.X` the major and minor version of Python like 2.7 or 3.2.

You can read back this static file, by using the `distutils.dist.DistributionMetadata` class and its `read_pkg_file()` method:

```
>>> from distutils.dist import DistributionMetadata
>>> metadata = DistributionMetadata()
>>> metadata.read_pkg_file(open('distribute-0.6.8-py2.7.egg-info'))
>>> metadata.name
'distribute'
>>> metadata.version
'0.6.8'
>>> metadata.description
'Easily download, build, install, upgrade, and uninstall Python packages'
```
Notice that the class can also be instantiated with a metadata file path to loads its values:

```python
>>> pkg_info_path = 'distribute-0.6.8-py2.7.egg-info'
>>> DistributionMetadata(pkg_info_path).name
'distribute'
```
